In a study of 110 U.S. counties, Powell et al. (2015) assessed the relationship between $PM_{10-2.5}$ and COPD-related hospital admissions among residents older than 65 years of age. The authors reported a positive, but imprecise association with COPD hospital admissions in single pollutant models (0.31% [95% PI: −0.39, 1.01]) and copollutant models with same-day $PM_{2.5}$ (0.19% [95% PI: −0.54, 0.92]). COPD-related admissions were also not associated with short-term $PM_{10-2.5}$ exposures occurring during a 1−3-day lag (which would be indicative of a more delayed response) in either single pollutant or copollutant models. Moreover, Cheng et al. (2015) assessed the relationship between $PM_{10-2.5}$ and COPD-related hospital admissions in a case-crossover study in Kaohsuing, Taiwan. This study observed an increase in hospital admissions of 1.02% (95% CI: 1.01,1.03).

5.3.3.1.2 Emergency Department (ED) Visits

In a multicity study conducted in 35 California counties, Malig et al. (2013) examined the association between short-term $PM_{10-2.5}$ exposures and respiratory ED visits, including COPD visits. The authors reported positive associations between $PM_{10-2.5}$ and COPD ED visits at lag 2 days (0.67% [95% CI: −0.04, 1.38]). In a copollutant model with $PM_{2.5}$, the association was stronger (1.48%) and more precise (95% CI: 0.40, 2.56) [results presented in Figure 5-6 and supplemental data, (Malig et al., 2013)]. The COPD relationship at lag 2 remained elevated for those living closer to the monitor (within 10 km vs. 10−20 km), but it was not present among those farther away indicating potential exposure measurement error based on distance to monitor (Section 3.4.2.2).

5.3.3.2 Other Epidemiologic Studies

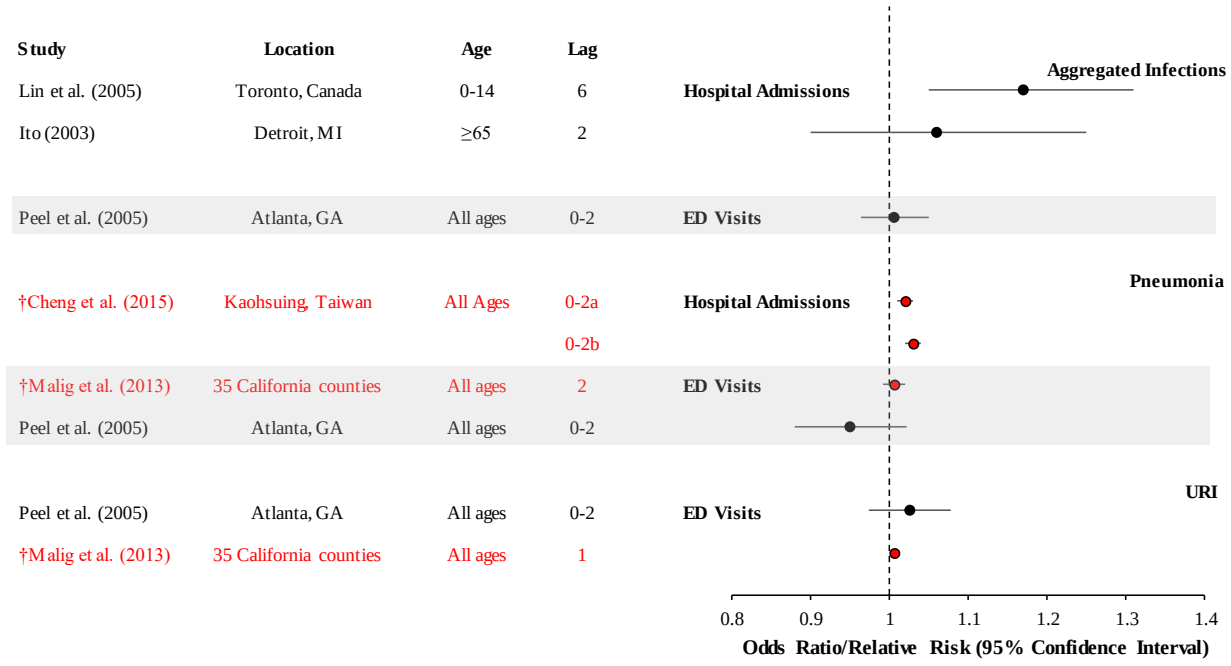
As discussed in the 2009 PM ISA (U.S. EPA, 2009), a limited number of previously evaluated studies provide contrasting evidence of an association between coarse PM and lung function changes in adults with COPD. Associations were not observed for $PM_{10–2.5}$ calculated from residential outdoor PM_{10} and $PM_{2.5}$ in Seattle (Trenga et al., 2006). Conversely, $PM_{10–2.5}$ exposure (24-hour average, lag 0) was associated with a decrease in FEV_1 in adults in Vancouver, Canada (Ebelt et al., 2005). $PM_{10–2.5}$ was calculated by estimating the ambient fractions of $PM_{2.5}$ and PM_{10} measured from personal monitors and subtracting $PM_{2.5}$ from PM_{10}. The $PM_{10–2.5}$ concentrations examined in Ebelt et al. (2005) were lower (mean = 2. µg/m^3) than those examined for COPD hospital admissions and ED visits (Table 5-9). Neither study examined other pollutants, so it is not clear whether the results reflect an independent association for $PM_{10–2.5}$. There are no recent studies available for review that examine the association between $PM_{10–2.5}$ and indicators of COPD exacerbation.

5.3.3.3 Summary of Exacerbation of Chronic Obstructive Pulmonary Disease (COPD)

Overall, the body of literature that examined the association between $PM_{10–2.5}$ and hospital admissions and ED visits for COPD is limited. Studies reported in the 2009 ISA (U.S. EPA, 2009) provided inconsistent evidence. Of the recent studies, there is some evidence of a positive association between short-term $PM_{10–2.5}$ exposure and COPD hospital admissions and ED visits, but evidence for other indicators of COPD exacerbation is inconsistent. In addition, there is a relative lack of information on potential copollutant confounding and the potential implications of exposure measurement error due to the different methods employed across studies to estimate $PM_{10–2.5}$ concentrations.

5.3.4 Respiratory Infection

The respiratory tract is protected from exogenous pathogens and particles through various lung host defense mechanisms that include mucociliary clearance, particle transport and detoxification by alveolar macrophages, and innate and adaptive immunity. Impairment of these defense mechanisms can increase the risk of respiratory infection. Previous epidemiologic studies consistently observed associations between short-term $PM_{10–2.5}$ exposure and hospital admissions, ED visits, or physician visits for aggregated respiratory infections or URI, but not pneumonia. In contrast, the few recent epidemiologic studies indicate associations with pneumonia, but not aggregated respiratory infections (Figure 5-43). The 2009 PM ISA (U.S. EPA, 2009) did not report any experimental studies of altered susceptibility to infectious agents following short-term exposure to $PM_{10–2.5}$ and no studies have become available since that time.



Note: †Studies published since the 2009 PM ISA. Black text = U.S. and Canadian studies included in the 2009 PM ISA. Corresponding quantitative results are reported in Supplemental Material (U.S. EPA, 2018).

Figure 5-43 Summary of associations between short-term $PM_{10-2.5}$ exposures and respiratory infection hospital admissions and emergency department (ED) visits for a 10 µg/m^3 increase in 24-hour average $PM_{10-2.5}$ concentrations.

5.3.4.1 Hospital Admissions and Emergency Department (ED) Visits

Although the body of literature was small, the few studies evaluated in the 2009 PM ISA reported inconsistent evidence of an association between $PM_{10-2.5}$ and hospital admissions and ED visits for respiratory infections. Some studies observed associations of respiratory infections with $PM_{10-2.5}$ among subjects younger than 15 years old, and others reported associations between $PM_{10-2.5}$ and outpatient visits for lower respiratory tract infections. The recent literature adds to the evidence base and provides some support for an association between short-term $PM_{10-2.5}$ exposure and hospital admissions/ED visits for pneumonia and respiratory infections considered in aggregate (see Figure 5-43). For each of the studies evaluated in this section, Table 5-33 presents the air quality characteristics of each city, or across all cities, the exposure assignment approach used, and information on copollutants examined in each asthma hospital admission and ED visit study.

In 110 U.S. counties Powell et al. (2015) reported a positive, but uncertain, association between short-term $PM_{10-2.5}$ exposure and respiratory infection hospital admissions among residents older than

65 years in single pollutant models (0.07% [95% PI: −0.46, 0.61]; lag 0). This association was attenuated in a copollutant model with $PM_{2.5}$ (−0.02% [95% PI: −0.59, 0.55]; lag 0). Respiratory infection-related admissions were also not associated with $PM_{10–2.5}$ exposures occurring 1−3 days prior to admission in either single pollutant or copollutant models. Cheng et al. (2015) assessed the relationship between $PM_{10–2.5}$ and pneumonia-related hospital admissions among residents older than 65 years of age in a case-crossover study in Kaohsuing, Taiwan between 2006−2010. This study observed a small positive association, with an increase in hospital admissions of 1.02% (95% CI: 1.01, 1.03) per 10-µg/m^3 increase in $PM_{10–2.5}$. This association was consistent after model adjustment for SO_2, NO_2, CO, and O_3 and was slightly stronger on colder days below 25°C (1.03% [95% CI: 1.02, 1.04]).

In a multicity study conducted in 35 California counties, Malig et al. (2013) reported no association between short-term $PM_{10–2.5}$ exposures at single-day lags 0−2 days and ED visits due to acute respiratory infection [RR 1.007, 95% CI: 1, 1.01]. This study also reported a very weak association between short-term $PM_{10–2.5}$ exposures at single-day lags 0−2 days for pneumonia visits RR 1.006 [95% CI: 0.99, 1.02].

5.3.4.2 Outpatient and Physician Visit Studies

In Atlanta, GA, Sinclair et al. (2010) compared air pollutant concentrations and relationships for acute respiratory visits for the 25-month time-period examined in a previous study (August 1998−August 2000) and an additional 28-month time-period of available data from the Atlanta Aerosol Research Inhalation Epidemiology Study (ARIES) (September 2000−December 2002). Across the two time periods, $PM_{10-2.5}$ mass concentrations (measured from ARIES) were essentially stable with only a 3% difference between the two study periods (9.6 $\mu g/m^3$ overall average). Unlike $PM_{2.5}$ mass, $PM_{10-2.5}$ mass did not change significantly across warm or cold seasons. A comparison of the two time periods indicated that associations for $PM_{10-2.5}$ tended to be larger in the earlier 25-month period compared to the later 28-month period. Associations with URI for lag 3−5 in the 25-month time period represented the highest finding (4.2% [95% CI: 0.75, 7.8]). For LRI in the 25-month period, associations were positive for all lags, with the largest for lag 3−5 (13.2% [95% CI: 3.2, 24.4]). As noted in Section 5.1.2.1, several factors may dictate whether an individual visits the doctor or a hospital, making it difficult to readily compare results between studies focusing on physician visits versus hospital admissions and ED visits.

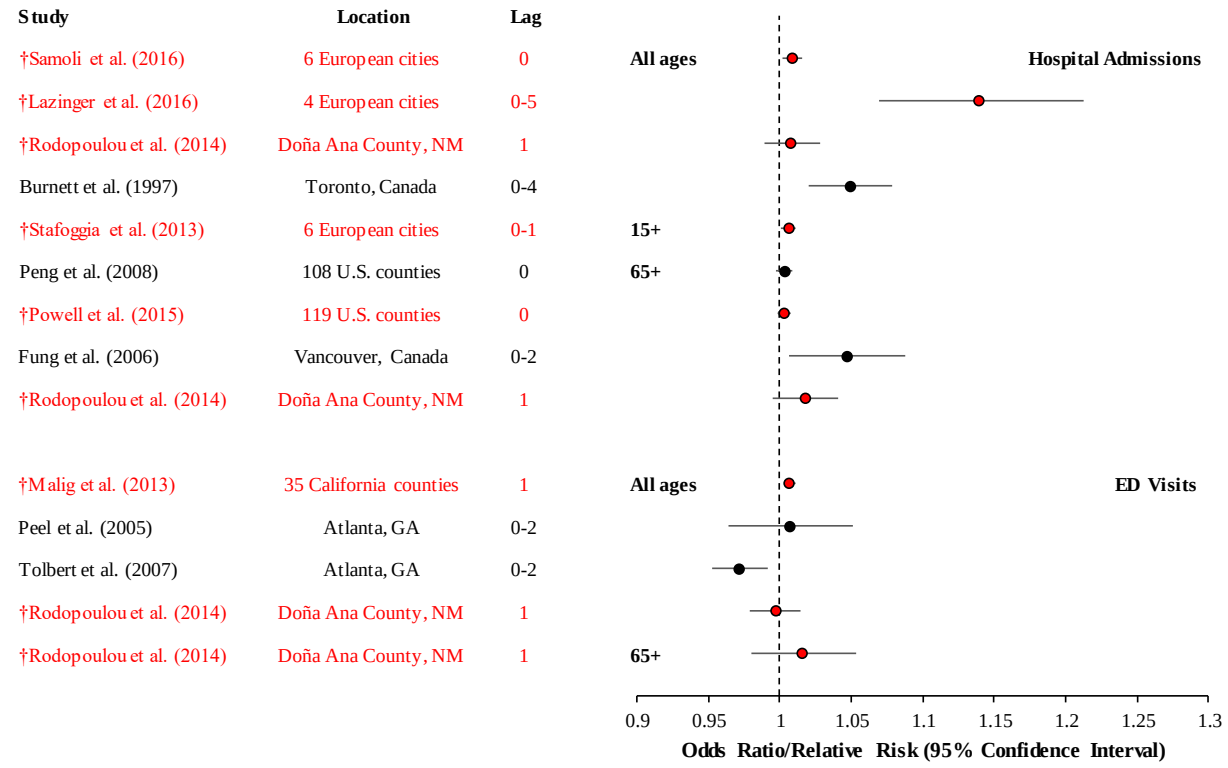
5.3.4.3 Summary of Respiratory Infection

The body of literature that examined the association between $PM_{10-2.5}$ and hospital admissions and ED visits for respiratory infection hospital admissions expanded since the 2009 PM ISA (U.S. EPA, 2009), but remains limited. Previous studies reported associations between $PM_{10-2.5}$ and both acute respiratory infection and a combination of respiratory infection, but not pneumonia. Recent studies are generally indicative of associations for both acute respiratory infection and pneumonia, but not the combination of respiratory infections. A multicity study conducted in the U.S. and several single-city studies in the U.S. and internationally report positive associations between $PM_{10-2.5}$ and hospital admissions/ED visits for pneumonia or acute respiratory infection. Despite some inconsistency between previous and recent findings, the evidence overall is supportive of a link between short-term $PM_{10-2.5}$ exposure and respiratory infection. However, previous and recent findings have similar uncertainties in exposure measurement error in $PM_{10-2.5}$ concentrations, particularly when PM_{10} and $PM_{2.5}$ concentrations that were not collocated were differenced to estimate $PM_{10-2.5}$ concentrations. Previous and recent findings also have uncertainties in limited examination of copollutant confounding and limited information from experimental studies to assess biological plausibility.

5.3.5 Combinations of Respiratory-Related Hospital Admissions and Emergency Department (ED) Visits

In the 2009 PM ISA (U.S. EPA, 2009), the evaluation of the relationship between short-term $PM_{10-2.5}$ exposure and hospital admissions and ED visits for respiratory-related diseases was limited to a rather small number of studies. Across hospital admissions studies, there was evidence of positive associations that varied in terms of the magnitude and precision of the estimates, while the evidence for ED visits was inconsistent. Of the studies evaluated in the 2009 PM ISA, the majority consisted of single-city studies, and different approaches were used to estimate ambient $PM_{10-2.5}$ concentrations. Across studies, there was limited to no information on potential copollutant confounding or other assessments of the relationship between short-term $PM_{10-2.5}$ exposure and hospital admissions and ED visits for respiratory-related diseases, such as model specification, lag structure of associations, or the C-R relationship.

Recent multi- and single-city studies that examine short-term $PM_{10-2.5}$ exposure and hospital admissions and ED visits for respiratory-related diseases add to the body of evidence detailed in the 2009 PM ISA (U.S. EPA, 2009). Consistent with the studies evaluated in the 2009 PM ISA, recent hospital admissions studies provide evidence of positive associations that are similar in magnitude and precision, while recent ED visits studies provide inconsistent evidence of an association (Figure 5-44). Similar to the studies evaluated in Section 5.1.6, the studies that examined combinations of respiratory-related diseases encompassed all respiratory-related diseases or only a subset, which can complicate the interpretation of results across studies. As described in preceding sections, the evidence for association with $PM_{10-2.5}$ is more consistent for asthma (Section 5.3.1) than for COPD (Section 5.3.2) or for respiratory infection (Section 5.3.4). For each of the studies evaluated in this section, Table 5-34 (summary table of studies) presents the air quality characteristics of each city, or across all cities, the exposure assignment approach used, and information on copollutants examined in each study. Other recent studies of hospital admissions and ED visits for respiratory-related diseases that did not address uncertainties and limitations in the evidence previously identified are not the focus of this evaluation. Additionally, many of these other studies were conducted in small single cities, encompassed a short study duration, or had insufficient sample size. The full list of these other studies can be found in HERO: https://hero.epa.gov/hero/particulate-matter.



Note: †Studies published since the completion of the 2009 PM ISA. Black text = U.S. and Canadian studies included in the 2009 PM ISA. Corresponding quantitative results are reported in Supplemental Material (U.S. EPA, 2018).

1

Recent multicity studies (Lanzinger et al., 2016b; Samoli et al., 2016a; Powell et al., 2015; Stafoggia et al., 2013) and single-city studies (Rodopoulou et al., 2014; Alessandrini et al., 2013; Atkinson et al., 2010) conducted in the U.S. and Europe that examined the association between short-term $PM_{10-2.5}$ exposure and respiratory-related hospital admissions provide evidence of positive associations that vary in terms of magnitude and precision (Figure 5-44), particularly in analyses of people of all ages. In a limited assessment of potential copollutant confounding, associations were often attenuated, but remained positive in copollutant models with $PM_{2.5}$, NO_2, and O_3 (Powell et al., 2015; Alessandrini et al., 2013; Stafoggia et al., 2013). The positive associations reported across these studies is supported by a meta-analysis focusing on $PM_{10-2.5}$ and respiratory hospital admissions that reported a RR = 1.01 (95% CI: 1.00, 1.02) (Adar et al., 2014). Additional analyses conducted by Adar et al. (2014) to assess potential copollutant confounding by $PM_{2.5}$ did not observe a consistent pattern in $PM_{10-2.5}$ associations as the correlation with $PM_{2.5}$ increased or when evaluating studies that examined associations with both $PM_{2.5}$ and $PM_{10-2.5}$.

Additional single-city studies conducted in London, U.K. (Atkinson et al., 2010) and Rome, Italy, (Alessandrini et al., 2013) also contribute to the total body of evidence for respiratory-related hospital admissions. Atkinson et al. (2010) when examining a number of urban particles, examined associations with $PM_{10-2.5}$ and across single-day lags ranging from 0 to 6 days. The authors reported evidence of a positive association at lag 1 in an all ages analysis, but there was no evidence of an association for the other lags examined (quantitative results not presented). Instead of focusing on urban particles, Alessandrini et al. (2013) examined the role of Saharan dust on the relationship between short-term $PM_{10-2.5}$ exposure and respiratory-related hospital admissions. Across the entire study duration, the authors reported a 4.4% increase (95% CI: −0.53, 9.60) in hospital admissions at lag 0−5 days. However, when differentiating between Saharan and non-Saharan dust days, Alessandrini et al. (2013) observed that the overall association reported was primarily attributed to the Saharan dust days (13.5%) compared to the non-Saharan dust days (−0.30%).

Across the hospital admissions studies evaluated, a few of the studies conducted sensitivity analyses to examine the lag structure of associations and model specification. Both Stafoggia et al. (2013) and Lanzinger et al. (2016b) examined whether there is evidence of immediate (lag 0−1), delayed (lag 2−5), or prolonged (lag 0−5) effects of $PM_{10-2.5}$ on respiratory-related hospital admissions. In both studies, positive associations were observed across each of the lags, with the association largest in magnitude at lag 0−5, indicating a potential prolonged effect [(Stafoggia et al., 2013): lag 0−1, 1.0% [95% CI: 0.10, 1.8]; lag 2−5: 1.2% [95% CI: −1.1, 3.6]; lag 0−5: 2.0% [95% CI: −0.51, 4.5]; (Lanzinger et al., 2016b): lag 0−1, 7.4% [95% CI: 1.9, 12.7]; lag 2−5: 10.7% [95% CI: 4.7, 16.9]; lag 0−5: 13.9% [95% CI: 6.9, 21.3]]. However, in Stafoggia et al. (2013), as the lag days increased, the confidence intervals did as well, resulting in more uncertain estimates. The results of Stafoggia et al. (2013) and Lanzinger et al. (2016b) are supported by Samoli et al. (2016a) when examining single-day lags ranging from 0 to 10 days where positive associations were observed through lag Day 4, but the strongest

association in terms of magnitude and precision was a lag 1 (quantitative results not presented). Stafoggia et al. (2013) and Powell et al. (2015) both examined the influence of alternative approaches to account for temporal trends and the confounding effects of weather and found that results were relatively unchanged.

Similar to the 2009 PM ISA (U.S. EPA, 2009), compared to studies that examined short-term $PM_{10-2.5}$ exposure and respiratory-related hospital admissions, fewer studies focused on ED visits with the evidence primarily limited to single-city studies. In analyses of all ages, there is no evidence of an association when examining the results from single-city studies. Rodopoulou et al. (2014) in a study conducted in Doña Ana County, NM reported a positive association for older adults, but no evidence of an association for an all ages analysis, which is consistent with the single-city studies evaluated in the 2009 PM ISA (Figure 5-44). However, Malig et al. (2013), in a study of 35 California counties, reported positive associations at lags 1 and 2 days, with the strongest association in terms of magnitude and precision at lag 1 (0.7% [95% CI: 0.3, 1.1]). The association with $PM_{10-2.5}$ was found to remain positive in copollutant models with O_3, NO_2, CO, SO_2, and $PM_{2.5}$. Additionally, associations were found to be slightly elevated in the warm compared to cold season, and robust to the exclusion of extreme $PM_{10-2.5}$ values (the highest and lowest 5% of calculated coarse particle levels) from the analysis. Rodopoulou et al. (2014) also examined the influence of season and extreme $PM_{10-2.5}$ concentrations and reported contradictory results to Malig et al. (2013), i.e., associations larger in magnitude in the cold season and that the $PM_{10-2.5}$ association increased in magnitude when excluding high $PM_{10-2.5}$ concentrations. Uncertainties in how $PM_{10-2.5}$ concentration was estimated in Rodopoulou et al. (2014) complicates the comparison between studies.

Recent studies of respiratory-related hospital admissions and ED visits provide an initial assessment of the C-R relationship, but is limited by the studies not conducting extensive empirical evaluations of alternatives to linearity, and whether there is evidence of a threshold below which effects are not observed. Malig et al. (2013) provides initial evidence of a linear relationship through an analysis where the inclusion of a squared term for $PM_{10-2.5}$ into the statistical model to account for possible nonlinearity did not improve the goodness of fit over the initial model that assumed linearity. Stafoggia et al. (2013) examined whether there was evidence of a threshold in a study of six European cities, which is similar the threshold analysis detailed for $PM_{2.5}$ (Section 5.1.10.6). As depicted in Table 5-45, the authors examined the percent increase in hospital admissions at various concentrations across the distribution of $PM_{10-2.5}$ concentrations, up to 40 $\mu g/m^3$, relative to 5 $\mu g/m^3$, and reported no evidence a threshold.

5.3.6 Respiratory Effects in Healthy Populations

The 2009 PM ISA (U.S. EPA, 2009) evaluated a limited number of studies that examined the effects of short-term exposure to $PM_{10-2.5}$ on respiratory effects in healthy populations. No epidemiologic studies were available on $PM_{10-2.5}$ exposure and respiratory effects in healthy populations. Null findings were reported for lung function in populations of children, but their health status was not reported (Dales et al., 2008; Moshammer et al., 2006). Evidence for inflammation was inconsistent in controlled human exposure studies. Alexis et al. (2006) found evidence of pulmonary inflammation, as well as innate immune responses of airway macrophages, and increased levels of eotaxin in healthy individuals. Some of these responses were reduced by biological inactivation (i.e., heat-treatment of $PM_{10-2.5}$) implicating a role for endotoxin. Additionally, short-term exposure to $PM_{10-2.5}$ particles was also shown to elicit increases in polymorphonuclear leukocytes and inflammatory cytokines in healthy adults (Graff et al., 2009). However, Jr et al. (2004) reported no effect of short-term $PM_{10-2.5}$ exposure on markers of airway inflammation in healthy subjects. Animal toxicological studies employed noninhalation routes of exposure since inhalation exposure of rodents to $PM_{10-2.5}$ is technically difficult given that rodents are obligatory nasal breathers. A number of studies of involving noninhalation routes of exposure (i.e., oropharyngeal aspiration, intra-tracheal instillation) support a potential role of short-term $PM_{10-2.5}$ exposure in pulmonary oxidative stress and inflammation (Gilmour et al., 2007; Happo et al., 2007; Dick et al., 2003). Evidence for pulmonary injury, oxidative stress, inflammation, and morphological changes

was also provided by Gerlofs-Nijland et al. (2007); Gerlofs-Nijland et al. (2005) in studies involving intra-tracheal instillation of $PM_{10–2.5}$ and an animal model of cardiovascular disease.

5.3.6.1 Epidemiologic Studies

Recent studies have used scripted exposures of healthy adults alternating between rest and exercise in high- and low-pollution locations. These studies minimize uncertainty in the $PM_{10–2.5}$ exposure metric by measuring personal ambient $PM_{10–2.5}$ at the site of exposure (calculated as the difference between PM_{10} and $PM_{2.5}$). In Utrecht, the Netherlands, $PM_{10–2.5}$ exposure of 5 hours was associated with a decrease in FVC and an increase in eNO (Strak et al., 2012). However, the observed associations were small in magnitude and the authors did not report confidence intervals or other measures of precision. Two-hour $PM_{10–2.5}$ exposure was also associated with increased eNO, but not with any of the number of lung function metrics measured in a study of healthy adults in Barcelona, Spain (Kubesch et al., 2015). In a follow-up study using a similar design, Matt et al. (2016) reported FEV_1, FVC, and PEF decrements associated with $PM_{10–2.5}$. Results appeared to be transient, as associations were observed immediately after exposure, but not 7 hours later during a follow-up spirometry test (Matt et al., 2016). Inconsistent associations among the vast number of pollutants and outcomes analyzed within studies is a limitation of all the reviewed studies.

There is limited evidence in healthy children in Chile, Sweden, and Taiwan for associations with 24-hour average $PM_{10–2.5}$ concentrations (difference between PM_{10} and $PM_{2.5}$ measured at monitors). Repeated measures of respiratory symptoms and eNO were associated with $PM_{10–2.5}$ concentrations at a monitor within 1.5 or 3 km of home or school (Prieto-Parra et al., 2017; Carlsen et al., 2016). In a cross-sectional analysis, $PM_{10–2.5}$ averaged across city monitors were associated with decreases in FEV_1, FVC, MMEF, FEV_1/FVC, and MMEF/FVC (Chen et al., 2015a). Cross-sectional measurements are generally less informative than repeated measures study designs because they do not establish a temporal relationship between the exposure and outcome of interest. Other findings in children are inconsistent, but do not provide insight into the respiratory effects of $PM_{10–2.5}$ exposure in healthy people because they are for a population with 66% prevalence of asthma or allergy (Chen et al., 2012; Chen et al., 2011a) or infants on cardiorespiratory monitors who may not spend much time outdoors away from home (Peel et al., 2011).

5.3.6.2 Controlled Human Exposure

In a recent study, Behbod et al. (2013) exposed subjects to $PM_{10–2.5}$ CAPs and measured multiple markers of airway inflammation, but relative to filtered air, no significant airway (sputum) responses were found (Table 5-35).

Table 5-35 Study-specific details from a controlled human exposure study of short-term $PM_{10-2.5}$ exposure and respiratory effects in a healthy population.

Study	Study Design	Disease Status; n; Sex; (Age)	Exposure Details (Concentration; Duration; Comparison Group)	Endpoints Measured
Behbod et al. (2013)	Double-blind, randomized cross-over block design	Healthy nonsmokers; n = 35; 11 M, 12 F (18−60 yr)	234.7 µg/m^3 $PM_{2.5}$ (IQR: 52.4 µg/m^3) for 130 min (120-min exposure + 10 min to complete tests) at rest. Comparison groups were either (1) filtered air or (2) medical air; a minimum 2-week washout period was used between exposures.	Sputum (pre- and 24-hour post-exposure): Total cell and neutrophil counts

BAL = bronchoalveolar lavage; IL-6 = interleukin-6, IL-8 = interleukin-8, IQR = interquartile range.

5.3.6.3 Animal Toxicological Studies

Recent studies involving intra-tracheal instillation confirm previous results showing that $PM_{10-2.5}$ collected during different seasons and from different locations exhibits variable potency in terms of pulmonary injury, inflammation, and morphologic changes (Lippmann et al., 2013a; Mirowsky et al., 2013; Halatek et al., 2011). In addition, two recent animal inhalation studies provide evidence for respiratory effects in healthy populations resulting from short-term exposure to $PM_{10-2.5}$. Amatullah et al. (2012) found that a 4-hour inhalation exposure of BALB/c mice to $PM_{10-2.5}$ CAPs in Toronto increased baseline total respiratory resistance ($p < 0.05$) and maximum response to methacholine ($p < 0.01$) immediately after exposure. In addition, quasi-static compliance was decreased ($p < 0.01$) and quasi-static elastance was increased ($p < 0.01$). These changes indicate airway obstruction. Amatullah et al. (2012) also found increased total cells and macrophages in the bronchoalveolar lavage fluid (BALF) ($p < 0.05$). Aztatzi-Aguilar et al. (2015) showed that multiday inhalation exposure of Sprague Dawley rats to $PM_{10-2.5}$ CAPs in Mexico City resulted in increased IL-6 protein in lung tissue ($p < 0.05$). In addition, a reduction in angiotensin converting enzyme was observed ($p < 0.05$). Angiotensin converting enzyme is a component of the RAS and regulates levels of the potent vasoconstrictor angiotensin II. Since deposition of inhaled $PM_{10-2.5}$ is expected to primarily occur in the extrathoracic airways (i.e., the nose) of rodents, recent animal toxicological studies links deposition in the nose to changes in pulmonary function including increased airway responsiveness, inflammation in the lower airways, and changes in the RAS. Additional study details for these recent toxicological studies are found in Table 5-36.

Table 5-36 Study-specific details from animal toxicological studies of short-term $PM_{10-2.5}$ exposure and respiratory effects in healthy animals.

Study/Study Population	Pollutant	Exposure	Endpoints
Amatullah et al. (2012) Species: Mouse Sex: Female Strain: BALB/c Age/Weight: 6−8 weeks, 18 g	$PM_{10-2.5}$ CAPs Toronto Particle size: $PM_{10-2.5}$ Control: HEPA-filtered air	Route: Nose-only inhalation Dose/Concentration: $PM_{10-2.5}$ 793 µg/m³, duration: 4 h Time to analysis: At end of exposure Modifier: Baseline ECG	Pulmonary function—airways resistance, quasi-static elastance BALF cells
Aztatzi-Aguilar et al. (2015) Species: Rat Sex: Male Strain: Sprague Dawley	$PM_{10-2.5}$ CAPs Mexico City Particle size: $PM_{10-2.5}$ Control: Filtered air	Route: Inhalation Dose/Concentration: $PM_{10-2.5}$ 32 µg/m³ Duration: Acute 5 h/day, 3 days Time to analysis: 24 h	Gene and protein expression in lung tissue • IL-6 • Components of RAS and kalikrein-kinin endocrine system • Heme oxygenase-1

BALF = bronchoalveolar lavage fluid; ECG = electrocardiogram; IL-6 = interleukin 6; RAS = renin-angiotensin system.

5.3.6.4 Summary of Respiratory Effects in Healthy Populations

Epidemiologic and controlled human exposure studies examining healthy populations do not consistently support a relationship between $PM_{10-2.5}$ and lung function or pulmonary inflammation. Animal toxicological studies provide evidence for decrements in lung function, inflammation, oxidative stress, and upregulation of the RAS system following short-term inhalation exposure to $PM_{10-2.5}$. Support for some of these findings in animals are provided by studies using noninhalation routes of exposure.

5.3.7 Respiratory Mortality

Studies that examine the association between short-term $PM_{10-2.5}$ exposure and cause-specific mortality outcomes, such as respiratory mortality, provide additional evidence for $PM_{10-2.5}$-related respiratory effects, specifically whether there is evidence of an overall continuum of effects. In the 2009 PM ISA (U.S. EPA, 2009), only a few studies examined the association between short-term $PM_{10-2.5}$ exposure and respiratory mortality, with only one U.S. based multicity study (Zanobetti and Schwartz, 2009). Across studies, there was evidence of generally positive associations with respiratory mortality even though studies used a variety of approaches to estimate $PM_{10-2.5}$ concentrations, but confidence intervals were wide in the single-city studies evaluated. Overall, there was limited evaluation of the

potential confounding effects of gaseous pollutants and the influence of model specification on the associations observed.

Recent multicity epidemiologic studies that examined associations between short-term $PM_{10-2.5}$ exposure and respiratory mortality provide evidence of positive associations in some locations, but not in others (Figure 11-27). However, a meta-analysis (Adar et al., 2014) indicates a $PM_{10-2.5}$ association similar in magnitude as the multicity U.S. based study (Zanobetti and Schwartz, 2009) evaluated in the 2009 PM ISA (U.S. EPA, 2009). Unlike the studies evaluated in the 2009 PM ISA, some recent studies have also further evaluated the $PM_{2.5}$-respiratory mortality relationship by examining cause-specific respiratory mortality outcomes (i.e., COPD, pneumonia, and LRTI) (Samoli et al., 2014; Janssen et al., 2013). Overall, the results reported in the studies that examine cause-specific respiratory mortality outcomes are generally consistent with the results for all respiratory mortality, but the smaller number of mortality events observed results in estimates with larger uncertainty. As a result, this section focuses on studies that examine all respiratory mortality outcomes and address uncertainties and limitations in the relationship between short-term $PM_{10-2.5}$ exposure and respiratory mortality, specifically: potential copollutant confounding, lag structure of associations, and effect modification by season and temperature.

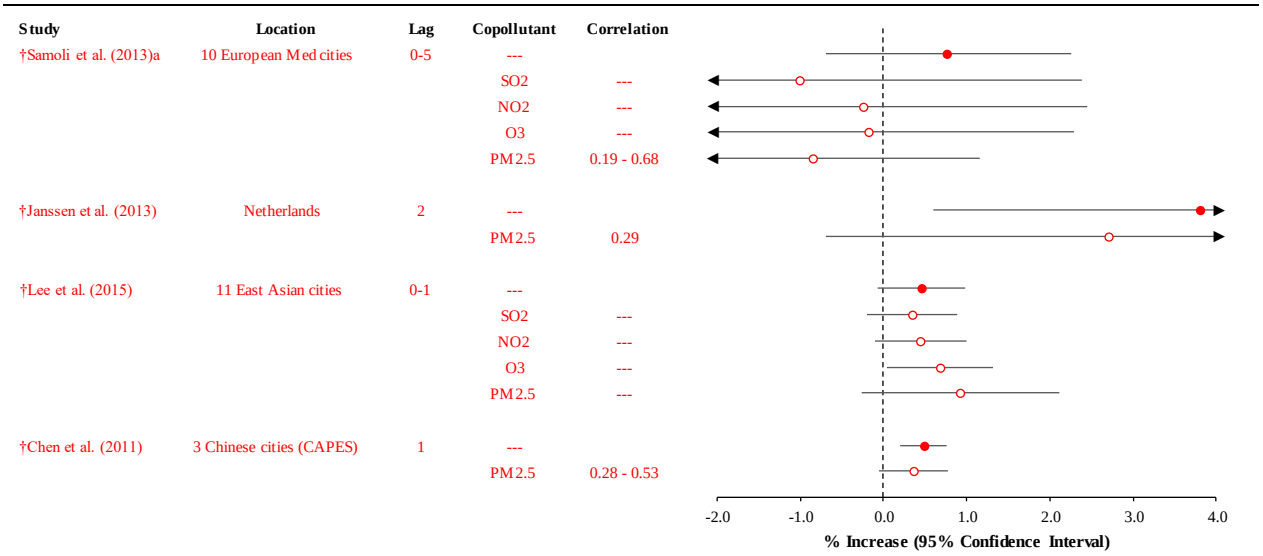
5.3.7.1 Characterizing the $PM_{10-2.5}$-Respiratory Mortality Relationship

Recent epidemiologic studies conducted additional analyses that address some of the uncertainties and limitations of the relationship between short-term $PM_{10-2.5}$ exposure and respiratory mortality identified in the 2009 PM ISA (U.S. EPA, 2009). Specifically, recent studies provide additional information on copollutant confounding, lag structure of associations, and seasonal associations. However, similar to those studies evaluated in the 2009 PM ISA, the approaches used to estimate $PM_{10-2.5}$ concentrations varies across studies and it remains unclear if the level of exposure measurement error varies by each approach (Table 11-9). Overall, these studies provide initial evidence that: $PM_{10-2.5}$-respiratory mortality associations remain positive but may be attenuated in copollutant models; $PM_{10-2.5}$ effects on respiratory mortality tend to occur within the first few days of exposure (i.e., lags 0 to 2 days); and it remains unclear if there are seasonal differences in associations.

5.3.7.1.1 Copollutant Confounding

Consistent with the evaluation of total (nonaccidental) mortality, the studies evaluated in the 2009 PM ISA (U.S. EPA, 2009) provided limited information on the potential confounding effects of gaseous pollutants and $PM_{2.5}$ on the relationship between short-term $PM_{10-2.5}$ exposure and respiratory mortality. Recent multicity studies (Lee et al., 2015; Janssen et al., 2013; Samoli et al., 2013; Chen et al., 2011b) and a meta-analysis (Adar et al., 2014) provide additional information concerning the role of copollutants on the $PM_{10-2.5}$-respiratory mortality relationship.

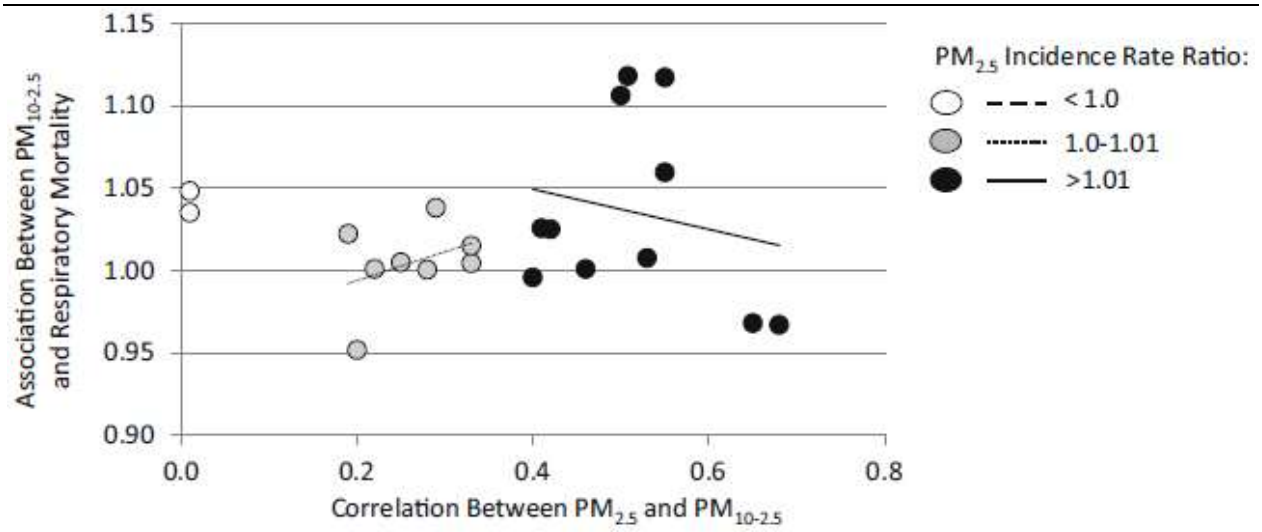
When focusing on potential copollutant confounding of the $PM_{10-2.5}$-respiratory mortality relationship by $PM_{2.5}$, there is evidence that the association generally remains positive (Figure 5-46). However, Samoli et al. (2013) in a study of 10 European Mediterranean cities within the MED-PARTICLES project did not find any evidence of $PM_{10-2.5}$-respiratory mortality association in copollutant models with $PM_{2.5}$. Unlike the other studies evaluated, the authors only presented copollutant model results for lag 0−5 days, which is a lag structure that is longer and inconsistent with the larger body of evidence (Section 5.3.7.1.2).



Note: †Studies published since the 2009 PM ISA. a = copollutant results only presented for a lag of 0−5 days. Corresponding quantitative results are reported in Supplemental Material (U.S. EPA, 2018).

Figure 5-46 Percent increase in respiratory mortality for a 10 μg/m³ increase in 24-hour average $PM_{10-2.5}$ concentrations in single- and copollutant models.

The studies that provide evidence of a $PM_{10-2.5}$-respiratory mortality association that remains positive in copollutant models with $PM_{2.5}$ are supported by analyses conducted by Adar et al. (2014) in the context of a meta-analysis. When examining studies that conducted copollutant models with $PM_{2.5}$, Adar et al. (2014) observed that the $PM_{10-2.5}$-respiratory mortality association was similar in magnitude to that observed in single-pollutant models (quantitative results not provided). The results from copollutant models were further supported when stratifying $PM_{10-2.5}$-mortality estimates by the correlation with $PM_{2.5}$ (low, $r < 0.35$; medium, $r = 0.35$ to <0.5; high, $r > 0.5$). The authors observed evidence of positive associations for the medium and high correlation categories that were similar in magnitude, but had wide confidence intervals. However, there was no evidence of an association for the low correlations. Adar et al. (2014) further examined potential copollutant confounding by $PM_{2.5}$ through an analysis focusing on whether $PM_{10-2.5}$-mortality associations were present when the correlation between $PM_{2.5}$ and $PM_{10-2.5}$ increased and when $PM_{2.5}$ was also associated with mortality. As highlighted in Figure 5-47, there was evidence of positive $PM_{10-2.5}$-respiratory mortality associations at both low and high correlations as well as low and high magnitudes of the $PM_{2.5}$-respiratory mortality association (Figure 5-47).



Source: Permission pending, Adar et al. (2014).

Figure 5-47 Associations between short-term $PM_{10-2.5}$ exposure and respiratory mortality as a function of the correlation between $PM_{10-2.5}$ and $PM_{2.5}$ stratified by strength of the association with $PM_{2.5}$.

Across the studies that examined potential copollutant confounding, only a few examined gaseous pollutants (Lee et al., 2015; Samoli et al., 2013) and the results contradict one another (see Figure 5-46).

As a result, it remains unclear whether gaseous copollutants confound the $PM_{10-2.5}$-respiratory mortality association.

Collectively, the recent epidemiologic studies that examined potential copollutant confounding provide initial evidence that $PM_{10-2.5}$-respiratory mortality associations remain generally positive in copollutant models particularly with $PM_{2.5}$. However, the lack of information on the correlations among the pollutants examined and the limited analyses of gaseous pollutants complicates the interpretation of the copollutant model results.

5.3.7.1.2 Lag Structure of Associations

Multicity epidemiologic studies that examined cause-specific mortality in the 2009 PM ISA (U.S. EPA, 2009) observed immediate effects on respiratory mortality attributed to short-term $PM_{10-2.5}$ exposure, with consistent positive associations observed at lags ranging from 0 to 2 days. However, the majority of these studies either examined single-day lags or selected lags a priori. Recent multicity studies have conducted more extensive examinations of the lag structure of associations by examining multiple sequential single-day lags or examining whether there is evidence of immediate (i.e., lag 0−1 days), delayed (i.e., lag 2−5 days), or prolonged (i.e., lag 0−5 days) effects of short-term $PM_{10-2.5}$ exposure on respiratory mortality.

Across the studies that examined single-lag days, most of the studies focused on lags within the range of 0 to 2 days. Although a few studies extended out to a longer duration, collectively the studies provided evidence that was generally in agreement with one another. Janssen et al. (2013), in a study conducted in the Netherlands, examined single-day lags of 0 to 3 days and reported no evidence of an association at lag 0 and 1 day. The largest association in terms of magnitude and precision was for lag 2 days (3.8% [95% CI: 0.6, 7.2]). Chen et al. (2011b), within the CAPES study, reported evidence of an immediate effect between short-term $PM_{10-2.5}$ exposure and respiratory mortality by observing evidence of a positive association at lag 1 and no evidence of an association at lag 0 and 2 days. Stafoggia et al. (2017), in a study of eight European cities, examined single-day lags ranging from 0 to 10 days also reported evidence of an immediate effect with positive associations at lags 0 and 1 day. However, the authors found evidence of positive associations at longer lags (i.e., lag 4 and 5), but confidence intervals were wide. The results across the studies that examined a series of single-day lags is further supported by the meta-analysis by Adar et al. (2014) where an examination of single-day lag risk estimates across studies found positive associations across lags ranging from 0 to 2 days with the strongest association in terms of magnitude and precision occurring at lag 1.

Although the studies that examined a series of single-day lags tend to support a $PM_{10-2.5}$-respiratory mortality association within the first few days after exposure, Samoli et al. (2013), in the MED-PARTICLES project, did not provide further support for this lag structure of associations. The authors examined both a series of multiday lags as well as single-day lags through a polynomial

distributed lag over 0−7 days. In the multiday lag analysis, Samoli et al. (2013) reported the strongest evidence of an association for a delayed effect (i.e., lag 2−5 days) (0.72% [95% CI: −0.31, 1.8]), with no evidence of an association at lag 0−1 days. This observation was confirmed when examining the polynomial distributed lag provided evidence of positive associations only at lags 3,4, and 5 (quantitative results not presented).

Overall, studies that examined the lag structure of associations generally support that short-term $PM_{10-2.5}$ exposure contributes to respiratory mortality effects within the first few days after exposure, ranging from 0−2 days. However, there is initial evidence that the $PM_{10-2.5}$-respiratory mortality association may be more delayed.

5.3.7.1.3 Effect Modification

Season

An examination of potential seasonal differences in associations between short-term $PM_{10-2.5}$ exposure and respiratory mortality in the 2009 PM ISA (U.S. EPA, 2009) was limited to one U.S. multicity study (Zanobetti and Schwartz, 2009) that provided initial evidence of associations being larger in magnitude in the spring and summer. Although still limited in number, some recent multicity studies conducted an examination of potential seasonal differences in associations (Lee et al., 2015; Samoli et al., 2013).

Samoli et al. (2013), in the MED-PARTICLES project, only examined warm (April−September) and cold months (October−March). In analyses focusing on lag 0−5 days, the authors observed evidence of positive associations in both seasons, with associations larger in magnitude during the warm season (1.21% [95% CI: −2.0, 4.6]) compared to the cold season (0.30% [95% CI: −1.8, 2.5]), but confidence intervals were wide. Lee et al. (2015), in a study conducted in 11 east Asian cities, observed a different pattern of seasonal associations. The authors reported larger associations in the cold season (1.2% [95% CI: 0.16, 2.3]) compared to the warm (0.42% [95% CI: −0.30, 1.2]). It is unclear why these results differ from the other studies, but mean $PM_{10-2.5}$ concentrations and mean temperature tended to be higher across the cities in Lee et al. (2015) compared to the cities in the other studies evaluated in this section. Overall, the inconsistent evidence across studies does not provide additional information on the seasonal pattern of associations between short-term $PM_{10-2.5}$ exposure and respiratory mortality.

Temperature

In addition to examining whether there is evidence that warm temperatures modify the $PM_{10-2.5}$-respiratory mortality relationship by conducting seasonal analyses, a recent study also examined whether there is evidence that high temperature days modify the $PM_{10-2.5}$-respiratory mortality

relationship. Although in all-year analyses, Pascal et al. (2014) reported no evidence of an association between short-term $PM_{10–2.5}$ exposure and respiratory mortality, the authors examined whether temperature modified the relationship. Pascal et al. (2014) examined the impact of temperature on the $PM_{10–2.5}$-respiratory mortality relationship across nine French cities by comparing associations on warm and nonwarm days, where warm days were defined as those days where the mean temperature exceeded the 97.5th percentile of the mean temperature distribution. When calculating the interaction ratio, which estimated the extra PM effect due to warm days, the authors observed no evidence of a positive modifying effect of warm days on respiratory mortality.

5.3.8 Summary and Causality Determination

Based on a small number of epidemiologic studies observing associations with some respiratory effects and limited evidence from experimental studies to support biological plausibility, the 2009 PM ISA (U.S. EPA, 2009) concluded that the relationship between short-term exposure to $PM_{10–2.5}$ and respiratory effects is suggestive of a causal relationship. Epidemiologic findings were consistent for respiratory infection and combined respiratory-related diseases, but not for COPD. Studies were characterized by overall uncertainty in the exposure assignment approach and limited information regarding potential copollutant confounding. Controlled human exposure studies of short-term $PM_{10–2.5}$ exposure found no lung function decrements and inconsistent evidence for pulmonary inflammation in healthy individuals or human subjects with asthma. Animal toxicological studies were limited to those using noninhalation (e.g., intra-tracheal instillation) routes of $PM_{10–2.5}$ exposure. Recent studies strengthen the evidence base for asthma exacerbation and respiratory mortality, but they do not rule out chance and confounding. The evidence for the relationship between short-term exposure to $PM_{2.5}$ and effects on the respiratory system is summarized in Table 5-37, using the framework for causality determinations described in the Preamble to the ISAs (U.S. EPA, 2015).

Table 5-37 Summary of evidence that is suggestive of, but not sufficient to infer, a causal relationship between short-term $PM_{10–2.5}$ exposure and respiratory effects.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{10–2.5}$ Concentrations Associated with Effects[c]
Asthma exacerbation			
Consistent epidemiologic evidence from a limited number of multiple, high quality studies at relevant $PM_{2.5}$ concentrations	Increases in asthma-related hospital admissions and ED visits. Evidence mostly from single-city studies conducted in the U.S.	Section 5.3.2.1	9.7−16.2 μg/m^3

Table 5-37 (Continued): Summary of evidence that is suggestive of, but not sufficient to infer, a causal relationship between short-term $PM_{10-2.5}$ exposure and respiratory effects.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{10-2.5}$ Concentrations Associated with Effects[c]
Uncertainty regarding confounding by copollutants	Potential copollutant confounding for asthma-related hospital admissions and ED visits is examined in a few studies, with some evidence that associations remain robust in models with gaseous pollutants and $PM_{2.5}$.	Section 5.3.2.1	
Uncertainty regarding exposure measurement error	Uncertainty in using $PM_{10-2.5}$ concentrations, estimated by differencing PM_{10} and $PM_{2.5}$ concentrations, as exposure surrogates, is not addressed.		
Limited coherence in epidemiologic studies across the continuum of effects	Providing support for asthma exacerbation are findings of associations for respiratory symptoms in children. There is no evidence for association with lung function decrements, and inconsistent evidence for eNO.	Section 5.3.2.2 Section 5.3.2.3 Section 5.3.2.4	
Inconsistent evidence from controlled human exposure studies	In adults with asthma, measures of lung function are unaffected. Results for pulmonary inflammation were inconsistent, with one study finding many effects on immune function.	Section 5.3.2.4.2 Alexis et al. (2014)	90 µg/m^3
Biological plausibility	Evidence from one controlled human exposure study provides biological plausibility with epidemiologic findings for allergic asthma, the most common asthma phenotype in children.		
Respiratory mortality			
Consistent epidemiologic evidence from multiple, high quality studies at relevant $PM_{10-2.5}$ concentrations	Associations are observed in single and multicity studies, with effects tending to occur between 0−2 days.	Section 5.3.7	
Uncertainty regarding confounding by copollutants and exposure measurement error	Potential copollutant confounding is examined in a few studies, with some evidence that associations remain robust in models with $PM_{2.5}$.	Section 5.3.7	
Uncertainty regarding exposure measurement error	Uncertainty in using $PM_{10-2.5}$ concentrations, estimated by differencing PM_{10} and $PM_{2.5}$ concentrations, as exposure surrogates, is not addressed.	Section 3.3.1	

Table 5-37 (Continued): Summary of evidence that is suggestive of, but not sufficient to infer, a causal relationship between short-term $PM_{10-2.5}$ exposure and respiratory effects.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{10-2.5}$ Concentrations Associated with Effects[c]
Some coherence with underlying causes of mortality	COPD and respiratory infection evidence provide some coherence.	Section 5.3.3 Section 5.3.4	
Exacerbation of COPD, respiratory infection and combined respiratory-related diseases			
Limited epidemiologic evidence and uncertainty regarding $PM_{10-2.5}$ independent effects	Generally positive associations for COPD-related hospital admissions in a limited number of studies conducted in the U.S., Canada, and Asia. Evidence is inconsistent for COPD ED visits.	Section 5.3.3.1	5.6−24.8 μg/m^3
	Generally positive associations ED visits for acute respiratory infection, pneumonia, and combinations of respiratory infections in a limited number of studies in the U.S., Canada, and Asia.	Section 5.3.4.1	5.6−24.8 μg/m^3
	Generally positive associations are observed for combined respiratory-related disease hospital admissions in single-city and multicity studies conducted in the U.S., Canada, and Europe. Evidence is inconsistent for combined respiratory-related disease visits.	Section 5.3.5	
Respiratory effects in healthy populations			
Inconsistent evidence from epidemiologic studies	A limited number of panel studies in healthy adults reported inconsistent evidence of associations with lung function and pulmonary inflammation.	Section 5.3.6.1	
Inconsistent evidence from controlled human exposure studies	Evidence is inconsistent for pulmonary inflammation.	Section 5.3.6.2 Behbod et al. (2013)	235 μg/m^3
Some evidence from toxicological studies at relevant concentrations	Results show altered lung function and pulmonary inflammation in rodents exposed by inhalation to $PM_{10-2.5}$ CAPs.	Amatullah et al. (2012) Aztatzi-Aguilar et al. (2015)	32−793 μg/m^3

[a]Based on aspects considered in judgments of causality and weight of evidence in causal framework in Table I and Table II of the Preamble to the ISAs (U.S. EPA, 2015).

[b]Describes the key evidence and references, supporting or contradicting, contributing most heavily to causality determination and, where applicable, to uncertainties or inconsistencies. References to earlier sections indicate where full body of evidence is described.

[c]Describes the $PM_{2.5}$ concentrations with which the evidence is substantiated.

Recent epidemiologic findings more consistently link $PM_{10–2.5}$ to asthma exacerbation than studies reported in the 2009 PM ISA (U.S. EPA, 2009). These studies of hospital admission and ED visits include children older than 5 years. These findings are supported by epidemiologic studies observing respiratory symptoms in children and by a controlled human exposure study showing PM-related effects on inflammation and the immune system. There is limited evidence that associations remain robust in models with gaseous pollutants and $PM_{2.5}$. Recent, but limited, epidemiologic findings are also more consistent for COPD exacerbation and combined respiratory-related diseases compared with studies reported in the 2009 PM ISA. However, the evidence for COPD hospital admissions is inconsistent across several U.S. cities and for direct $PM_{10–2.5}$ measurements. Recent epidemiologic findings for respiratory infection differ than findings reported in the 2009 ISA in that they indicate associations with pneumonia, but not combinations of respiratory infections. The respiratory effects related to short-term $PM_{10–2.5}$ exposure in healthy individuals remain inconsistent, although some controlled human exposure and animal toxicological studies show effects. The evidence base for respiratory mortality is expanded since the 2009 PM ISA (U.S. EPA, 2009) and is generally supportive of associations with short-term exposure to $PM_{10–2.5}$. Studies provide initial evidence that $PM_{10–2.5}$-respiratory mortality associations remain positive but may be attenuated in copollutant models. In addition, $PM_{10–2.5}$ effects on respiratory mortality tend to occur within the first few days of exposure (i.e., lags 0 to 2 days). Across most of these respiratory outcome groups, copollutant confounding remains uncertain. An uncertainty spanning all epidemiologic studies examining associations with $PM_{10–2.5}$ is the lack of a systematic evaluation of the various methods used to estimate $PM_{10–2.5}$ concentrations and the resulting uncertainty in the spatial and temporal variability in $PM_{10–2.5}$ concentrations compared to $PM_{2.5}$ (Section 2.5.1.2.3 and Section 3.3.1.1). **Overall, the collective evidence is suggestive of, but not sufficient to infer, a causal relationship between short-term $PM_{10–2.5}$ exposure and respiratory effects.**

5.4 Long-Term $PM_{10–2.5}$ Exposure and Respiratory Effects

The 2009 PM ISA concluded that the evidence was inadequate to assess the relationship between long-term exposure to $PM_{10–2.5}$ and respiratory effects (U.S. EPA, 2009).[60] At that time, the evidence consisted of a single epidemiologic study. Some recent epidemiologic findings link $PM_{10–2.5}$ to lung function metrics (Section 5.4.2), the development of asthma (Section 5.4.3), and respiratory infection (Section 5.4.5) in children. However, there is little or no evidence for the development of allergic disease (Section 5.4.4), severity of asthma (Section 5.4.6), or respiratory effects in healthy populations (Section 5.4.7). In all recent studies, $PM_{10–2.5}$ concentrations were estimated by LUR models, dispersion models, or by subtracting monitored $PM_{2.5}$ concentrations from monitored PM_{10} concentrations. The major uncertainties for these studies involve the potential for exposure measurement error, especially

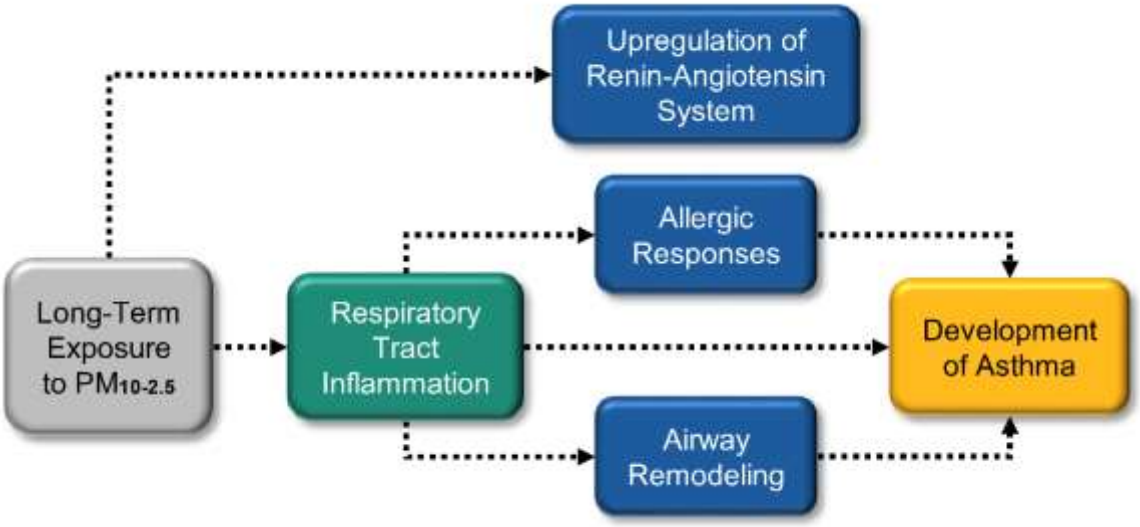
[60] As detailed in the Preface, risk estimates are for a 5 $\mu g/m^3$ increase in annual $PM_{10-2.5}$ concentrations unless otherwise noted.

relating to the errors due to subtracting $PM_{2.5}$ concentration from PM_{10} concentration, notably when the monitors are not collocated, and the potential for confounding related to copollutants. Experimental evidence is limited to a single inhalation exposure in healthy animals, although additional studies using noninhalation routes of exposure provide biological plausibility for a relationship between long-term exposure to $PM_{10–2.5}$ and asthma severity.

5.4.1 Biological Plausibility

This section describes biological pathways that potentially underlie respiratory health effects resulting from long-term exposure to $PM_{10–2.5}$. Figure 5-48 graphically depicts the proposed pathways as a continuum of upstream events, connected by arrows, that may lead to downstream events observed in epidemiologic studies. This discussion of "how" long-term exposure to $PM_{10–2.5}$ may lead to respiratory health effects contributes to an understanding of the biological plausibility of epidemiologic results evaluated later in Section 5.4.

Once $PM_{10–2.5}$ deposits in the respiratory tract, it may be retained, cleared, or solubilized (see CHAPTER 4). Insoluble and soluble components of $PM_{10–2.5}$ may interact with cells in the respiratory tract, such as epithelial cells, inflammatory cells, and sensory nerve cells. One way in which this may occur is through reduction-oxidative (redox) reactions. As discussed in Section 2.3.3, PM may generate reactive oxygen species (ROS) and this capacity is termed "oxidative potential." Furthermore, cells in the respiratory tract may respond to the presence of PM by generating ROS. Further discussion of these redox reactions, which may contribute to oxidative stress, is found in Section 5.1.1 of the 2009 PM ISA (U.S. EPA, 2009). In addition, poorly soluble particles may translocate to the interstitial space beneath the respiratory epithelium and accumulate in the lymph nodes (see CHAPTER 4). Immune system responses due to the presence of particles in the interstitial space may contribute to respiratory health effects.



Note: The boxes above represent the effects for which there is experimental or epidemiologic evidence, and the dotted arrows indicate a proposed relationship between those effects. Progression of effects is depicted from left to right and color-coded (gray, exposure; green, initial event; blue, intermediate event; orange, apical event). Here, apical events generally reflect results of epidemiologic studies, which often observe effects at the population level. Epidemiologic evidence may also contribute to upstream boxes. When there are gaps in the evidence, there are complementary gaps in the figure and the accompanying text below.

Figure 5-48 Potential biological pathways for respiratory effects following long-term $PM_{10-2.5}$ exposure.

Evidence that long-term exposure to $PM_{10-2.5}$ may affect the respiratory tract generally informs one proposed pathway (Figure 5-48). It begins with respiratory tract inflammation and leads to allergic responses and airway remodeling that may underly the development or worsening of asthma. Epidemiologic evidence links long-term exposure to $PM_{10-2.5}$ and eNO, a marker of airway inflammation (Dales et al., 2008). Supportive evidence is provided by several animal toxicological studies involving intra-tracheal instillation (Liu et al., 2014; He et al., 2013a; He et al., 2013b). In these studies, multiple exposures to dust storm-associated $PM_{10-2.5}$ resulted in allergic inflammation and airway remodeling in nonallergic mice and enhanced allergen-induced responses in allergic mice. These findings are supportive of a link between long-term $PM_{10-2.5}$ exposure and incident asthma (Section 5.4.3). This proposed pathway provides biological plausibility for epidemiologic evidence of respiratory health effects and will be used to inform a causality determination, which is discussed later in the chapter (Section 5.4.9).

In addition, a study of long-term $PM_{10-2.5}$ exposure in animals (Aztatzi-Aguilar et al., 2015) found decreases in tissue levels of heme oxygenase-1 and IL-6, markers of oxidative stress and inflammation, respectively. Increases in mRNA and protein levels of angiotensin receptor Type 1 and mRNA levels of angiotensin converting enzyme, which are components of the RAS, were also observed. Angiotensin receptor Type 1 mediates the effects of angiotensin II, which is a potent vasoconstrictor and mediator in the vasculature. Deposition of inhaled $PM_{10-2.5}$ is expected to primarily occur in the extrathoracic airways

(i.e., the nose) of rodents and to result in a much smaller fraction deposited in the lower respiratory tract compared with humans. This study links deposition of $PM_{10–2.5}$ in the nose to increased activity of the RAS and to a possible dampening of oxidative stress and inflammation in the lung.

5.4.2 Lung Function and Lung Development

As evaluated in the 2009 PM ISA (U.S. EPA, 2009), a cross-sectional analysis of 1,613 schoolchildren in Windsor, Ontario reported that a 5 ug/m^3 increase in $PM_{10–2.5}$ was not associated with percent predicted FEV_1 (0.26 [95% CI: −4.22, 4.74]) and was associated with small, imprecise (i.e., wide 95% CIs) increase in percent predicted FVC: (1.10 [95% CI: −8.11, 10.39]) (Dales et al., 2008). Recent analyses of European birth cohorts have observed consistent associations between $PM_{10–2.5}$ and an array of lung function metrics. In the PIAMA cohort, $PM_{10–2.5}$ estimated at children's current addresses was associated with decreases in FEV_1, FVC, and $FEF_{25–75}$ measures collected at age 8 and 12 (Gehring et al., 2015a). Similarly, in an ESCAPE project analysis of five European cohorts, $PM_{10–2.5}$ estimates at both birth address and current address were negatively associated with FEV_1 measured at ages 6 and 8, but the effect was stronger when current address was used in the exposure assignment (Gehring et al., 2013). $PM_{10–2.5}$ at current address was also associated with higher odds of FEV_1 <85% of predicted values (OR: 1.81 [95% CI: 0.94, 3.47]), a clinically significant indicator of impaired lung function.

Cross-sectional studies of schoolchildren in 24 Taiwanese provinces (Chen et al., 2015a) and 9−10-year olds participating in the Child Heart and Health Study in England (Barone-Adesi et al., 2015) provided inconsistent evidence of an association between $PM_{10–2.5}$ and lung function. While Chen et al. (2015a) reported reductions of 102 ml (95% CI: 16, 189 ml) in FEV_1 and 121 ml (95% CI: 15, 227 ml) in FVC per 5 µg/m^3 increase in $PM_{10–2.5}$ over the past 2 months, Barone-Adesi et al. (2015) did not observe any associations between annual $PM_{10–2.5}$ exposure and the same lung function metrics. Additionally, it is unclear whether Chen et al. (2015a) estimated $PM_{10–2.5}$ using collocated PM_{10} and $PM_{2.5}$ monitors.

In addition to studies conducted among children, one epidemiologic study evaluated the effects of long-term exposure to $PM_{10–2.5}$ on pulmonary function in adults. Results for the various indices of pulmonary function were inconsistent among adults participating in the ESCAPE project (Adam et al., 2015). $PM_{10–2.5}$ was associated with decrements in FEV_1 and FVC in a cross-sectional analysis, but an increase in FEV_1 in longitudinal analyses. Due to the strengths of a longitudinal study design compared to a cross-sectional design, it's possible that the negative association may have been the result of unmeasured confounding in the cross-sectional analysis.

5.4.3 Development of Asthma

There were no studies examining the association between long-term exposure to $PM_{10–2.5}$ and the development of asthma available for inclusion in the 2009 PM ISA (U.S. EPA, 2009). A few recent studies report associations between $PM_{10–2.5}$ and asthma incidence. In the PIAMA cohort in the Netherlands (Gehring et al., 2015a) and a pooled analysis of four European birth cohorts (Gehring et al., 2015b), asthma incidence was associated with $PM_{10–2.5}$ concentrations outside birth residences. The associations were attenuated, but still positive when $PM_{10–2.5}$ concentrations were assigned at the address of the participant at the time of follow-up. This indicates the potential importance of early life exposures.

Studies examining asthma prevalence in children reported contrasting evidence. The Gehring et al. (2015b) pooled analysis, discussed above, observed inconsistent evidence of an association across cohorts, and reported a null association in a meta-analysis combining results from all cohorts. Another ESCAPE project analysis of five European birth cohorts estimated $PM_{10–2.5}$ at participants' birth addresses and addresses at age 4 and age 8 (Mölter et al., 2014). Birth and current address $PM_{10–2.5}$ was not associated with higher odds of prevalent asthma at age 4. However, $PM_{10–2.5}$ estimated at both birth and current address was associated with an increase in odds of asthma by age 8. Contrary to the results for asthma incidence, the association was higher in magnitude and more precise when asthma prevalence was related to current address $PM_{10–2.5}$ concentrations (OR: 1.16 [95% CI: 0.93, 1.44]) rather than birth address exposure (1.10 [0.72, 1.69]).

No recent studies have examined subclinical effects underlying the development of asthma in association with long-term exposure to $PM_{10–2.5}$. A cross-sectional analysis of 1,613 schoolchildren in Windsor, Ontario, reviewed in the 2009 PM ISA (U.S. EPA, 2009), reported a null association between $PM_{10–2.5}$ and Ln(eNO) (Dales et al., 2008). Results from a prior CHS analysis (Bastain et al., 2011) showed that elevated eNO was associated with increased risk of new onset asthma.

In addition to studies conducted among children, one epidemiologic study evaluated the effects of long-term $PM_{10–2.5}$ exposure in adults. An ESCAPE project analysis also examined associations between $PM_{10–2.5}$ and incident asthma (Jacquemin et al., 2015). In a meta-analysis of all cohorts, annual $PM_{10–2.5}$ was not associated with higher odds of incident asthma (OR: 0.99 [95% CI: 0.87, 1.14]).

Animal toxicological studies related to the development of asthma are typically conducted in nonallergic animal models. Inhalation exposure of rodents to $PM_{10–2.5}$ is technically difficult since rodents are obligatory nasal breathers. A group of recent studies examined the effects of long-term $PM_{10–2.5}$ using Asian sand dust and noninhalation routes of exposure (i.e., intra-tracheal instillation). Results provide biological plausibility for a potential role of $PM_{10–2.5}$ in allergic inflammation and airway remodeling (Liu et al., 2014; He et al., 2013a; He et al., 2013b).

5.4.4 Development of Allergic Disease

There were no studies examining the association between long-term exposure to $PM_{10-2.5}$ and the development of allergic disease available for inclusion in the 2009 PM ISA (U.S. EPA, 2009). A small number of recent epidemiologic studies examined the association between long-term exposure to $PM_{10-2.5}$ and allergic disease. The relation between early-life exposure to $PM_{10-2.5}$ and allergic sensitization at age 4 and 8 years was examined in the ESCAPE pooled analysis of five European cohorts (Gruzieva et al., 2014). There were no clear associations between $PM_{10-2.5}$ concentrations estimated at birth address and sensitization at age 4 or age 8. Similarly, another European birth cohort pooled analysis did not observe an association between $PM_{10-2.5}$ and rhinoconjunctvitis (Gehring et al., 2015b). The PIAMA cohort reported on associations between $PM_{10-2.5}$ and allergic outcomes (Gehring et al., 2015a) noting that $PM_{10-2.5}$ was associated with increases in self-reported hay fever, rhinitis and allergic sensitization during the first 11 years of life (ORs ranging from 1.3 to 1.6 per 5 μg/m^3 increase). In a 2006 U.S. National Health Interview Survey (NHIS) cross-sectional analysis, $PM_{10-2.5}$ was examined as a potential predictor of allergy in children aged 3−17 years living within 20 miles of an air-quality monitor (Parker et al., 2009). $PM_{10-2.5}$ was not associated with respiratory allergy/hay fever.

5.4.5 Respiratory Infection

There were no studies examining the association between long-term exposure to $PM_{10-2.5}$ and respiratory infection available for inclusion in the 2009 PM ISA (U.S. EPA, 2009). Recently, an ESCAPE project study examined respiratory infections in relation to $PM_{10-2.5}$ (MacIntyre et al., 2014b). $PM_{10-2.5}$ estimated at birth residence was associated with an imprecise increase in odds of pneumonia in the first 36 months of life (OR: 1.24 [95% CI: 1.03, 1.5] per 5 ug/m^3 increase), but was not associated with increased odds of otitis media or croup. A sensitivity analysis looking at alternative outcome windows showed the strongest association between long-term $PM_{10-2.5}$ and pneumonia diagnosed in the first year of life (OR: 1.46 [95% CI: 1.11, 1.92]). The association between $PM_{10-2.5}$ and pneumonia at 36 months was attenuated, but still positive in a two-pollutant model adjusting for NO_2 (1.13 [0.72, 1.76]; r = 0.34−0.93).

5.4.6 Severity of Asthma

There were no studies examining the association between long-term exposure to $PM_{10-2.5}$ and severity of asthma available for inclusion in the 2009 PM ISA (U.S. EPA, 2009). Recent studies are limited in number. In an epidemiologic study conducted in northern California, Balmes et al. (2014) examined the association between annual $PM_{10-2.5}$ and symptomatic asthma in a cross-sectional cohort study of adults with both asthma and allergies. The middle and highest tertiles of annual $PM_{10-2.5}$ exposure (10.68−12.68 and ≥12.71 μg/m^3, respectively) were not associated with increased odds of asthma symptoms compared to the lowest tertile of exposure (<10.68 μg/m^3).

Animal toxicological studies related to asthma severity are typically conducted in allergic animal models, which share phenotypic features with asthma (see Section 5.1.2.4). Inhalation exposure of rodents to $PM_{10–2.5}$ is technically difficult since rodents are obligatory nasal breathers. A group of recent studies examined the effects of long-term $PM_{10–2.5}$ using Asian sand dust and noninhalation routes of exposure (i.e., intra-tracheal instillation). Results provide biological plausibility for a potential role of $PM_{10–2.5}$ in enhancing allergic responses (Liu et al., 2014; He et al., 2013a; He et al., 2013b).

5.4.7 Subclinical Effects in Healthy Populations

Animal toxicological and epidemiologic studies provide evidence for subclinical effects potentially underlying the development of respiratory disease in healthy populations. As reported in the 2009 PM ISA (U.S. EPA, 2009), Dales et al. (2008) found a positive association between long-term exposure to $PM_{10–2.5}$ and eNO, a marker of inflammation, in an epidemiologic study among children living in Windsor, ON. In a recent animal toxicological study, Aztatzi-Aguilar et al. (2015) evaluated pulmonary oxidative stress and inflammatory responses in Sprague Dawley rats exposed for 8 weeks to $PM_{10–2.5}$ CAPs in Mexico City. A decrease in lung tissue heme oxygenase-1 activity was found ($p < 0.05$), but there was no change in γ-glutamyl cysteine synthetase catalytic subunit, another index of oxidative stress. Long-term exposure to $PM_{10–2.5}$ CAPs also resulted in a decrease in IL-6 protein ($p < 0.05$) and changes in the RAS. An increase in angiotensin receptor Type 1 protein was observed along with a decrease in its mRNA levels in lung tissue ($p < 0.05$). Angiotensin receptor Type 1 mediates the effects of angiotensin II, which is a potent vasoconstrictor and mediator in the vasculature. Protein and mRNA levels of angiotensin converting enzyme, which catalyzes the conversion of angiotensin I to angiotensin II, increased following long-term exposure to $PM_{10–2.5}$ CAPs ($p < 0.05$). Since deposition of inhaled $PM_{10–2.5}$ is expected to primarily occur in the extrathoracic airways (i.e., the nose) of rodents, this study links deposition in the nose to increased activity of the RAS and to a possible dampening of oxidative stress and inflammation in the lower airways. Additional study details are found in Table 5-38.

Table 5-38 Study-specific details from an animal toxicological study of long-term exposure to $PM_{10-2.5}$ and respiratory effects in healthy animals.

Study/Study Population	Pollutant	Exposure	Endpoints
Aztatzi-Aguilar et al. (2015) Species: Rat Sex: Male Strain: Sprague Dawley Age/Weight:	$PM_{10-2.5}$ CAPs Mexico City Particle size: $PM_{10-2.5}$ Control: Filtered air	Route: Inhalation Dose/Concentration: Coarse $PM_{10-2.5}$ 32 µg/m^3 Duration: Acute 5 h/day, 3 days Subchronic 5 h/day, 4 days/week, 8 weeks Time to analysis: 24 h	Gene and protein expression in lung tissue • IL-6 • Components of RAS and kalikrein-kinin endocrine system • Heme oxygenase-1

IL-6 = interleukin 6; RAS = renin-angiotensin system.

5.4.8 Respiratory Mortality

Two recent European cohort studies evaluated the association between long-term $PM_{10-2.5}$ exposure and mortality and observed inconsistent results. In a pooled analysis of 22 cohorts from 13 European cohorts, Dimakopoulou et al. (2014) observed a null association with respiratory mortality in the ESCAPE cohort. In a French cohort, Bentayeb et al. (2015) observed a positive association between long-term $PM_{10-2.5}$ exposure and respiratory mortality. Both studies used statistical models to predict area-wide PM_{10} and $PM_{2.5}$ concentrations and used the subtraction method to estimate $PM_{10-2.5}$ concentrations, which contributes to uncertainty regarding exposure measurement error.

5.4.9 Summary and Causality Determination

Based on limited epidemiologic evidence demonstrating associations with some respiratory effects and a lack of evidence from experimental studies to support biological plausibility, the 2009 PM ISA (U.S. EPA, 2009) concluded that evidence was inadequate to assess the relationship between long-term exposure to $PM_{10-2.5}$ and respiratory effects. The evidence characterizing the relationship between long-term exposure to $PM_{10-2.5}$ and respiratory effects is detailed below (Table 5-39), using the framework for causality determinations described in the Preamble to the ISAs (U.S. EPA, 2015). A limited number of recent epidemiology studies expand the evidence base for decrements in lung function, the development of asthma, and respiratory infection in children. Uncertainty regarding copollutant confounding and exposure measurement error results in an inability to rule out chance and confounding. An animal toxicological study examined the potential for inhalation of $PM_{10-2.5}$ to affect the respiratory

system and found upregulation of the RAS and a dampening of oxidative stress and inflammation in the lung. Several animal toxicological studies involving noninhalation routes of exposure found allergic inflammation and airway remodeling, which provides biological plausibility for the development of asthma. Overall, **the evidence is inadequate to infer the presence or absence of a causal relationship between long-term $PM_{10–2.5}$ exposure and respiratory effects.**

Table 5-39 Summary of evidence that is inadequate to infer the presence or absence of a causal relationship between long-term $PM_{10-2.5}$ exposure and respiratory effects.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{2.5}$ Concentrations Associated with Effects[c]
Limited epidemiologic evidence from multiple, high quality studies at relevant $PM_{10-2.5}$ concentrations	Decrements in attained lung function in children consistently observed in a limited number of cohort studies.	Gehring et al. (2013) Gehring et al. (2015a)	7.6−8.4 µg/m^3
	Increases in asthma incidence in children in a limited number of cohort studies. Supporting evidence from studies of asthma prevalence in children are inconsistent.	Gehring et al. (2015b) Gehring et al. (2015a)	8.4 µg/m^3
Coherence provided by epidemiologic studies of airway inflammation	Results from a single study show an association with eNO in children.	Dales et al. (2008)	7.3 µg/m^3
Uncertainty regarding confounding by copollutants	Potential copollutant confounding is not addressed.		
Uncertainty regarding exposure measurement error	Studies rely on subtraction method to estimate exposure to $PM_{10-2.5}$ adding uncertainty to the interpretation of effect estimates.	Section 3.3.1	
Biological plausibility	Evidence from a few animal toxicological studies involving intra-tracheal exposure provides biological plausibility for limited epidemiologic findings of the development of asthma.	Section 5.4.1	
Limited evidence from a toxicological study at relevant concentrations	Results from a single inhalation study in rodents show respiratory effects.	Aztatzi-Aguilar et al. (2015)	32 µg/m^3

[b]Describes the key evidence and references, supporting or contradicting, contributing most heavily to causality determination and, where applicable, to uncertainties or inconsistencies. References to earlier sections indicate where full body of evidence is described.

[c]Describes the $PM_{2.5}$ concentrations with which the evidence is substantiated.

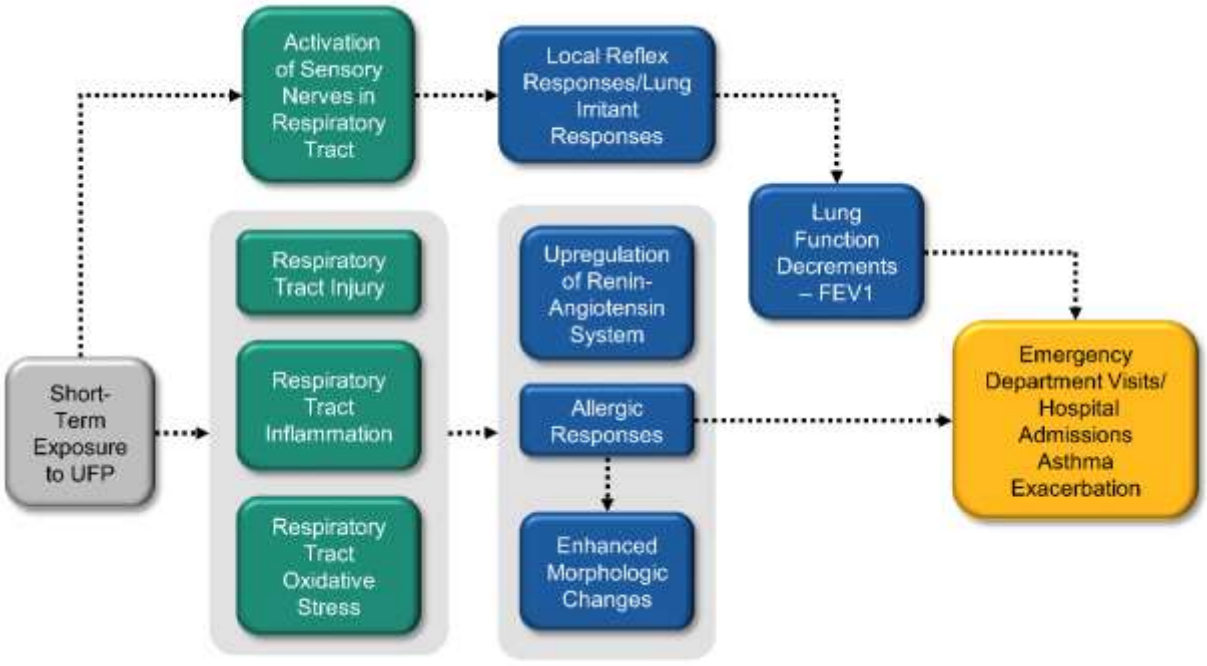
5.5 Short-Term UFP Exposure and Respiratory Effects

The 2009 PM ISA concluded that the relationship between short-term exposure to UFP and respiratory effects is "suggestive of a causal relationship" (U.S. EPA, 2009). This conclusion was based on limited, but supporting, epidemiologic evidence indicating associations with hospital admissions or ED visits for respiratory-related diseases, respiratory infection, and asthma exacerbation. Also providing support, personal ambient UFP exposure from time spent in high- and low-traffic areas was associated with lung function decrements in adults with asthma. The few available experimental studies provided limited coherence with epidemiologic findings for asthma exacerbation. Experimental studies of healthy human subjects and animals were also limited in number. Despite some evidence indicating a relationship between UFP exposure and respiratory effects, there was substantial uncertainty due to the small evidence base, a heterogeneous array of respiratory endpoints examined, indeterminate adequacy of UFP measurements, and limited biological plausibility.

For many respiratory outcomes, recent studies have not changed the overall evidence base. For asthma exacerbation, there continues to be some epidemiologic evidence, which is not entirely consistent, as well as some animal toxicological evidence (Section 5.5.2). Epidemiologic evidence continues to be consistent for respiratory-related diseases (Section 5.5.5) and inconsistent for COPD exacerbation (Section 5.5.3). Unlike findings reported in the 2009 PM ISA (U.S. EPA, 2009), recent findings are inconsistent for respiratory infection (Section 5.5.4). Recent experimental findings in healthy populations and animal models of cardiovascular disease show that short-term UFP exposure affects some respiratory responses in rodents (Section 0 and Section 5.5.7). Epidemiologic findings in healthy populations are inconsistent, including those for personal ambient exposures (Section 0). Evidence for respiratory mortality is limited (Section 5.5.8). Information on confounding by traffic-related copollutants continues to be limited, and inference about an independent effect of UFP exposure is limited because of uncertainty in the representativeness of UFP measurements, assessed mostly at fixed-site monitors.

5.5.1 Biological Plausibility

This section describes biological pathways that potentially underlie respiratory effects resulting from short-term exposure to UFP. Figure 5-49 graphically depicts the proposed pathways as a continuum of upstream events, connected by arrows, that may lead to downstream events observed in epidemiologic studies. This discussion of "how" short-term exposure to UFP may lead to respiratory effects contributes to an understanding of the biological plausibility of epidemiologic results evaluated later in Section 5.5.



Note: The boxes above represent the effects for which there is experimental or epidemiologic evidence, and the dotted arrows indicate a proposed relationship between those effects. Shading around multiple boxes denotes relationships between groups of upstream and downstream effects. Progression of effects is depicted from left to right and color-coded (gray, exposure; green, initial event; blue, intermediate event; orange, apical event). Here, apical events generally reflect results of epidemiologic studies, which often observe effects at the population level. Epidemiologic evidence may also contribute to upstream boxes. When there are gaps in the evidence, there are complementary gaps in the figure and the accompanying text below.

Figure 5-49 Potential biological pathways for respiratory effects following short-term UFP exposure.

Once UFP deposits in the respiratory tract, it may be retained, cleared, or solubilized (see CHAPTER 4). UFP and its soluble components may interact with cells in the respiratory tract, such as epithelial cells, inflammatory cells, and sensory nerve cells. One way in which this may occur is through reduction-oxidative (redox) reactions. As discussed in Section 2.3.3, PM may generate ROS and this capacity is termed "oxidative potential." Furthermore, cells in the respiratory tract may respond to the presence of PM by generating ROS. Further discussion of these redox reactions, which may contribute to oxidative stress, is found in Section 5.1.1 of the 2009 PM ISA (U.S. EPA, 2009). In addition, poorly soluble particles may translocate to the interstitial space beneath the respiratory epithelium and accumulate in the lymph nodes (see CHAPTER 4). Immune system responses due to the presence of particles in the interstitial space may contribute to respiratory health effects.

Although all size fractions of PM may contribute to oxidative stress, UFPs may contribute disproportionately more as a function of their mass due to their large surface/volume ratio. The relative enrichment of redox active surface components, such as metals and organics, per unit mass may translate

to a relatively greater oxidative potential of UFPs compared with larger particles with similar surface components. In addition, the greater surface per unit volume may deliver relatively more adsorbed soluble components to cells. These components may undergo intra-cellular redox cycling following cellular uptake. Furthermore, per unit mass, UFPs may have more opportunity to interact with cell surfaces due to their greater surface area and their greater particle number compared with larger PM. These interactions with cell surfaces may lead to ROS generation, as described in Section 5.1.1 of the 2009 PM ISA (U.S. EPA, 2009). Recent studies have also demonstrated that UFPs have the capacity to cross cellular membranes by nonendocytic mechanisms involving adhesive interactions and diffusion, as described in CHAPTER 4. This may allow UFPs to interact with or penetrate intra-cellular organelles.

Evidence that short-term exposure to UFP may affect the respiratory tract generally informs two proposed pathways (Figure 5-49). The first pathway begins with injury, inflammation, and oxidative stress responses, which are difficult to disentangle. Inflammation generally occurs as a consequence of injury and oxidative stress, but it may also lead to further oxidative stress and injury due to secondary production of ROS by inflammatory cells. The second pathway begins with the activation of sensory nerves in the respiratory tract that can trigger local reflex responses and transmit signals to regions of the central nervous system that regulate autonomic outflow.

Injury, Inflammation, and Oxidative Stress

Experimental evidence that short-term exposure to UFP affects the respiratory tract is provided by numerous studies and supports a role for injury, inflammation, and oxidative stress. A few studies demonstrate markers of injury (i.e., decreased CC16 protein) and oxidative stress (4-hydroxynoneal, 3-nitrotyrosine, Ym1) (Cheng et al., 2016; Li et al., 2010; Kooter et al., 2006). Seagrave et al. (2008) exposed rats to GE containing UFP and found increased lung tissue chemiluminescence that was not present when GE was filtered, indicating that the particulate fraction played a role in the oxidative stress response. In the study by Cheng et al. (2016), a time-course analysis demonstrated oxidative stress in olfactory epithelium after a single exposure of 5 hours, as well as after multiple exposures over 3 weeks. Inflammatory responses were seen in some studies (Cheng et al., 2016; Aztatzi-Aguilar et al., 2015), but not others (Tyler et al., 2016; Amatullah et al., 2012). In Tyler et al. (2016), evidence for inflammation was found in a model of cardiovascular disease but not in healthy animals. In Cheng et al. (2016), time course analysis showed that inflammatory responses occurred concomitantly with oxidative stress responses.

Inflammation was not seen in human subjects with asthma following short-term exposure to UFP (Gong et al., 2008). However, supportive evidence for enhancement of allergic responses is provided by a study in human subjects with allergic asthma who were exposed to ultrafine carbon (Schaumann et al., 2014). Enhancement of allergic responses was also found in two studies in animals (Li et al., 2010; Kleinman et al., 2005). In Li et al. (2010), intra-nasal cosensitization with OVA and UFP was required for exacerbation of responses to inhaled UFP and OVA. These responses included increased BALF

eosinophils and neutrophils, upregulation of Th2 and Th17 cytokines, increased plasma OVA-specific IgE, and enhanced morphologic changes that extended to more distal parts of the lung. These results are consistent with some epidemiologic evidence of asthma-related hospital admissions and ED in association with UFP concentrations (Section 5.5.2.1).

Activation of Sensory Nerves

Short-term exposure to UFP did not alter pulmonary function in animal studies (Amatullah et al., 2012; Seagrave et al., 2008). However, in human subjects with asthma, decreases in FEV_1 and oxygen saturation were observed (Gong et al., 2008). Although lung irritant responses can sometimes result in decreased FEV_1, it is not clear whether inhalation of $PM_{2.5}$ led to FEV_1 changes by this pathway or whether it was mediated by inflammation. Epidemiologic panel studies conducted in people with asthma also found associations with lung function decrements (Mirabelli et al., 2015; McCreanor et al., 2007). These results are also consistent with some epidemiologic evidence of asthma-related hospital admissions and ED in association with UFP concentrations (Section 5.5.2.1).

Another study found upregulation of the RAS, as indicated by an increase in mRNA for angiotensin receptor Type 1 and angiotensin converting enzyme, in the lung (Aztatzi-Aguilar et al., 2015). Angiotensin receptor Type 1 mediates the effects of angiotensin II, which is a potent vasoconstrictor and mediator in the vasculature. The SNS and the RAS are known to interact in a positive feedback fashion (Section 8.1.2) with important ramifications in the cardiovascular system. However, it is not known whether SNS activation or some other mechanism mediated the changes in the RAS observed in the respiratory tract in this study.

Summary

As described here, there are two proposed pathways by which short-term UFP exposure may lead to respiratory health effects. One pathway involves respiratory tract inflammation and allergic responses, which are linked to asthma exacerbation. The second pathway involves the activation of sensory nerves in the respiratory tract leading to lung function decrements, which are also linked to asthma exacerbation. While experimental studies involving animals or human subjects contribute most of the evidence of upstream effects, epidemiologic studies found associations between short-term UFP exposure and lung function decrements. Together, these proposed pathways provide biological plausibility for epidemiologic evidence of respiratory health effects and will be used to inform a causality determination, which is discussed later in the chapter (Section 5.5.9).

5.5.2 Asthma Exacerbation

In the 2009 PM ISA (U.S. EPA, 2009), the evaluation of the relationship between short-term UFP exposure and asthma exacerbation consisted of a limited number of epidemiologic, controlled human exposure, and animal toxicological studies. Epidemiologic studies provided some evidence of an association between short-term UFP exposure and asthma exacerbation. Evidence for decrements in pulmonary function was found in subjects with asthma in the controlled human exposure study. Evidence for enhanced allergic responses was found in the animal toxicological study in a model of allergic airway disease that shares phenotypic features with asthma.

5.5.2.1 Epidemiologic Studies

In the 2009 PM ISA (U.S. EPA, 2009), studies of hospital admissions, ED visits (Andersen et al., 2008b; Halonen et al., 2008), and physician visits (Sinclair and Tolsma, 2004) reported evidence of associations across a range of lags, as well as for different UFP concentration metrics (i.e., number concentration [NC] and surface area [SA]). In panel studies of asthma symptoms in adults with asthma, supporting evidence of asthma exacerbation was observed across size fractions from $NC_{10–100}$ nm to $NC_{500–2,500}$ nm (Mar et al., 2004; von Klot et al., 2002). Supporting evidence was also provided by a study of lung function in adults with asthma in which $NC_{10–100}$ nm was associated with decrements in FEV_1, FVC, $FEF_{25–75\%}$, but not with increases in eNO after walking on a high-traffic road or in a park (McCreanor et al., 2007). This study of scripted exposure minimized uncertainty in the UFP exposure metric by measuring personal ambient UFP at the site of exposure. The evidence across studies was not entirely consistent, as associations between UFP exposure and ED visits for asthma were not observed in the Atlanta-based SOPHIA study (Peel et al., 2005). Additionally, the overall interpretation of results from epidemiologic studies that examined UFP exposures, including those focusing on asthma exacerbation, is complicated by the spatial variability in UFP concentrations, the correlation between UFPs and other traffic-related pollutants, and the various size fractions and concentration metrics used as UFP exposure surrogates.

A few recent epidemiologic studies add to those from the 2009 PM ISA (U.S. EPA, 2009) and continue to provide some, but not entirely consistent, support for associations between increases in short-term UFP concentrations exposure and asthma exacerbation. The supporting evidence comes from an array of outcomes related to asthma exacerbation, including hospital admissions, ED visits, and physician visits for asthma to asthma symptoms and medication use. Additional evidence from studies in adults with asthma using personal ambient UFP exposures via scripted exposures in high-traffic locations is more consistent for lung function decrements than pulmonary inflammation. The relatively small body of recent studies of asthma hospital admissions, ED visits, and physician visits examined a range of UFP size fractions, which complicates the interpretation of results across studies. Several studies examined $NC_{10–100}$ nm exposure among older children (>3 years), in whom the ascertainment of asthma is more

reliable. All the recent studies used NC to represent UFP exposure; and as detailed in the Preface , when examining the size distribution of particles 67 to 90% of NC contains particles <0.1 µm. Samoli et al. (2016a) reported no association with asthma hospital admissions in a study of five European cities. In contrast, Iskandar et al. (2012) reported an association with $NC_{10–700}$ nm in a study conducted in Copenhagen, Denmark. Across studies, a similar array of lags was examined and no particular lag was identified as having a stronger association with asthma hospital admissions, but many results support associations with UFP concentrations with a lag of 1 to 5 days or averaged over 3 to 6 days (Table 5-40). While the examination of the relationship between short-term UFP exposure and asthma hospital admissions focused on studies that examined daily changes in UFP concentrations and hospital admissions (e.g., time-series, case-crossover analyses), the assessment of the relationship with ED visits was limited to a study that focused on asthma exacerbations that led to an ED visit (Evans et al., 2014). In a group of children with asthma enrolled in the School-Based Asthma Therapy trial, Evans et al. (2014) examined whether exposure to traffic-related pollutants, including UFPs, resulted in an asthma exacerbation that lead to an ED visit over multiday averages up to 0−7 days. There was some evidence of an association for lag 0−3 days (OR = 1.3 [95% CI: 0.90, 1.8] for a 2,088 increase in UFPs per cm^{-3}); however, the association was more evident in children receiving preventative medication at school compared to at home. A recent study examined the association between UFP exposure and lung function and subclinical effects in adults with asthma. In this panel study of 18 adults in Atlanta, GA, NC_{total} was associated with increased eNO and decreased FEV_1 (Mirabelli et al., 2015). Personal NC_{total} was measured during two morning commutes through rush-hour traffic, resulting in higher exposure levels. The observed associations with FEV_1 were consistent across spirometry test conducted 0, 1, 2, and 3 hours post-commute, while increased eNO was only associated with UFP exposure in adults with below-median asthma control.

1

The epidemiologic studies of short-term exposure to UFP and asthma hospital admissions each have 1 to 2 monitors per study, covering a 15-km radius in some cases (Table 5-40). Spatial variability in UFP concentration may not be captured over this area, introducing some uncertainty in the exposure surrogate (Section 2.5; Section 3.4.2.2). It is possible that associations are related to similarities in temporal variability of UFP sources throughout study areas, as Sarnat et al. (2010) observed for spatially-variable NO_2, but this remains an uncertainty since spatiotemporal variability across cities has not been well characterized. In addition to major uncertainties regarding the spatial variability in UFP and the various size fractions and concentration metrics used as UFP exposure surrogates, confounding by traffic-related pollutants also remains a concern, as studies have not thoroughly examined potential copollutant confounding. Studies evaluated in the 2009 PM ISA (U.S. EPA, 2009), which focused on both asthma hospital admissions (Andersen et al., 2008b) and lung function changes (McCreanor et al., 2007) in people with asthma, provided initial evidence that UFP associations persisted after adjustment for NO_2 or CO even when UFP was moderately correlated with copollutants [e.g., $r = 0.58$ for personal ambient UFP and NO_2 exposures (McCreanor et al., 2007)]. Recent results show robust UFP associations to adjustment for CO and O_3, but null associations with adjustment for NO_2 or NO_X (Table 5-40).

5.5.2.2 Controlled Human Exposure

Only one study evaluated in the 2009 PM ISA (U.S. EPA, 2009) investigated the effects of short-term UFP exposure and respiratory effects in individuals with asthma. In this study, Gong et al. (2008) reported decreases in pulmonary function (oxygen saturation and FEV_1) following a 2-hour exposure to 100 µg/m^3 UFP CAPs (less than 0.18 µm aerodynamic diameter). No changes in pulmonary inflammation were found.

5.5.2.3 Animal Toxicological Studies

As described in the 2009 ISA for PM (U.S. EPA, 2009), Kleinman et al. (2005) found that a multiday exposure to roadway ultrafine PM (UFP) CAPs in Los Angeles enhanced allergic responses in OVA-sensitized and challenged BALB/c mice, and that this effect was dependent on proximity to the PM source. Recently, Li et al. (2010) extended these observations in OVA-sensitized and challenged BALB/c mice. A hybrid exposure to Los Angeles UFP CAPs was conducted by intra-nasal cosensitization with OVA and UFP (Days 1, 2, and 4), followed 2 weeks later with inhalation exposures to concentrated UFP (Days 18, 19, 22, 23 and 24) that overlapped with intra-nasal OVA challenge (Days 23 and 24). Only mice that were cosensitized with UFP responded to secondary OVA challenges with increases in lavaged eosinophils, plasma OVA-specific IgE, and pulmonary expression of eotaxin, IL-5, IL-13, and Muc5ac ($p < 0.05$). Inhalation exposure to UFP during the challenge phase enhanced these allergic responses compared to filtered air exposed mice ($p < 0.05$). Similarly, UFP exposure during OVA challenge

enhanced neutrophil influx and pulmonary expression of IL-17 and Ym1, a marker of oxidative stress, in mice which were cosensitized with UFP and OVA ($p < 0.05$). These results demonstrate that short-term UFP exposure exacerbated the effects of allergen and suggest the involvement of Th2 and Th17 helper cells in the response. Pulmonary histopathology revealed that UFP inhalation during the OVA challenge extended allergic inflammation to more distal regions of the lung (i.e., the proximal alveolar duct and adjacent alveolar parenchyma). Their small size may have allowed UFPs to evade phagocytosis and deposit in the deep lung due to diffusion, as well as to stick to the airways walls due to Van der Waal's forces. The oxidative potential of urban UFP (Li et al., 2009) may have also contributed to inflammatory responses. It should be noted that in the recent study by Li et al. (2010) PM and allergens were coinstilled during sensitization prior to the inhalation challenge. This study design more clearly demonstrates the exacerbation of allergic responses than adjuvant activity. Short-term exposure to UFP may also promote allergic sensitization and additional experiments employing different study designs are needed to show this effect. Additional study details are found in Table 5-41.

Table 5-41 Study-specific details from an animal toxicological study of short-term exposure to UFP and subclinical effects underlying asthma exacerbation in a model of allergic airway disease.

Study/Study Population	Pollutant	Exposure	Endpoints
Li et al. (2010) Species: Mouse Sex: Female Strain: BALB/c Age/Weight: 8−10 weeks	Ultrafine—ambient Los Angeles OVA Particle size: <0.18 µm Particle mass: 101.3 ± 5.1 µg/m^3	Route: Intra-nasal sensitization with PM and OVA (2 days) Inhalation of PM on days of OVA challenge Dose/Concentration: 4 h/day for 5 days	PM characterization Serum IgE, IgG1 BALF cells BALF cytokines Histopathology—lung

IgE = immunoglobulin E; IgG1 = immunoglobulin G1; BALF = bronchoalveolar lavage fluid; OVA = ovalbumin.

5.5.3 Chronic Obstructive Pulmonary Disease (COPD) Exacerbation

The 2009 PM ISA (U.S. EPA, 2009) evaluated a small body of literature examining the association between UFP and hospital admissions and ED visits for COPD. The studies evaluated in the 2009 PM ISA, limited to single-cities, provided inconsistent evidence of associations with UFPs. There are a few recent studies of UFP exposure and COPD exacerbation, but the evidence base remains small and does not clearly support a relationship. This applies to COPD hospital admissions and ED visits (Table 5-42), which can result from uncontrollable respiratory symptoms that are hallmarks of COPD

exacerbation such as cough, sputum production, and shortness of breath. The uncertain adequacy of the UFP concentration metrics used for exposure surrogates is a major limitation in the evidence base overall.

Recently, some studies examined associations with COPD, but they are limited to studies of hospital admissions and again are conducted in individual cities. Recent studies examine COPD hospital admissions in Europe and observe an association in Rome, Italy (Belleudi et al., 2010) but not a multicity study that includes Rome (Samoli et al., 2016a) (Table 5-42). UFP concentrations were averaged over 24 hours, and all studies examined an array of lags (up to 10 days). In Rome, Italy, (Belleudi et al., 2010) found evidence of a positive association between UFP and COPD hospital admissions at 0−1-day distributed lag among adults aged 35 years and older (0.95 [95% CI: −0.8, 2.73]). Adjustment for PM_{10} or for $PM_{2.5}$ did not alter the association of COPD (lag 0) with particle NC (1.9% [95% CI: 0.1, 3.8] and 1.3% [95% CI: 0.8, 3.5%], per 10,000 particles/cm^3, respectively). There was some evidence that associations were stronger in terms of magnitude and precision in the spring and fall season (3.72% [95% CI: 0.81, 6.70]). Additionally, in a study conducted in Helsinki, Finland, Halonen et al. (2009b) reported an association between COPD hospital admissions in the nucleation mode (<0.03 μm), with an 0.8% (95% CI: −2.28, 3.97) increase in hospital admissions for a 3,583-count increase in the nucleation mode, and a 0.82% (95% CI: −1.51, 3.20) increase in hospital admissions for a 2,467-count increase in the Aitken mode (0.03−0.1 μm) (lag 3). Among adults with COPD in Erfurt, Germany, $NC_{10–100}$ nm was not associated with blood levels of the proinflammatory cells neutrophils and eosinophils or most markers of blood coagulation that are linked to cardiovascular effects rather than COPD (Bruske et al., 2010; Hildebrandt et al., 2009).

Epidemiologic studies examining respiratory infection are limited by their UFP exposure assessment, because they relied on data from one or two monitors and thus could not capture the spatial variability in UFP concentrations across study locations (Section 2.5.1, Section 3.4.2.2). Additionally, the limited assessment of potential copollutant confounding complicates the interpretation of results and understanding whether UFPs are independently associated with COPD exacerbations or may be serving as an indicator of highly correlated copollutants.

5.5.4 Respiratory Infection

Regarding the association between UFP and hospital admissions/ED visits for respiratory infections, the body of literature reviewed in the 2009 PM ISA (U.S. EPA, 2009) was very small and provided no evidence of associations with respiratory infections and was limited to single-city studies. Consistent with the 2009 PM ISA, recent studies are limited in number and focus on examining associations between short-term UFP exposure and respiratory infections in individual cities. In Rome, Italy, Belleudi et al. (2010) found no evidence of an association between UFP (UFPs were measures using particle NC from a single monitor) and lower respiratory tract infection hospital admissions at any lag among adults aged 35 years and older. The effect was positive, but imprecise at lag 2 and lag 3 (0.19% [95% CI: −1.48, 1.90] and 0.29% [95% CI: −1.37, 1.98], per 10,000 particles/cm^3, respectively). In a study of UFPs and respiratory hospital admissions in five European cities in 2001−2011, Samoli et al. (2016a) found no overall association using city-specific estimates to obtain pooled estimates but did identify a positive association with hospital admissions during warm months of April−September of 4.27% (95% CI 1.68−6.92) for an increase in 10,000 particles/cm^3 (lag 2). This effect estimate was robust to inclusion of CO and NO_2 in the statistical model. Halonen et al. (2009b), in a study conducted in Helsinki, Finland, reported no associations for pneumonia hospital admissions in the nucleation mode (<0.03 μm), but observed a 1.5% (95% CI: −0.72, 3.77) increase in hospital admissions for a 2,467-count increase in the Aitken mode (0.03−0.1 μm) (lag 3). Some similarity of the effect estimates was expected by the authors due to the high correlation between these particle fractions.

The body of literature that studied the association between UFPs and hospital admissions/ED visits for respiratory infection hospital admissions expanded since the 2009 PM ISA (U.S. EPA, 2009) but remains somewhat limited. The available evidence suggests small associations between UFPs and respiratory infections, though the distinct size fractions under analysis in each study make cross-study comparisons difficult. The limited evidence from previous and recent studies does not clearly link short-term UFP exposure to increases in respiratory infection, based largely on hospital admissions, ED visits, and physician visits for URI, pneumonia, or LRI, which combines pneumonia and bronchitis (Table 5-43). There is little information to assess the biological plausibility for the supporting findings. Host defense mechanisms that protect the respiratory tract from pathogens such as mucociliary clearance, alveolar macrophage clearance, or innate and adaptive immunity were not assessed in relation to short-term UFP exposure. For the supporting evidence, information also is lacking on sources of heterogeneity, C-R, and the influence of other traffic-related pollutants.

5.5.5 Combinations of Respiratory-Related Hospital Admissions and Emergency Department (ED) Visits

The evidence more consistently links increases in UFP concentration to increases in respiratory-related diseases broadly than to asthma, COPD, or respiratory infections. Recent findings not only add consistency for hospital admissions or ED visits, but they also indicate lung function changes among adults with asthma or COPD. As is observed with asthma exacerbation (Section 5.5.2), distinguishing an association for UFP and respiratory-related diseases independent of NO_2 remains uncertain. As noted previously, studies of respiratory-related diseases examine either all respiratory-related diseases or only a subset, which can complicate the interpretation of results across studies.

There is considerable variation across studies in the size fractions examined and, in the fraction, most strongly associated with hospital admissions and ED visits for respiratory-related diseases (Table 5-44). Associations were consistently observed for NC up to 100 nm (Lanzinger et al., 2016b; Samoli et al., 2016b; Leitte et al., 2011; Andersen et al., 2008b; Halonen et al., 2008). In Beijing, China, associations were observed with UFP NC and SC (Leitte et al., 2011). Results also are consistent with NC with an upper bound that included larger particles (Table 5-44); however, as detailed in CHAPTER 1, it has been demonstrated that 67−90% of NC represents particles <0.1 μm although the upper bound of the UFP size distribution measured by NC may include larger size particles. In contrast, hospital admissions and ED visits for respiratory-related diseases are inconsistently associated with size fractions with upper bounds less than 50 nm (Leitte et al., 2011; Halonen et al., 2008).

A few recent epidemiologic studies focusing on individuals with a combination of respiratory-related diseases that also examined associations with UFP concentrations provide evidence that supports an association with respiratory-related hospital admissions and ED visits. For adults with asthma and COPD in four European cities (Helsinki, Finland; Athens, Greece; Amsterdam, the Netherlands; Birmingham, U.K.), NC_{total} measured outside the home but not at a monitor in the city was associated with lung function decrements (de Hartog et al., 2010). Additionally, within the UFIREG study, within Augsberg, Germany, NC_{total} was found to be highly correlated across four traffic and nontraffic sites (r = 0.77−0.95) (Lanzinger et al., 2016b; Cyrys et al., 2008).

Recent results from copollutant models provide additional indication that adjustment for NO_2 or CO has varying effect on UFP associations with respiratory-related diseases. Associations for NC with upper bounds of 100 nm are sometimes attenuated with adjustment for NO_2 (Lanzinger et al., 2016b; Leitte et al., 2011). Other results are for larger sized NC with upper bounds ranging from 290−3,000 nm, with many showing that associations persist with adjustment for NO_2 or CO (Samoli et al., 2016a; Halonen et al., 2009b) and some showing attenuation (Andersen et al., 2008b) (Table 5-44). A wide range of correlations was reported for UFP concentrations with NO_2 and CO (r = 0.33−0.69 NO_2, 0.07−0.69 CO), and the magnitude of correlation does not relate to the copollutant model results.

5.5.6 Respiratory Effects in Healthy Populations

Evidence for a relationship between short-term exposure to UFP and respiratory effects in healthy populations was very limited in the 2009 PM ISA (U.S. EPA, 2009). Epidemiologic studies found an association with wheeze in infants. Controlled human exposure studies found inconsistent evidence for decrements in lung function or pulmonary inflammation following short-term UFP exposure. Animal toxicological studies focused on exposure to mixtures such as woodsmoke and motor vehicle emissions and did not distinguish between the effects of particles and gases in the mixture.

5.5.6.1 Lung Function

5.5.6.1.1 Epidemiologic Studies

While the 2009 PM ISA (U.S. EPA, 2009) did not have a delineated discussion of epidemiologic studies that examined respiratory effects in healthy populations, an association between UFPs and wheeze was reported in a study of infants (Andersen et al., 2008a), in whom wheeze is common and transient. Several recent studies have employed scripted exposures to further inform the relationship between UFPs and respiratory effects in healthy populations. Scripted studies measuring personal ambient UFP exposures are designed to minimize uncertainty in the UFP exposure metric by always measuring UFPs at the site of exposure, ensuring exposure to sources of UFPs, such as traffic, and measuring outcomes at well-defined lags after exposure. A limitation of recent scripted exposure studies is that outcome assessment is only performed up to 6 hours after exposure, such that scripted studies do not inform understanding of the persistence of effects. There are recent epidemiologic studies in populations that include a mix of healthy participants and participants with pre-existing respiratory and/or cardiovascular disease, some of which indicate UFP-associated increases in respiratory effects. However, these studies are not evaluated in this section, as it is not known whether the results apply to the healthy portion of the population or are instead driven solely by an association in individuals with pre-existing respiratory conditions.

Respiratory effects were evaluated in recent panel studies of scripted exposures in high or low traffic areas, commute routes, or participants assigned to spend time at varying distance to a steel plant., Exposures ranged from 1 to 8 hours and the nature of exposure varied among the traffic studies, including cycling on roadways (Weichenthal et al., 2011; Zuurbier et al., 2011b), riding in a car or bus on roadways (Zuurbier et al., 2011b), and exercising near high and low traffic areas on stationary bicycles (Matt et al., 2016; Kubesch et al., 2015; Steenhof et al., 2013; Strak et al., 2012). In addition to traffic studies, Dales et al. (2013) randomly assigned participants to spend alternating weeks in a neighborhood within 1 km of a steel plant, and at a neighboring college campus, 4.5 km from the plant. In addition to varying study designs, UFP concentration metrics also varied across studies. Most studies examined NC, with a few specifying sampling in the 10−1,000 nm range (Matt et al., 2016; Kubesch et al., 2015; Dales et al., 2013).

In recent studies, increases in personal ambient UFP exposure were inconsistently associated with decreases in lung function and increases in markers of pulmonary inflammation in healthy adults in recent studies. Some studies provided evidence of transient respiratory effects associated with UFP exposure. Strak et al. (2012) reported decreases in FVC and FEV_1, and increases in eNO immediately after exposure, but not 6 or 18 hours later. Similarly, Matt et al. (2016) observed UFP-related FEV_1 decrements immediately after exposure that were positive 7-hour post exposure. Other studies observed associations with several lung function metrics, including FEV_1, FEV_1/FVC, $FEF_{25–75\%}$, total lung capacity (TLC), and residual volume (RV) (Dales et al., 2013) immediately after exposure, and PEF 2 and 6 hours after exposure (Zuurbier et al., 2011b). Notably, many studies that reported some evidence of associations had inconsistent results across an array of lung function metrics (Matt et al., 2016; Strak et al., 2012; Zuurbier et al., 2011b). Similarly, some studies reported UFP associations with lung function and eNO, but not other subclinical pulmonary effects, including nasal lavage levels of the proinflammatory cytokine IL-6 (Steenhof et al., 2013; Strak et al., 2012) or plasma CC16 levels (Zuurbier et al., 2011a), an indicator of decreased lung epithelial barrier function. Additional studies did not observe any associations between UFP concentrations and lung function or pulmonary inflammation in healthy populations up to 7 hours after exposure (Kubesch et al., 2015; Weichenthal et al., 2011; Strak et al., 2010). While respiratory symptoms are frequently studied in populations with pre-existing respiratory conditions, such as asthma or COPD, the outcome is less often examined in healthy populations. As such, no recent studies of UFP exposure evaluate respiratory symptoms or medication use in healthy populations.

In addition to major uncertainties regarding the spatial variability in UFP and the various size fractions and concentration metrics used as UFP exposure surrogates, the ability to attribute inconsistently observed associations to UFP exposure in the presence of moderately-to-highly correlated traffic-related copollutants (r = 0.50−0.70) remains limited. Only Strak et al. (2012) examined models with these copollutants. The authors reported that UFP associations observed immediately after exposure persisted in copollutant models including EC, Fe, Cu, NO_2, or NO_X, but results may be unreliable for models with moderately-to-highly correlated pollutants.

5.5.6.1.2 Controlled Human Exposure Studies

The 2009 PM ISA (U.S. EPA, 2009) reported evidence of small decrements in lung function following short-term UFP CAPs exposure in healthy humans in one study (Gong et al., 2008) but not another (Samet et al., 2009). In contrast, an increase in BALF IL-8 was found in Samet et al. (2009), but no evidence of pulmonary inflammation was found in Gong et al. (2008).

5.5.6.1.3 Animal Toxicological Studies

The 2009 PM ISA (U.S. EPA, 2009) did not report any animal toxicological studies investigating the effects of short-term exposure to UFP on pulmonary function. Animal toxicological studies investigating the effects of short-term exposure to UFP-containing mixtures on subclinical effects did not distinguish between effects due to particles or gases in the mixture.

Two recent studies examined this endpoint. In one study, Sprague Dawley rats were exposed for 6 hours to filtered and unfiltered GE (count median diameter of 15−20 nm, mass median diameter of approximately 150 nm) (Seagrave et al., 2008). Neither filtered nor unfiltered GE exposure caused any change in breathing frequency, tidal volume, minute volume, or Penh. In the other study, Amatullah et al. (2012) found that a 4-hour exposure of BALB/c mice to Toronto near-UFP CAPs had no effect on pulmonary function. Additional study details for these and other recent animal toxicological studies are found in Table 5-45.

Table 5-45 Study-specific details from animal toxicological studies of short-term exposure to UFP and respiratory effects in healthy animals.

Study/Study Population	Pollutant	Exposure	Endpoints
Aztatzi-Aguilar et al. (2015) Species: Rat Sex: Male Strain: Sprague Dawley	UFP CAPs Mexico City Particle size: (UF) Ultrafine $PM_{0.2}$ Control: Filtered air	Route: Inhalation Dose/Concentration: Ultrafine $PM_{0.2}$ 107 µg/m^3 Duration: Acute 5 h/day, 3 days Time to analysis: 24 h	Gene and protein expression in lung tissue • IL-6 • Components of kallikrein-kinin endocrine system and RAS • Heme oxygenase-1
Cheng et al. (2016) Species: Mouse Strain: C57Bl/6J Sex: Male Age: 3 mo	Re-aerosolized collected ambient PM near a Los Angeles freeway Particle sizes: Ultrafine PM < 180 nm, median 60.6 nm Control: Reaerosolized extracts of sham filters	Route: Whole-body inhalation Dose/concentration: 343 µg/m^3 Duration of exposure: 5 h/day, 3 days/week for 5, 20 and 45 h over 3 weeks	Immunohistochemistry of nasal epithelium and brain tissue • Oxidative stress markers • Macrophage activation marker
Seagrave et al. (2008) Species: Rat Strain: Sprague-Darley Sex: Male Age/Weight: 8−10 weeks, 250−300 g	Gasoline engine exhaust (GE) Filtered GE Particle Size: GE MMD 150 nm	Route: Whole-body inhalation Dose/Concentration: GE filtered 2.4 µg/m^3 GE 59 µg/m^3 Duration of exposure: 6 h Coexposure: Combustion vapors	Pulmonary function • Breathing frequency • Tidal volume • Minute volume • Penh
Tyler et al. ApoE = apolipoprotein E; DE = diesel exhaust; GE = gasoline exhaust; MMD = mass median diameter; Penh = enhanced pause.

Pulmonary Oxidative Stress

The 2009 PM ISA (U.S. EPA, 2009) did not report any animal toxicological studies investigating the effects of short-term UFP exposure on pulmonary oxidative stress. Two recent studies examined this endpoint. Seagrave et al. (2008) exposed rats to GE (count median diameter 15−20 nm, mass median diameter 150 nm) and found increased lung tissue chemiluminescence that was not present when GE was filtered, indicating that the particulate fraction had a role in the oxidative stress response. Recently,

oxidative stress in olfactory epithelium, as well as olfactory bulb and other brain regions, was examined in mice exposed to resuspended urban UFP (Cheng et al., 2016) (see Section 8.5.2). A single 5-hour exposure to UFP resulted in enhanced markers of oxidative stress in olfactory epithelium, but not olfactory bulb, cerebellum, or cerebral cortex. Multiple exposures over 3 weeks also increased oxidative stress markers in olfactory epithelium, as well as decreased levels of a protein expressed by olfactory sensory nerves, and increased levels of apoptosis-related proteins.

Pulmonary Inflammation

The 2009 PM ISA (U.S. EPA, 2009) did not report any animal toxicological studies investigating the effects of short-term UFP exposure on pulmonary inflammation. Several recent studies examined this endpoint. No effects were observed in terms of BALF inflammatory cells in response to a 4-hour exposure of BALB/c mice to Toronto UFP CAPs (Amatullah et al., 2012) or in response to a 6-hour exposure of C57BL/6 mice to UFP generated from motor vehicle exhaust (Tyler et al., 2016), despite effects observed in the hippocampus of the latter study (see Section 8.5.2). However, inflammation was observed in two other studies measuring effects in lung tissue. Cheng et al. (2016) found inflammatory responses in olfactory epithelium, as well as olfactory bulb and other brain regions, in C57BL/6J mice exposed to resuspended urban UFP (Section 8.5.2). The number of Iba1 positive-macrophages, an indicator of inflammation, increased in olfactory epithelial turbinates and in the olfactory bulb after 5-hours of exposure to UFP ($p < 0.05$). In addition, Aztatzi-Aguilar et al. (2015) found increased levels of IL-6 in lung tissue in Sprague Dawley rats exposed to UFP CAPs in Mexico City for several days ($p < 0.05$). Aztatzi-Aguilar et al. (2015) also found that short-term UFP CAPs exposure had several effects on the two counterbalancing endocrine systems—the RAS and the kallikrein-kinin system in the lung ($p < 0.05$). These effects included upregulation of genes encoding angiotensin 1 receptor and angiotensin converting enzyme and reduced levels of reduced angiotensin 1 receptor protein. Levels of angiotensin converting enzyme protein and angiotensin 2 receptor mRNA were not impacted. The RAS plays an important role in pulmonary and systemic vasculature, with binding of angiotensin to the angiotensin 1 receptor mediating vasoconstriction and oxidative stress. In addition, short-term UFP CAPs exposure resulted in upregulation of the gene encoding kallikrein-1 ($p < 0.05$). Kallikrein-1 is a serine protease enzyme required to produce kinin peptides, which are necessary to activate bradykinin receptors. Bradykinin receptors are involved in the regulation of nitric oxide which mediates vasodilation.

5.5.6.2 Summary of Respiratory Effects in Healthy Populations

Evidence linking short-term UFP exposure and respiratory effects in healthy populations is inconsistent or minimal in epidemiologic studies and controlled human exposure studies. Animal toxicological studies found pulmonary oxidative stress following short-term UFP exposure, but inconsistent evidence of pulmonary inflammation and no evidence of changes in lung function.

5.5.7 Respiratory Effects in Populations with Cardiovascular Disease

As described in the 2009 PM ISA (U.S. EPA, 2009), Kooter et al. (2006) found that a multiday exposure of SH rats to UFP-enriched CAPs in the Netherlands decreased CC16 in BALF. CC16 is a secretory product of nonciliated bronchiolar Club cells and is thought to contribute to control of inflammation. Recently, Tyler et al. (2016) exposed C57BL/7 and ApoE knockout mice for 6-hour to UFP generated from motor vehicle exhaust. No increases in BALF inflammatory cells were observed. However, increases in TNF-α levels in BALF and particle uptake into bronchial macrophages were found in ApoE knockout ($p < 0.001$) but not in C57BL/6 mice. Effects were also seen in the hippocampus (Section 8.5.2). Additional study details are presented in Table 5-45.

5.5.8 Respiratory Mortality

In the 2009 PM ISA (U.S. EPA, 2009), no studies specifically examined associations between short-term UFP exposure and respiratory mortality. Although recent studies examine the relationship between short-term UFP exposure and respiratory mortality, the total body of evidence remains small, as detailed in CHAPTER 11 (Section 11.4.1). Across studies that examined the UFP—respiratory mortality relationship, there is inconsistency in the particle size distribution that was used to represent UFP exposures with some studies measuring NC, while other studies measured NC with the upper end of the size distribution ranging from 100—3,000 nm. This disparity in the measurement of UFPs between studies complicates the overall interpretation of results.

The assessment of the relationship between short-term UFP exposure and respiratory mortality is limited to studies conducted in Europe (Stafoggia et al., 2017; Lanzinger et al., 2016a; Samoli et al., 2016b) and China (Leitte et al., 2012). Across studies of respiratory mortality, NC was used to examine associations with respiratory mortality. Both Lanzinger et al. (2016a), in a study of five central European cities as part of the UFIREG project, and Leitte et al. (2012), in Beijing, China, reported generally positive associations that were imprecise across each of the UFP size distributions examined (Table 11-9, UFP studies in mortality chapter), while Samoli et al. (2016b) did not report any evidence of an association with respiratory mortality. Although there is some evidence of a positive association between short-term UFP exposure and respiratory mortality, within each study only a single monitor was used to estimate exposure to UFPs (Table 11-9, UFP studies in mortality chapter). As detailed in CHAPTER 2 (Section 2.5.1.1.5, Section 2.5.1.2.4, and Section 2.5.2.2.3), the use of a single monitor does not adequately account for the spatial and temporal variability in UFP concentrations as well as the change in the particle size distribution that changes with distance from source.

5.5.9 Summary and Causality Determination

A limited number of studies examining short-term exposure to UFPs and respiratory effects were reported in the 2009 PM ISA (U.S. EPA, 2009), which concluded that the relationship between short-term exposure to UFP and respiratory effects is "suggestive of a causal relationship". This conclusion was based on epidemiologic evidence indicating associations with combined respiratory-related diseases, respiratory infection, and asthma exacerbation. In addition, personal ambient UFP exposure from time spent in high- and low-traffic areas were associated with lung function decrements in adults with asthma. The few available experimental studies provided limited coherence with epidemiologic findings for asthma exacerbation. Recent studies add to this evidence base and support epidemiologic evidence for asthma exacerbation and combined respiratory-related diseases but do not rule out chance, confounding, and other biases. Several animal toxicological studies showing effects related to allergic asthma provide biological plausibility. The evidence characterizing the relationship between short-term exposure to UFP and effects on the respiratory is detailed below (Table 5-46), using the framework for causality determinations described in the Preamble to the ISAs (U.S. EPA, 2015).

For asthma exacerbation, there is some epidemiologic evidence that is not entirely consistent. Associations persisted in one epidemiologic study with adjustment for NO_2, but not in another. Additional supporting evidence, showing decrements in lung function and enhancement of allergic inflammation and other allergic responses, is provided by a controlled human exposure study in adults with asthma and by animal toxicological studies in an animal model of allergic airway disease. For combined respiratory-related diseases, recent findings add consistency for hospital admissions and ED visits and indicate lung function changes among adults with asthma or COPD. Uncertainty remains regarding the representativeness of UFP concentrations as a surrogate for exposure and for copollutant confounding, which limits inference about an independent effect of UFP. Additionally, there remains limited information on the spatial and temporal variability of UFP concentrations (Section 2.4.3.1). **Overall, the evidence is suggestive of, but not sufficient to infer, a causal relationship between short-term UFP exposure and respiratory effects.**

Table 5-46 Summary of evidence for that is suggestive of, but not sufficient to infer, a causal relationship between short-term UFP exposure and respiratory effects.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	UFP Concentrations Associated with Effects[c]
Asthma exacerbation and combined respiratory-related diseases			
Evidence from multiple, high quality epidemiology studies at relevant UFP concentrations is generally consistent, but limited	Increases in asthma-related hospital admissions, ED visits, and physician visits in children and all ages combined.	Samoli et al. (2016a) Iskandar et al. (2012) Evans et al. (2014)	
	Increases in combined respiratory-related diseases observed in single-city and multicity studies.	Section 5.5.5	
Uncertainty regarding confounding by copollutants	Potential copollutant confounding for asthma-related hospital admissions and lung function is examined in a few studies, with some evidence that associations remain robust in models with gaseous pollutants.	Andersen et al. (2008b) McCreanor et al. (2007) Samoli et al. (2016a) Halonen et al. (2009b)	
Limited coherence in epidemiologic studies across the continuum of effects	Increases in respiratory symptoms, pulmonary inflammation and lung function decrements observed in a limited number of panel studies in adults with asthma provide limited support for asthma exacerbation in children.	Mar et al. (2004) von Klot et al. (2002) McCreanor et al. (2007) Mirabelli et al. (2015)	
Uncertainty regarding exposure measurement error	Most studies relied on one monitor to measure UFPs, which is inadequate based on limited data demonstrating both that there is greater spatial variability in UFPs (i.e., NC) and that the particle size distribution changes with distance from source. Additionally, there is limited information on the temporal variability in UFP concentrations.	Section 2.4.3.1	
Uncertainty regarding exposure metric and UFP size fraction	Inconsistency in the UFP metric used (i.e., NC, SC, and MC) and UFP size fraction examined complicating interpretation of results across studies.	Table 5-40 Table 5-42 Table 5-43 Table 5-44 Section 5.5.8	

Table 5-46 (Continued): Summary of evidence for that is suggestive of, but not sufficient to infer, a causal relationship between short term ultrafine particle (UFP) exposure and respiratory effects.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	UFP Concentrations Associated with Effects[c]
Limited evidence from controlled human exposure studies	In adults with asthma, decreases in pulmonary function are observed.	Gong et al. (2008)	100 µg/m^3
Limited evidence from toxicological studies at relevant concentrations	Enhancement of allergic inflammation and other allergic responses is observed in animal model of allergic airway disease.	Section 5.5.2.3 Li et al. (2009)	101 µg/m^3
Biological plausibility for allergic asthma	Evidence from animal toxicological studies provides biological plausibility for epidemiologic findings of allergic asthma, the most common phenotype in children.	Section 5.5.1 Section 5.5.2.3	
Respiratory effects in healthy populations			
Some evidence from toxicological studies at relevant concentrations	Pulmonary function was not affected. Inconsistent results were found for pulmonary inflammation, while some evidence was found for oxidative stress and changes in the RAS.	Section 5.5.6.1.3	59−793 µg/m^3

[a]Based on aspects considered in judgments of causality and weight of evidence in causal framework in Table I and Table II of the Preamble to the ISAs (U.S. EPA, 2015).

[b]Describes the key evidence and references, supporting or contradicting, contributing most heavily to causality determination and, where applicable, to uncertainties or inconsistencies. References to earlier sections indicate where full body of evidence is described.

[c]Describes the UFP concentrations and metric (i.e., number concentration [NC], surface area concentration [SC], mass concentration [MC]) with which the evidence is substantiated.

5.6 Long-Term UFP Exposure and Respiratory Effects

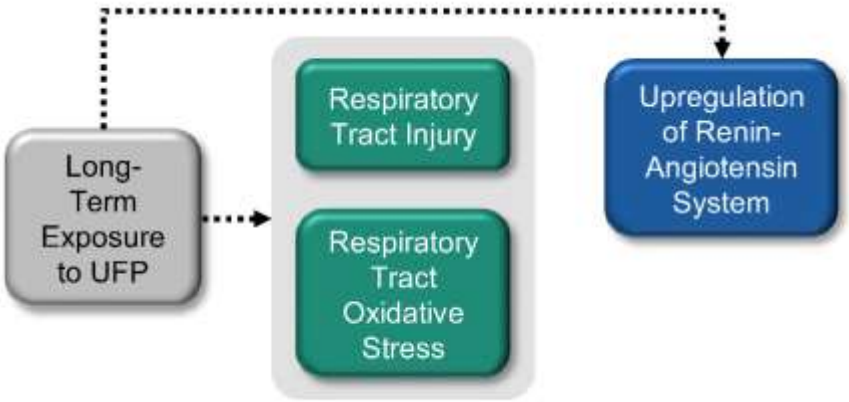
The 2009 PM ISA concluded that the evidence was inadequate to assess the relationship between long-term exposure to UFP and respiratory effects (U.S. EPA, 2009). At that time, there were no epidemiologic studies available to address this relationship. Animal toxicological studies found that long-term exposure to UFP CAPs had no effect, while long-term exposure to GE and DE altered respiratory-related endpoints. Studies with DE did not determine whether the effects were due to the particulate or gaseous part of the mixture. However, the effects of the GE were attributable to particulate matter. Recent studies consist of one epidemiologic study that examines the association between long-term exposure to UFP and respiratory outcomes and a small number of recent animal toxicological studies that provide evidence for respiratory effects.

5.6.1 Biological Plausibility

Due to a paucity of data, it is not possible to describe biological pathways that potentially underlie respiratory effects resulting from long-term exposure to UFP. Figure 5-50 graphically depicts the upstream events that may lead to downstream events observed in the single epidemiologic study. This discussion of "how" long-term exposure to UFP may lead to respiratory effects contributes to an understanding of the biological plausibility of epidemiologic results evaluated later in Section 5.6.

Once UFP deposits in the respiratory tract, it may be retained, cleared, or solubilized (see CHAPTER 4). UFP and its soluble components may interact with cells in the respiratory tract, such as epithelial cells, inflammatory cells, and sensory nerve cells. One way in which this may occur is through reduction-oxidative (redox) reactions. As discussed in Section 2.3.3, PM may generate ROS and this capacity is termed "oxidative potential." Furthermore, cells in the respiratory tract may respond to the presence of PM by generating ROS. Further discussion of these redox reactions, which may contribute to oxidative stress, is found in Section 5.1.1 of the 2009 PM ISA (U.S. EPA, 2009). In addition, poorly soluble particles may translocate to the interstitial space beneath the respiratory epithelium and accumulate in the lymph nodes (see CHAPTER 4). Immune system responses due to the presence of particles in the interstitial space may contribute to respiratory health effects.

Although all size fractions of PM may contribute to oxidative stress, UFPs may contribute disproportionately more as a function of their mass due to their large surface/volume ratio. The relative enrichment of redox active surface components, such as metals and organics, per unit mass may translate to a relatively greater oxidative potential of UFPs compared with larger particles with similar surface components. In addition, the greater surface per unit volume may deliver relatively more adsorbed soluble components to cells. These components may undergo intra-cellular redox cycling following cellular uptake. Furthermore, per unit mass, UFPs may have more opportunity to interact with cell surfaces due to their greater surface area and their greater particle number compared with larger PM. These interactions with cell surfaces may lead to ROS generation, as described in Section 5.1.1 of the 2009 PM ISA (U.S. EPA, 2009). Recent studies have also demonstrated that UFPs have the capacity to cross cellular membranes by nonendocytotic mechanisms involving adhesive interactions and diffusion, as described in CHAPTER 4. This may allow UFPs to interact with or penetrate intra-cellular organelles.



Note: The boxes above represent the effects for which there is experimental or epidemiologic evidence, and the dotted arrows indicate a proposed relationship between those effects. Progression of effects is depicted from left to right and color-coded (gray, exposure; green, initial event; blue, intermediate event; orange, apical event). Here, apical events generally reflect results of epidemiologic studies, which often observe effects at the population level. Epidemiologic evidence may also contribute to upstream boxes. When there are gaps in the evidence, there are complementary gaps in the figure and the accompanying text below.

Figure 5-50 Potential biological pathways for respiratory effects following long-term UFP exposure.

Evidence that long-term exposure to UFP may affect the respiratory tract is provided by a limited number of experimental studies. While markers of injury and oxidative stress were increased (Zhang et al., 2012; Reed et al., 2008), no inflammatory changes were observed (Tyler et al., 2016; Aztatzi-Aguilar et al., 2015; Araujo et al., 2008; Reed et al., 2008). In Tanaka et al. (2013a), the enhancement of allergic responses seen following long-term exposure to UFP-enriched DE was not attributable to particulate components, suggesting a role for combustion gases in mediating the response. Similarly, the presence of 8-OH deoxy-guanosine observed in lung tissue was likely due to combustion gases. Upregulation of the RAS, as indicated by an increase in mRNA and protein levels of angiotensin receptor Type 1, was observed in the lung (Aztatzi-Aguilar et al., 2015). Angiotensin receptor Type 1 mediates the effects of angiotensin II, which is a potent vasoconstrictor and mediator in the vasculature. The SNS and the RAS are known to interact in a positive feedback fashion (Section 8.1.2) with important ramifications in the cardiovascular system. However, it is not known whether SNS activation or some other mechanism mediated the changes in the RAS observed in the respiratory tract in this study. The upstream events presented here may provide biological plausibility for epidemiologic evidence of respiratory health effects and will be used to inform a causality determination, which is discussed later in the chapter (Section 5.4.9).

5.6.2 Development of Asthma

The 2009 PM ISA (U.S. EPA, 2009) did not report any studies evaluating allergic responses resulting from long-term exposure to UFP. Recently, Tanaka et al. (2013a) evaluated the enhancement of allergic responses by exposure to UFP-enriched DE. ICR mice were exposed to two concentrations of diluted DE and to particle-depleted diesel exhaust (0DE) for 8 weeks. Concentrations of gaseous components of DE were similar in the high DE and 0DE atmospheres (3.3 ppm CO, 1.4 ppm NO_X, and 0.51 ppm NO_2), but the low DE had approximately 1/3 of these concentrations (1.2, 0.41, and 0.15, respectively). Mice were sensitized and challenged with OVA administered by intra-tracheal instillation during the 8-week inhalation exposure. Mice exposed to filtered air and OVA had a modest increase in airway eosinophils that was enhanced by exposure to low and high DE in a dose-dependent fashion ($p < 0.05$ compared with OVA controls). This response was not dependent on the particulate part of the aerosol, since numbers of eosinophils in allergic animals exposed to 0DE, which was depleted of particles, were similar in the high DE group. Furthermore, increases in IL-5, IL-13, eotaxin, and myeloperoxidase protein in lung tissue reached similar levels in allergic mice exposed to either high DE or 0DE ($p < 0.05$ compared with OVA controls). Interestingly, only the allergic mice exposed to the particle-depleted 0DE had increases in lung tissue IL-4, IL-17α, IL-1β, lipid peroxidase, and serum IgE ($p < 0.05$ compared with OVA controls). Results from this study indicate a critical role for the combustion gases in DE-associated enhancement of allergic responses. Companion studies also detected the presence of 8-OH deoxy-guanosine in lung tissue in high DE and particle-depleted 0DE allergic mice (Tanaka et al., 2013b). Additional study details are found in Table 5-47.

Table 5-47 Study-specific details from animal toxicological studies of long-term UFP exposure and allergic responses.

Study/Study Population	Pollutant	Exposure	Endpoints
Tanaka et al. (2013a) Species: Mouse Sex: Female Strain: ICR Age/Weight: 6 weeks	Diesel engine exhaust Low DE = 36 μg/m^3 High DE = 169 μg/m^3 Particle size: 26−27 nm in low and high DE	Route: Whole-body inhalation Dose/Concentration: 5 h/day, 5 days/week for 8 weeks OVA intra-tracheal every other week (5 total) Time to analysis: 24 h after last instillation	BALF cells BALF cytokines Serum IgE
Tanaka et al. (2013b) Species: Mouse Sex: Female Strain: ICR Age/Weight: 6 weeks	Diesel engine exhaust Low DE = 36 μg/m^3 High DE = 169 μg/m^3 Particle size: 26−27 nm in low and high DE	Route: Whole-body inhalation Dose/Concentration: 5 h/day, 5 days/week for 8 weeks OVA intra-tracheal every other week (5 total) Time to analysis: 24 h after last instillation	Oxidative stress • -Lung 8-OH deoxy guanosine levels

BALF = bronchoalveolar lavage fluid; DE = diesel exhaust; IgE = Immunoglobulin E; OVA = ovalbumin.

5.6.3 Subclinical Effects in Healthy Populations and Populations with Cardiovascular Disease

Animal toxicological studies provide evidence for subclinical effects potentially underlying the development of respiratory disease in healthy populations and in populations with cardiovascular disease. The 2009 PM ISA (U.S. EPA, 2009) reported several studies that evaluated the effects of long-term exposure to UFP on subclinical effects. Reed et al. (2008) exposed F344 rats for 6 months to GE containing UFP (count median diameter 15−20 nm, MMD 150 nm). LDH was increased in BALF of rats, but no inflammatory or histopathologic changes were found except for the accumulation of PM-containing macrophages. However, hypermethylation of lung DNA was observed. The significance of DNA methylation in terms of respiratory health is unclear, although it is known that altered patterns of DNA methylation can affect gene expression and are sometimes associated with altered immune responses and/or the development of cancer. The LDH and hypermethylation responses were prevented by addition of a particle filter, indicating that the particulate portion of the GE mixture played a role in the response. In a study in ApoE knockout mice exposed to UFP CAPs for 40 days, Araujo et al. (2008) found no increase in BALF inflammatory cells exposed to UFP CAPs for 40 days.

Several recent studies have become available since the 2009 PM ISA that examine the effects of long-term UFP exposure on pulmonary oxidative stress and inflammation. Zhang et al. (2012) collected ambient UFP near a Los Angeles freeway. Exposure of C57BL/6J mice to the reaerosolized UFP for

10 weeks resulted in increases in mRNA and protein levels of heme oxygenase-1, NADPH quinone oxidoreductase 1, γ-glutamyl cysteine ligase catalytic subunit, and γ-glutamyl cysteine synthetase modifier subunit in the lung ($p < 0.05$). These are Phase II regulated detoxifying enzymes and are important in defense against oxidative stress. Young mice (3 months) had a more robust increase in gene expression and protein levels than older mice (18 months). Zhang et al. (2012) also found evidence of upregulation of Phase II enzymes in specific brain regions (Section 8.6.3) and the liver. In contrast, Aztatzi-Aguilar et al. (2015) found decreased lung tissue heme oxygenase-1 activity in Sprague-Dawley rats following 8-weeks exposure to Mexico City UFP CAPs ($p < 0.05$) and no change in γ-glutamyl cysteine ligase catalytic subunit was observed. Aztatzi-Aguilar et al. (2015) also found decreased protein levels of IL-6 in lung tissue ($p < 0.05$). Further, Tyler et al. (2016) exposed C57BL/7 and ApoE-knockout mice to UFP generated from motor vehicle exhaust. A 30-day exposure resulted in no increase in inflammatory cells or cytokines in the BALF. Particle uptake into bronchial macrophages was increased in both C57BL/6 and ApoE knockout mice ($p < 0.05$). Effects were also seen in the hippocampus (Section 8.6.3). Aztatzi-Aguilar et al. (2015) found that long-term UFP CAPs exposure had several effects on the RAS, including induced lung expression of the angiotensin 1 receptor gene, and increased angiotensin 1 receptor protein levels ($p < 0.05$). Protein levels and mRNA of angiotensin converting enzyme were not impacted. Components of the RAS play an important role in the pulmonary circulation. Overall, older and recent studies provide some limited evidence for pulmonary injury, DNA hypermethylation, and changes in the RAS, inconsistent evidence for pulmonary oxidative stress and no evidence for pulmonary inflammation. Additional study details for these recent animal toxicological studies are found in Table 5-48.

Table 5-48 Study-specific details from animal toxicological studies of long-term UFP exposure and respiratory effects in healthy animals.

Study/Study Population	Pollutant	Exposure	Endpoints
Aztatzi-Aguilar et al. (2015) Species: Rat Sex: Male Strain: Sprague Dawley	UFP CAPs Mexico City Particle size: Ultrafine $PM_{0.2}$ Control: Filtered air	Route: Inhalation Dose/Concentration: Ultrafine $PM_{0.2}$ 107 µg/m^3 Duration: Subchronic 5 h/day, 4 days/week, 8 weeks Time to analysis: 24 h	Gene and protein expression in lung tissue • IL-6 • Components of kallikrein-kinin endocrine system and RAS • Heme oxygenase-1
Reed et al. (2008) Species: Rat Sex: Male and Female Strain: F344 Age/Weight:	DE and filtered DE Particle size: MMAD 150 nm	Route: Whole-body Inhalation Dose/Concentration: 3 concentrations, H 59 µg/m^3, M 30 µg/m^3, L 6.6 µg/m^3, high filtered 2 µg/m^3 Duration: 6 h/day for 7 days/week, 3 days (1 week), 6 mo Coexposure: Combustion products	Lung Injury • -BALF LDH Lung DNA Alteration—Hypermethylation
Tyler et al. (2016) Species: Mouse Strain: C57BL/6 and ApoE knockout Age/Weight: 6−8 weeks	Motor vehicle exhaust (DE and GE) passed through a denuder to generate UFP Particle size: 147.1 nm ± 1.3 nm Control: Filtered air	Route: Whole-body inhalation Dose/Concentration: 371.3 ± 15.6 µg/m^3 Duration: 6 h/day for 30 days	BALF cells and cytokines Particle uptake in bronchial macrophages
Zhang et al. (2012) Species: Mouse Strain: C57BL/6J Sex: Male Age: 3 mo, 18 mo	Reaerosolized collected ambient PM near a freeway Particle size: Ultrafine PM < 200 nm	Route: Whole-body inhalation Dose/concentration: 200−400 ug/m^3 Duration of exposure: 5 h/day, 3 days/week for 10 weeks	Oxidative Stress Markers—Lung GCLC and GCLM mRNA and protein

ApoE = apolipoprotein E; BALF = bronchoalveolar lavage fluid; DNA = deoxyribonucleic acid; DE = diesel exhaust; GCLC = glutamate cysteine ligase catalytic subunit; GCLM = glutamate cysteine ligase modifier subunit; H = high; IL-6 = interleukin 6; L = low; M = medium; MMAD = mass median aerodynamic diameter; LDH = lactate dehydrogenase; Mrna = messenger ribonucleic acid; RAS = renin-angiotensin system.

1

5.6.4 Respiratory Mortality

2 Overall, the literature base for long-term UFP exposure and respiratory mortality remains very
3 small, with one study (Ostro et al., 2015) reporting results for UFP mass concentration. The authors
4 examined the association between UFP (<0.1 µm) mass concentrations and respiratory mortality among

women in the California Teachers Cohort using a CTM to predict UFP concentrations with a 4-km spatial resolution and observed an association near the null value.

5.6.5 Summary and Causality Determination

Based on limited evidence from animal toxicological studies and a lack of epidemiologic studies, the 2009 PM ISA (U.S. EPA, 2009) concluded that evidence was inadequate to assess the relationship between long-term exposure to UFP and respiratory effects. Since then, only a few new studies have become available. The evidence characterizing the relationship between long-term exposure to $PM_{10-2.5}$ and respiratory effects is detailed below (Table 5-49), using the framework for causality determination described in the Preamble to the ISAs (U.S. EPA, 2015). Currently, there is limited epidemiologic evidence for respiratory mortality. But uncertainty regarding copollutant confounding and exposure measurement error results in an inability to rule out chance and confounding. A few animal toxicological studies provide evidence of effects resulting from long-term exposure to UFP. **Overall, the evidence is inadequate to infer the presence or absence of a causal relationship between long-term UFP exposure and respiratory effects.**

Table 5-49 Summary of evidence that is inadequate to infer the presence or absence of a causal relationship between long-term UFP exposure and respiratory effects.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	UFP Concentrations Associated with Effects[c]
Limited epidemiologic evidence does not support a relationship	No association was observed with UFP mass concentrations in a single study of respiratory mortality from the California Teachers Study cohort.	Ostro et al. (2015)	UF mass concentration: 1.29
Uncertainty regarding confounding by copollutants and exposure measurement error	Uncertainties are not addressed.	Ostro et al. (2015)	
Some evidence for respiratory effects from toxicological studies at relevant concentrations	Results show injury, oxidative stress, DNA hypermethylation, and changes in the RAS, but no pulmonary inflammation.	Section 0	59−400 µg/m^3

CHAPTER 6 CARDIOVASCULAR EFFECTS

Summary of Causality Determinations for Short- and Long-Term Particulate Matter (PM) Exposure and Cardiovascular Effects

This chapter characterizes the scientific evidence that supports causality determinations for short- and long-term PM exposure and cardiovascular effects. The types of studies evaluated within this chapter are consistent with the overall scope of the ISA as detailed in the Preface (see Section P 3.1). In assessing the overall evidence, strengths and limitations of individual studies were evaluated based on scientific considerations detailed in the Appendix. More details on the causal framework used to reach these conclusions are included in the Preamble to the ISA (U.S. EPA, 2015). The evidence presented throughout this chapter support the following causality conclusions:

Size Fraction	Causality Determination
Short-Term Exposure	
$PM_{2.5}$	Causal
$PM_{10-2.5}$	Suggestive of, but not sufficient to infer
UFP	Suggestive of, but not sufficient to infer
Long-Term Exposure	
$PM_{2.5}$	Causal
$PM_{10-2.5}$	Suggestive of, but not sufficient to infer
UFP	Inadequate

6.1 Short-Term $PM_{2.5}$ Exposure and Cardiovascular Effects

The 2009 PM ISA concluded that "a causal relationship exists between short-term exposure to $PM_{2.5}$ and cardiovascular effects." This conclusion was based on multiple lines of evidence including consistently positive associations between short-term exposure to $PM_{2.5}$ and emergency department (ED) visits and hospital admissions for cardiovascular disease (U.S. EPA, 2009). Results from HA and ED visit studies were supported by associations between $PM_{2.5}$ and cardiovascular mortality. In addition, controlled human exposure (CHE) and animal toxicological studies provided evidence of changes in various measures of cardiovascular function to establish biological plausibility for the epidemiologic findings. The most consistent $PM_{2.5}$ effect was for reduced vascular function. Toxicological studies finding reduced myocardial blood flow during ischemia and altered vascular reactivity provided coherence and biological plausibility for the myocardial ischemia that was observed in both controlled

human exposure and epidemiologic studies. Further, $PM_{2.5}$ effects on ST segment depression—an electrocardiogram change that potentially indicates ischemia—were also observed.

Key uncertainties from the last review included inconsistent results across disciplines with respect to the relationship between short-term exposure to $PM_{2.5}$ and changes in blood pressure, blood coagulation markers, and markers of systemic inflammation. In addition, uncertainties remained with respect to biological plausibility; that is, how inhalation exposure to $PM_{2.5}$ could trigger molecular, cellular, and tissue responses that result in serious cardiovascular outcomes. For example, in the 2009 PM ISA (U.S. EPA, 2009), there was a growing body of evidence from CHE, animal toxicological, and epidemiologic studies demonstrating changes in markers of systemic oxidative stress following $PM_{2.5}$ exposure. However, uncertainties remained as to the relationship between changes in markers of oxidative stress and more serious cardiovascular health outcomes.

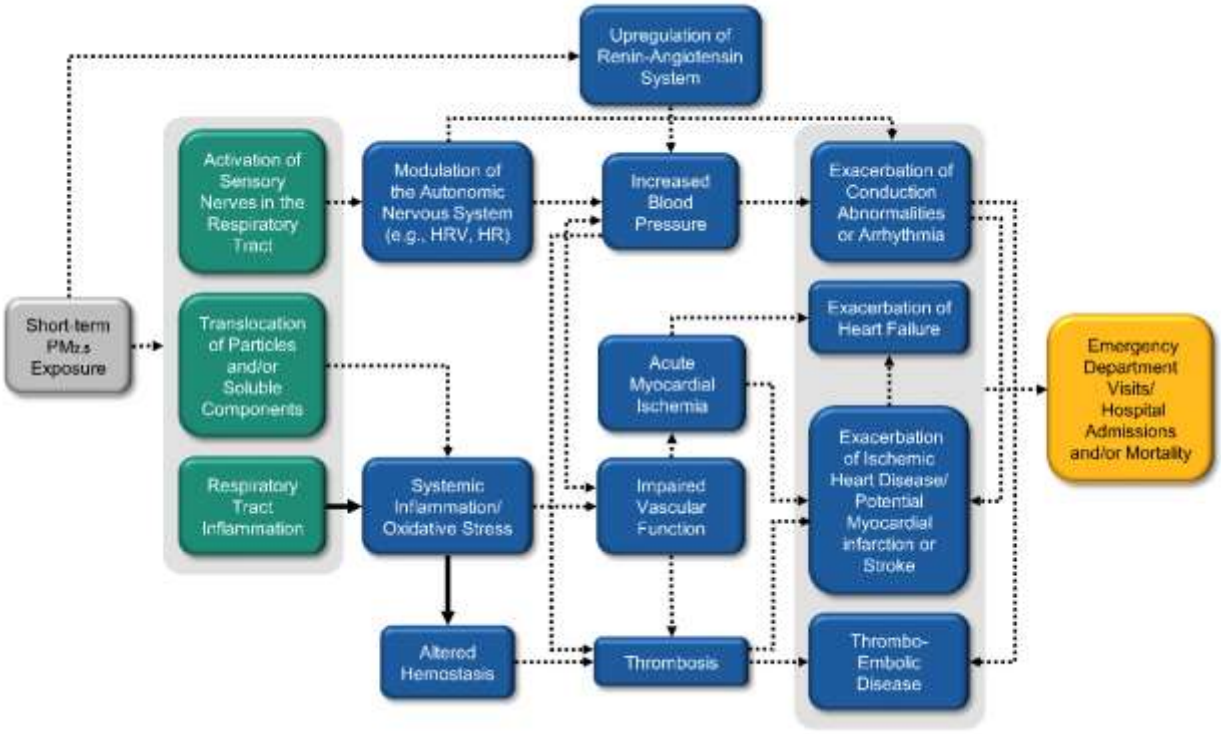
Since the last review, the evidence relating short-term $PM_{2.5}$ CAP exposure and cardiovascular health effects has expanded greatly, further strengthening the conclusions reached in the 2009 PM ISA. Recent health evidence continues to show a clear relationship between short-term $PM_{2.5}$ exposure and cardiovascular outcomes such as ED visits and hospital admissions for ischemic heart disease (IHD) and heart failure (HF). Additionally, recent epidemiologic studies confirm the relationship between short-term exposure to $PM_{2.5}$ and cardiovascular mortality. Results from epidemiologic studies are supported by CHE and animal toxicological evidence demonstrating that exposure to $PM_{2.5}$ can result in a variety of cardiovascular effects including endothelial dysfunction, increases in blood pressure, and conduction abnormalities. Thus, the epidemiologic, CHE and animal toxicological evidence presented in this section continues to support a causal relationship between short-term $PM_{2.5}$ exposures and cardiovascular effects, with the strongest evidence supporting this determination still coming from the epidemiologic literature. As discussed in detail below, recent evidence also reduces uncertainties from the previous review with respect to the potential for copollutant confounding and provides additional evidence for biological plausibility.

The subsections below provide an evaluation of the most policy relevant scientific evidence relating-short-term $PM_{2.5}$ exposure to cardiovascular health effects. To clearly characterize and put this evidence into context, there is first a discussion of the biological plausibility of cardiovascular effects following short-term $PM_{2.5}$ exposure (Section 6.1.1). Following this discussion, the health evidence relating short-term $PM_{2.5}$ exposure and specific cardiovascular health outcomes is discussed in detail: ischemic heart disease and myocardial infarction (Section 6.1.2), heart failure and impaired heart function (Section 6.1.3) cardiac electrophysiology and arrhythmia (Section 6.1.4), cerebrovascular disease and stroke (Section 6.1.5), increased blood pressure and hypertension (Section 6.1.6), peripheral vascular disease (PVD), venous thromboembolism and pulmonary embolisms (Section 6.1.7), aggregated cardiovascular outcomes (Section 6.1.8), and cardiovascular-related mortality (Section 6.1.9). The evidence for an effect of $PM_{2.5}$ exposures on endpoints such as changes in heart rate variability (HRV) and endothelial function are discussed (Section 6.1.10, Section 6.1.11, Section 6.1.12, and

Section 6.1.13), as are policy relevant considerations (Section 6.1.14), and the relationship between health effects and exposure to specific $PM_{2.5}$ components (Section 6.1.15). Finally, considering the all of the information presented above, summary and causal determinations are presented (Section 6.1.16). Of note, when discussing the health evidence and causal determinations, effect estimates from epidemiologic studies adjusted for potential confounders are presented when available and new epidemiologic, CHE, and animal toxicological studies that address uncertainties and limitations noted in the previous review are emphasized.

6.1.1 Biological Plausibility

This subsection describes the biological pathways that potentially underlie cardiovascular health effects resulting from short-term inhalation exposure to $PM_{2.5}$. Figure 6-1 graphically depicts these proposed pathways as a continuum of pathophysiological responses—connected by arrows—that may ultimately lead to the apical cardiovascular events observed in epidemiologic studies (e.g., ED visits and hospital admissions). This discussion of "how" short-term exposure to $PM_{2.5}$ may lead to these cardiovascular events also provides biological plausibility for the epidemiologic results reported later in Section 6.1. In addition, most studies cited in this subsection are discussed in greater detail throughout Section 6.1.



Note: The boxes above represent the effects for which there is experimental or epidemiologic evidence, and the dotted arrows indicate a proposed relationship between those effects. Solid arrows denote direct evidence of the relationship as provided, for example, by an inhibitor of the pathway or a genetic knock-out model used in an experimental study. Progression of effects is depicted from left to right and color-coded (grey, exposure; green, initial event; blue, intermediate event; orange, apical event). Here, apical events generally reflect results of epidemiologic studies, which often observe effects at the population level. Epidemiologic evidence may also contribute to upstream boxes.

Figure 6-1 Potential biological pathways for cardiovascular effects following short-term exposure to $PM_{2.5}$.

When considering the available health evidence, plausible pathways connecting short-term exposure to $PM_{2.5}$ to the apical events reported in epidemiologic studies are proposed in Figure 6-1. The first pathway begins as respiratory tract inflammation leading to systemic inflammation[61]. The second pathway involves activation of sensory nerve pathways in the respiratory tract that lead to modulation of the autonomic nervous system. Once these pathways are initiated, there is evidence from experimental and observational studies that short-term exposure to $PM_{2.5}$ may result in a series of pathophysiological responses that could lead to cardiovascular events such as emergency department (ED) visits and hospital admissions for ischemic heart disease (IHD) and heart failure (HF), and ultimately mortality.

[61] It is also possible that particles ~200 nm or less, or soluble particle components can translocate directly into the circulatory system (Chapter 4) and lead to systemic inflammation, although the extent to which particle translocation occurs remains unclear.

Short-term inhalation exposure to $PM_{2.5}$ may result in respiratory tract inflammation and oxidative stress (CHAPTER 5). Inflammatory mediators such as cytokines produced in the respiratory tract have the potential to enter into the circulatory system where they may amplify the initial inflammatory response and/or cause distal pathophysiological events that can contribute to overt cardiovascular disease. For example, following short-term $PM_{2.5}$ exposure in mice, Budinger et al. (2011) demonstrated that inflammation that began in the lung resulted in an increase in circulating markers of coagulation. Thus, it is important to note that there is evidence from CHE (Behbod et al., 2013; Urch et al., 2010; Brook et al., 2009; Gong et al., 2004); epidemiologic panel (Steenhof et al., 2014; Strak et al., 2013a; Huttunen et al., 2012; Delfino et al., 2009b), and animal toxicological (Xu et al., 2013) studies that short-term exposure to $PM_{2.5}$ can result in an increase in circulating inflammatory cells and cytokines. Elevated levels of cytokines such as interlukin-6 (IL-6) have been correlated with elevated markers of thrombosis (Chiarella et al., 2014; Budinger et al., 2011). It is therefore also important to note that in CHE (Lucking et al., 2011; Ghio et al., 2003; Jr et al.; Ghio et al., 2000), epidemiologic panel (Croft et al., 2017; Strak et al., 2013a), and animal toxicological (Budinger et al., 2011; Kodavanti et al.) studies that there is evidence of increased protein levels associated with coagulation and/or decreased protein levels associated with fibrinolysis following short-term $PM_{2.5}$ exposure. This alteration in hemostasis increases the potential for thrombosis (Lucking et al., 2011), which can potentially exacerbate existing IHD and HF.

In addition to affecting hemostasis, systemic inflammation may result in impaired vascular function that could potentially lead to rupture of existing plaques (Halvorsen et al., 2008). Dislodged plaques may then obstruct blood flow to the heart or stimulate intravascular clotting (Karoly et al., 2007), both of which could result in acute myocardial ischemia, and set the stage for HF. If the dislodged plaque obstructs blood flow to the brain, the potential for a stoke exists. Impaired vascular function has been reported following short-term $PM_{2.5}$ exposure in CHE (Hemmingsen et al., 2015b; Tong et al., 2015; Lucking et al., 2011; Brook et al., 2009), epidemiologic panel (Ljungman et al., 2014; Madrigano et al., 2010; Liu et al., 2009) and animal toxicological studies (Davel et al., 2012; Haberzettl et al., 2012; O'Toole et al., 2010). In addition, clinical indicators of potential ischemia (e.g., ST segment depression on an electrocardiogram) have been shown in epidemiologic panel studies (Delfino et al., 2011; Zhang et al., 2009) following short-term exposure to $PM_{2.5}$. Impaired vascular function can also lead to increases in blood pressure (BP) through vasoconstriction. Given that increases in BP may exacerbate IHD or HF through shear stress induced arterial thrombosis and/or impaired vascular function, it is notable that following short-term $PM_{2.5}$ exposure, there is direct evidence for increases in BP from CHE (Tong et al., 2015; Bellavia et al., 2013; Brook et al., 2009), epidemiologic panel (Hicken et al., 2014; Brook et al., 2011; Dvonch et al., 2009), and animal toxicological studies (Bartoli et al., 2009; Ito et al., 2008; Chang et al., 2007; Chang et al., 2004). These studies are consistent with additional evidence from animal toxicological studies (Aztatzi-Aguilar et al., 2015; Ghelfi et al., 2010) reporting increases in renin-angiotensin system gene expression consistent with vasoconstriction and increases in BP. Taken together, there are plausible pathways by which respiratory tract inflammation could exacerbate existing

IHD and HF, contribute to the development of a myocardial infarction or stroke, and lead to ED visits and hospital admissions.

There is also evidence that exposure to $PM_{2.5}$ could lead to these outcomes through activation of sensory nerves in the respiratory tract (CHAPTER 5). Once activated, autonomic nervous system modulation may cause a shift toward increased sympathetic tone. Shifts toward increased sympathetic nervous system tone may result in increases in BP and decreased in vascular function, which as mentioned above, could exacerbate IHD and/or HF. It is therefore important to note that there is evidence from CHE (Tong et al., 2012); epidemiologic panel (Liu et al., 2015b; Hampel et al., 2014; Weichenthal et al., 2014a; Zanobetti et al., 2010) and animal toxicological studies (Wagner et al., 2014a; Wagner et al., 2014b; Rohr et al., 2011) of autonomic nervous system modulation—including a shift toward increased sympathetic tone (as evidenced by changes in HRV and/or HR)—following short-term $PM_{2.5}$ exposure. Modulation of the autonomic nervous system may also contribute to conduction abnormalities (Ghelfi et al., 2010) or worsening of arrhythmia (Cascio, 2016). Thus, also of note is evidence from CHE (Tong et al., 2012; Sivagangabalan et al., 2011), epidemiologic panel (Zanobetti et al., 2014a; Link et al., 2013; Dockery et al., 2005a; Dockery et al., 2005b; Rich et al., 2005; Peters et al., 2000)and animal toxicological studies (Farraj et al., 2015; Ghelfi et al., 2010; Nadziejko et al., 2004) that short-term exposure to $PM_{2.5}$ can result in conduction abnormalities or arrhythmia. Conduction abnormalities or arrhythmia could then potentially exacerbate IHD and subsequently, HF. Taken together, there are multiple potential pathways by which activation of sensory nerves in the respiratory tract may lead to worsening of IHD or HF.

When considering the available evidence, there are plausible pathways connecting short-term exposure to $PM_{2.5}$ to cardiovascular health effects (Figure 6-1). The first potential pathway begins with respiratory tract inflammation that may lead to systemic inflammation, altered hemostasis, impaired vascular function and potential worsening of IHD and HF. The second potential pathway involves the activation of sensory nerves in the respiratory tract that may modulate autonomic nervous system responses potentially leading to exacerbation of IHD and HF through changes in BP and worsening of conduction abnormalities or arrhythmia. Collectively, these proposed pathways provide biological plausibility for epidemiologic results of ED visits and hospital admissions for cardiovascular-related causes and will be used to inform a causal determination, which is discussed later in the chapter (Section 0).

6.1.2 Ischemic Heart Disease and Myocardial Infarction

IHD is a chronic condition characterized by atherosclerosis and reduced blood flow to the heart (Section 6.2.2 and Section 6.2.4). Myocardial infarction (MI), more commonly known as a heart attack, occurs when heart tissue death occurs secondary to prolonged ischemia. The effect of short-term $PM_{2.5}$ exposure on acute MI, complications from recent MI, and other acute or chronic IHD are generally

evaluated using ICD codes recorded when a patient is admitted or discharged from the hospital or emergency department (ICD9: 410−414 or ICD10: I20−I25). In experimental or epidemiologic panel studies, indicators of MI include ST segment depression as measured by an electrocardiograph (ECG). The ST segment of an electrocardiogram recorded by surface electrodes corresponds to the electrical activity of the heart registered between ventricular depolarization and repolarization, and is normally isoelectric.

In the 2009 PM ISA, most of the evidence for IHD and MI was from epidemiologic studies of emergency department (ED) visits and hospital admissions. This evidence included the U.S. Medicare Air Pollution Study (MCAPS) (Dominici et al., 2006), a four-city study in Australia (Barnett et al., 2006), and a study among older adults in several French cities (Host et al., 2008). The positive associations reported in these studies were important considerations in the determination of a causal relationship between short-term $PM_{2.5}$ exposure and cardiovascular effects.

Evidence from the current review strengthens the epidemiologic results reported in the 2009 PM ISA. Several new epidemiologic studies conducted in the U.S. and Europe provide additional evidence of positive associations between short-term $PM_{2.5}$ exposure and IHD ED visits and hospital admissions (Section 6.2.2.1). Uncertainties noted in the last review with respect to exposure measurement error for those not living near a $PM_{2.5}$ monitor were reduced in the current review by consideration of recent studies that applied hybrid exposure assessment techniques that combine land use regression data with satellite aerosol optical depth (AOD) measurements and $PM_{2.5}$ concentrations measured at fixed-site monitors to estimate $PM_{2.5}$ concentrations. In addition to these ED visit and hospital admissions studies, there is also evidence for ST segment depression from epidemiologic panel studies (Section 6.1.2.2).

6.1.2.1 Emergency Department Visits and Hospital Admissions

In the last review, epidemiologic studies that examined the effect of $PM_{2.5}$ on IHD ED visits and hospital admissions provided some of the strongest evidence supporting the causal relationship between short-term $PM_{2.5}$ exposure and cardiovascular disease, including several multicity studies [U.S. Medicare Air Pollution Study (MCAPS) (Dominici et al., 2006), a study among older adults (65+ years) in four cities in Australia (Barnett et al., 2006), and a study among older adults in several French cities (Host et al., 2008)]. In the current review, several recent multicity studies in the U.S. and Europe provide additional evidence for positive associations between short-term $PM_{2.5}$ exposure and IHD ED visits and HA, including some studies conducted in areas of lower $PM_{2.5}$ concentrations than those included in the 2009 PM ISA. This section first reviews recent studies that have considered IHD as a composite endpoint, and subsequently considers those studies focusing specifically on MI and angina. Additional study details and results are presented in Table 6-1.

Table 6-1 Epidemiologic studies of short-term $PM_{2.5}$ exposure and ischemic heart disease and myocardial infarction hospital admission and emergency department visits.

Study/Location/Population	Exposure Assessment	Outcome	Mean and Upper Percentile Concentrations µg/m^3	Copollutant Examination
Dominici et al. (2006) 204 U.S. Urban Counties (1999−2002) Age ≥65 yr	Monitors in county averaged Number NR. Study population reside an average of 5.9 miles from monitor. †Weichenthal et al. (2016b) 16 Cities in Ontario, Canada (2004−2011)	Nearest monitor to patient's population-weighted postal code centroid	MI	6.91 (5.97) Max: 56.8	Correlation (*r*): NO_2: 0.51, O_3: −0.49 Copollutant models with: NO_2, O_3

CMAQ = Community Multiscale Air Quality Modeling System, CO = carbon monoxide, HR = hazard ratio, IHD = Ischemic Heart Disease, max = maximum, MI = Myocardial Infarction, NO_2 = nitrogen dioxide, NR = not reported, OR = odds ratio, $PM_{2.5}$ = particulate matter with mean aerodynamic diameter 2.5 µm, PM_{10} = particulate matter with mean aerodynamic diameter 10 µm, $PM_{10-2.5}$ = particulate matter with mean aerodynamic diameter between 2.5 µm and 10 µm, RR = relative risk, SO_2 = sulfur dioxide.

For the included epidemiologic studies, the focus is on those studies conducted in areas where mean $PM_{2.5}$ concentrations are <20 µg/m³ or in the case of a multi-city study where more than half of the cities have concentrations <20 µg/m³. Other studies maybe be included if they contribute to evaluating important uncertainties (see Preface).

†Studies published since the 2009 PM ISA.

Since the 2009 PM ISA, studies making use of the large Medicare database have evaluated IHD hospital admission records and observed an 0.18% (95% CI: −0.09, 0.45%) increase in admissions associated with $PM_{2.5}$ concentrations on the same day (Bell et al., 2015), and 0.99% (95% CI: 0.62, 1.37%) increase over the previous two days (lag 0−1) (Kloog et al., 2014). Notably, unlike most previous studies that rely on monitored $PM_{2.5}$ concentrations, Kloog et al. (2014) applied land use regression (LUR) in conjunction with satellite AOD observations and monitoring data to estimate $PM_{2.5}$ exposures across the study area. This hybrid prediction model attempts to reduce exposure measurement error through more spatially resolved exposure estimates and increase coverage by estimating exposure for populations that do not live near a $PM_{2.5}$ monitor. Similarly, two multicity studies conducted in New York observed positive associations between short-term $PM_{2.5}$ concentrations and ED visits and hospital admissions for IHD (Hsu et al., 2017; Haley et al., 2009). Hsu et al. (2017) utilized a hybrid estimation of $PM_{2.5}$ from monitoring data and CMAQ output, and reported a positive association with IHD in the greater New York City (NYC) region (including NYC, counties to the north of NYC, and Long Island), but null associations in the remaining regions of the state. Talbott et al. (2014) examined hospital admissions for IHD in seven U.S. states (Florida, Massachusetts, New Hampshire, New Jersey, New Mexico, New York, and Washington) and reported positive associations in New Jersey and New York, but not in the other five states. Neither Hsu et al. (2017) nor Talbott et al. (2014) presented pooled results across all study areas; however, inconsistent results between regions provide evidence of potential regional heterogeneity. In contrast to other large, multicity studies, an administrative database study across England and Wales observed a decrease in risk of hospitalizations for IHD corresponding to increasing $PM_{2.5}$ concentrations averaged over the previous 5 days (RR: 0.986, 95% CI: 0.975, 0.996), and in sensitivity analyses at lag 0−1 (quantitative results not presented) (Milojevic et al., 2014). Recent single-city studies were inconsistent in observing associations between $PM_{2.5}$ concentrations and IHD, with one study observing positive associations in Denver, CO (Kim et al., 2012) and another observing a null association in St. Louis, MO (Sarnat et al., 2015).

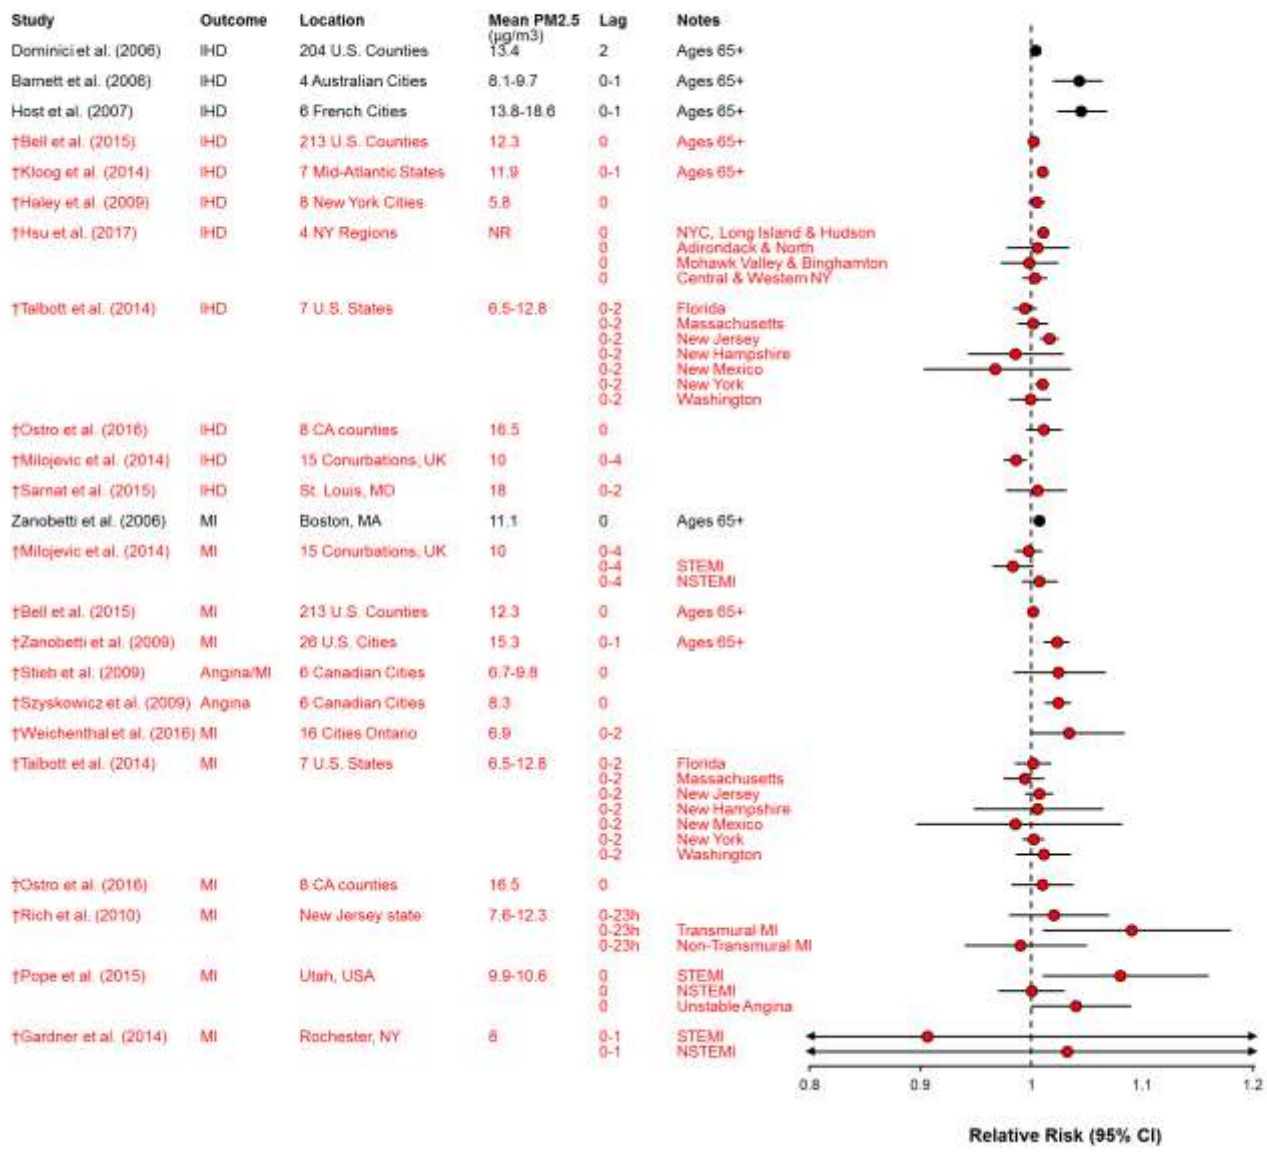
Overall, recent epidemiologic studies continue to provide evidence for positive associations between short-term $PM_{2.5}$ exposure and IHD ED visits and HA. Several recent studies used hybrid exposure assessment techniques incorporating both remote sensing and monitor data, allowing them to include study subjects that do not live near PM monitors, and addressing a previous source of uncertainty in these studies.

6.1.2.1.1 Emergency Department (ED) Visits and Hospital Admissions for Acute Myocardial Infarction (MI) and Angina Pectoris

A prevailing hypothesis in the literature is that $PM_{2.5}$ could be more strongly associated with the more specific outcome of MI as compared to studies considering the composite endpoint of IHD. In the 2009 PM ISA, a limited number of epidemiologic studies generally observed positive associations between $PM_{2.5}$ and MI, although not without some inconsistency in results across registry-based studies

(Sullivan et al., 2005; Peters et al., 2004; Peters et al., 2001). Recent studies evaluating the potential association between $PM_{2.5}$ and MI continue to provide evidence of a positive association based on additional administrative database and registry-based studies; however, some inconsistency in results still remains, and the evidence overall is less consistent when compared to associations between $PM_{2.5}$ and IHD.

Among recent investigations of MI, larger administrative database studies generally reported positive associations (Figure 6-2), using either $PM_{2.5}$ concentration estimates from local monitors or spatiotemporal models incorporating land use variables, AOD observations, and monitor measurements (Section 3.3, Table 6-1). Several U.S. studies reported positive associations at short lag periods (Ostro et al., 2016; Talbott et al., 2014; Zanobetti et al., 2009), with the notable exception of a large, nationwide Medicare study that observed null associations at lag 0 (Bell et al., 2015). Similarly, a study in England and Wales observed a negative association for MI (Milojevic et al., 2014) for a longer multi-day lag period (lag 0−4), and a null association for analyses at lag 0−1. It should also be noted that Talbott et al. (2014) observed some evidence of regional heterogeneity, with positive associations in three of the seven U.S. states. Meanwhile, recent multicity Canadian studies reported positive associations between short-term $PM_{2.5}$ exposure and ED visits and hospital admissions for MI (Weichenthal et al., 2016b; Stieb et al., 2009; Szyszkowicz, 2009) (Figure 6-2). Weichenthal et al. (2016b) also examined effect modification by city-level PM2.5 oxidative potential and observed an increasing association between $PM_{2.5}$ and MI as oxidative potential increased. Recent administrative studies of MI add to the limited number of studies from the 2009 PM ISA. Although not all studies observed positive associations, overall, recent administrative studies continue to provide evidence of a positive association between $PM_{2.5}$ and MI, particularly for immediate lag periods (see Section 6.2).



Note: †Studies published since the 2009 PM ISA. IHD = ischemic heart disease, MI = myocardial infarction, STEMI = ST segment elevation MI, NSTEMI = non-ST segment elevation MI, NR = not reported. Corresponding quantitative results are reported in Supplemental Table S6-1 (U.S. EPA, 2018).

Figure 6-2 Results of studies of short-term ambient $PM_{2.5}$ exposure and hospital admissions and emergency department visits for ischemic heart disease.

While these administrative-based studies generally observe positive associations between $PM_{2.5}$ and MI, smaller recent studies based on MI registries, which are thought to have less outcome misclassification compared to administrative data sets, have not consistently observed associations between $PM_{2.5}$ exposure and MI incidence (Pope et al., 2015; Gardner et al., 2014; Rich et al., 2010).

$PM_{2.5}$ exposure estimates from studies were based on either data from the nearest available monitoring station, or averages of measured concentrations from multiple monitors. This is consistent with the 2009 PM ISA, where registry-based MI studies reported inconsistent results for an association between $PM_{2.5}$ and MI; however, some inconsistency may be due to the type of event, as studies of ST segment elevation MI (STEMI) (Pope et al., 2015; Gardner et al., 2014) and transmural MI (Rich et al., 2010) reported positive associations, while null or negative associations were observed in studies of non-ST segment elevation MI (Pope et al., 2015; Gardner et al., 2014). In contrast, results from European studies, which had generally higher mean $PM_{2.5}$ concentrations, do not provide consistent evidence for an association between $PM_{2.5}$ and STEMI (Caussin et al., 2015; Claeys et al., 2015).

While the above studies reported inconsistent associations, recent meta-analyses by Mustafic et al. (2012) and Luo et al. (2015) reported overall associations between $PM_{2.5}$ and ED visits or hospital admissions for MI that were both positive and statistically significant. The magnitude of the association based on the meta-analytic summary estimates is on the order of 2% to 2.5% excess risk of ED visits and hospital admissions for MI.

In summary, several large studies published since the release of the 2009 PM ISA (U.S. EPA, 2009) provide continued support for an association between $PM_{2.5}$ exposure and ED visits or hospital admissions for IHD among study populations that generally had lower $PM_{2.5}$ exposures (Table 6-1) than those reported in the 2009 PM ISA. There were generally consistent results across recent studies looking specifically at MI, and registry studies, which are likely to reduce outcome misclassification, report evidence of positive associations with MI subtypes. The positive associations reported across these studies is supported by formal meta-analyses that document the presence of an association between $PM_{2.5}$ and MI. Additionally, few studies utilized modeled $PM_{2.5}$ concentrations to study a wider population, including rural populations. The rest of the studies conducted exposure assessment using a single monitor or an average of fixed-site monitors, which restricts the study population to people living near monitors. Consistent, positive associations across multicity and single-city studies continue to provide strong evidence for the relationship between short-term $PM_{2.5}$ and IHD that is unlikely to be driven by chance or systematic bias.

6.1.2.2 Panel Epidemiologic Studies of ST Segment Depression

The 2009 PM ISA reviewed a handful of panel studies investigating ST-segment changes in relation to short-term exposure to $PM_{2.5}$. These studies reported associations between 1 hour−2 days $PM_{2.5}$ concentrations and ST-segment depression. Since the 2009 PM ISA, two studies have examined potential changes in ST segment depression relative to $PM_{2.5}$ concentrations. In a study of 38 older adults with IHD in nursing homes in Los Angeles, CA, Delfino et al. (2011) observed that $PM_{2.5}$ concentrations averaged over 1 hour up to 4 days were associated with ST-segment depression ≥1.0 mm [OR 1.68 (95% CI: 1.20, 2.35) Notably, this association was attenuated in models including BC or primary OC, but remained

positive. In another study, Zhang et al. (2009) observed associations between $PM_{2.5}$ concentrations and ST-abnormality in the Women's Health Initiative at lag 0−2-days [4% (95% CI–3%, to 10%)]. Evidence from these recent studies further support results from the 2009 PM ISA. More information on these studies can be found in Table 6-2 below.

Table 6-2 Details from panel studies of ST segment depression.

6.1.3 Heart Failure and Impaired Heart Function

HF refers to a set of conditions in which the heart's pumping action is weakened. In congestive heart failure (CHF), the flow of blood from the heart slows, failing to meet the oxygen demands of the body, and returning blood can back up, causing swelling or edema in the lungs or other tissues (typically in the legs and ankles). The effect of short-term $PM_{2.5}$ exposure on people with CHF—which is a chronic

condition—is generally evaluated using ICD codes recorded when a patient is admitted or discharged from the hospital or ED. The relevant diagnostic codes for heart failure are ICD9 428 and ICD10 I50. These codes encompass left, systolic, diastolic and combined heart failure (Section 6.2.5). In experimental studies, indicators of HF include decreased contractility and/or relaxation in response to pharmacological challenge, reduced ejection fraction (i.e., the percent of blood pumped from the ventricle during each contraction), and decreases in left ventricular developed pressure (LVDP). Effects on endpoints such as these are plausible given that there is evidence that short-term $PM_{2.5}$ exposure can result in a number of cardiovascular effects, including arrhythmia and increases in BP.

In the 2009 PM ISA, the majority of the evidence for HF was from epidemiologic studies of ED visits and HA. The strongest evidence for an association came from multicity studies in the U.S. (Dominici et al., 2006) and Australia (Barnett et al., 2006). Results from single-city studies reviewed in the 2009 PM ISA also provided supporting evidence of a positive association between short-term exposure to $PM_{2.5}$ and CHF-related ED visits and hospital admissions (Section 6.1.3.1). In the 2009 PM ISA, there was also limited evidence of decreased contractility in mice following exposure to carbon black, but not in studies using $PM_{2.5}$ CAPS.

Evidence from the current review strengthens the epidemiologic results reported in the 2009 PM ISA. Since the last review, multicity epidemiologic studies conducted in the U.S., Canada, and Europe generally report positive associations between short-term $PM_{2.5}$ exposure and ED visits and hospital admissions for HF. Additional evidence of these associations was also found in single-city studies, although these results tended to be more inconsistent. Supporting the ED visit and hospital admissions studies was a single toxicological study showing impaired contractility and LVDP following short-term $PM_{2.5}$ exposure.

6.1.3.1 Emergency Department Visits and Hospital Admissions

Numerous studies reviewed in the 2009 PM ISA provided evidence of positive associations between short-term $PM_{2.5}$ exposure and ED visits or hospital admissions for heart failure. The strongest evidence came from multicity studies in the U.S. (Dominici et al., 2006) and Australia (Barnett et al., 2006). Results from single-city studies reviewed in the 2009 PM ISA provided additional evidence of positive associations between $PM_{2.5}$ and CHF.

Since the 2009 PM ISA, a number of recent studies add to the available evidence and further support the presence of a positive association between short-term $PM_{2.5}$ exposure and ED visits and hospital admissions for heart failure (Table 6-3), including among study populations that had lower $PM_{2.5}$ exposures than populations in the 2009 PM ISA.

Table 6-3 Epidemiologic studies of short-term $PM_{2.5}$ exposure and congestive heart failure hospital admission and emergency department visits.

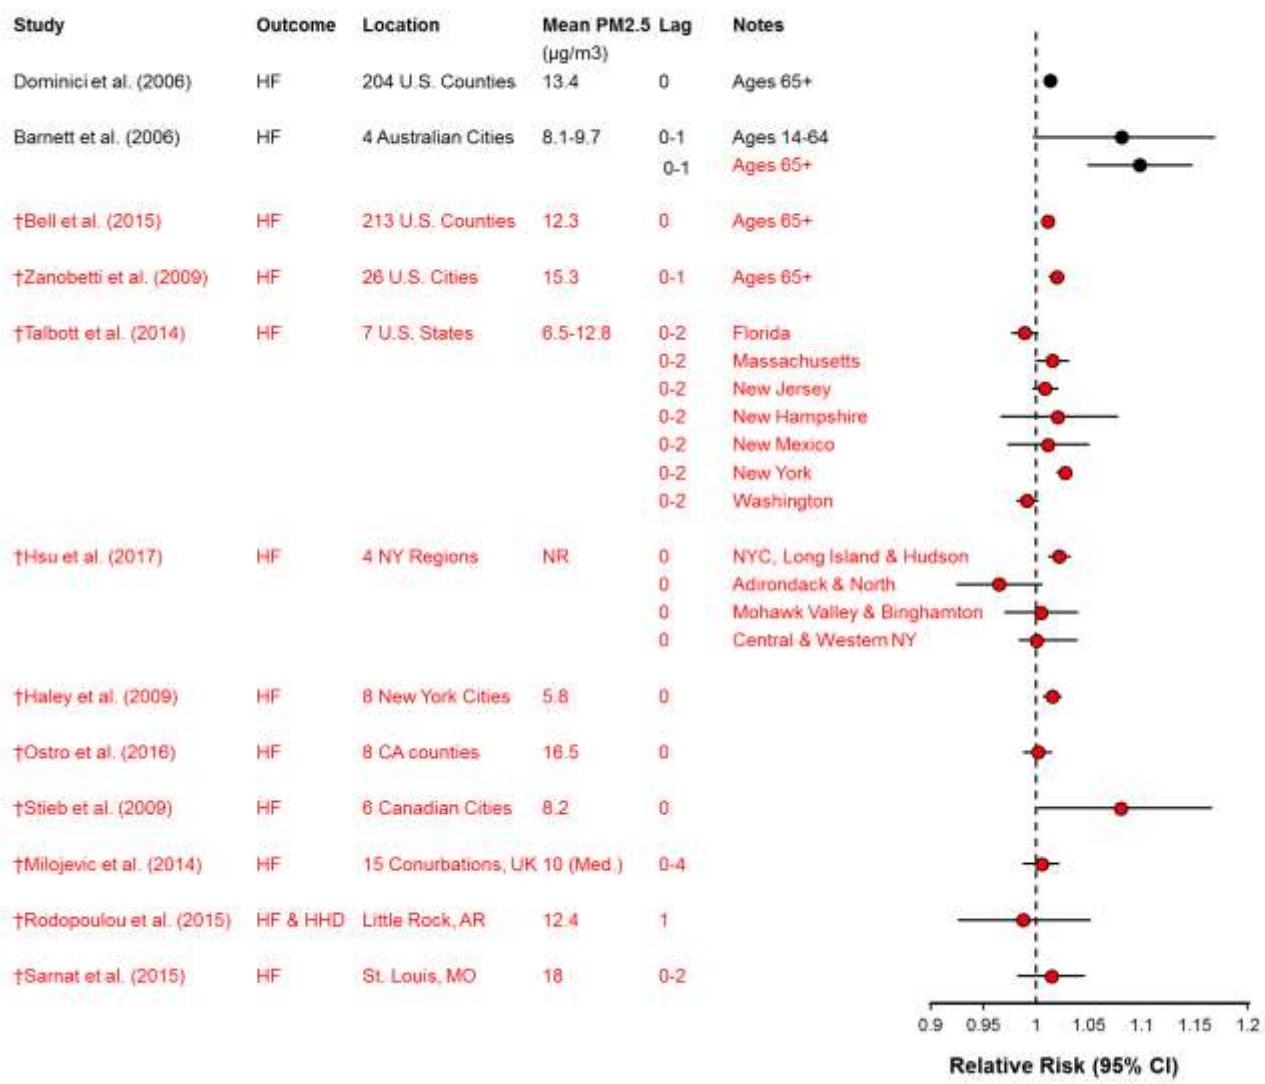
†Studies published since the 2009 PM ISA.

For the included epidemiologic studies, the focus is on those studies conducted in areas where mean $PM_{2.5}$ concentrations are <20 $\mu g/m^3$ or in the case of a multi-city study where more than half of the cities have concentrations <20 $\mu g/m^3$. Other studies maybe be included if they contribute to evaluating important uncertainties (see Preface).

Several recent multicity studies in the U.S., Canada, and Europe examined the relationship between $PM_{2.5}$ and ED visits and hospital admissions for heart failure and generally observed positive associations (Figure 6-3). Two large Medicare studies (Bell et al., 2015; Zanobetti et al., 2009) observed similar estimates to those published by Dominici et al. (2006), reporting a 1.1% (95% CI: 0.8, 1.5%) and 1.9% (95% CI: 1.2, 2.5%) increase in HA, respectively. Talbott et al. (2014) examined hospital

admissions in seven U.S. states and, though they did not pool their results, they observed positive associations between hospital admissions for heart failure and $PM_{2.5}$ concentrations on the same day in Massachusetts, New Jersey, and New York, but not in New Hampshire, Washington, New Mexico, or Florida. Similarly, another large administrative data study in New York, which estimated $PM_{2.5}$ exposures using a hybrid of both monitored $PM_{2.5}$ data and modeled $PM_{2.5}$ estimates, reported a positive association with heart failure in the greater NYC region, but null associations throughout the remainder of the state (Hsu et al., 2017). The observed differences in effect estimates within or between states in Talbott et al. (2014) and Hsu et al. (2017) indicates the potential for regionally heterogeneous associations. Smaller multicity studies in New York (Haley et al., 2009), California (Ostro et al., 2016), and Canada (Stieb et al., 2009) reported positive associations between $PM_{2.5}$ exposure and ED visits and hospital admissions for heart failure, ranging from 1.1% to 8.0% increases in ED visits and HA. In contrast, a study of hospital admissions for heart failure in England and Wales reported a null association between short-term $PM_{2.5}$ exposure and heart failure (Milojevic et al., 2014).



Note: †Studies published since the 2009 PM ISA. HF = heart failure, HHD = hypertensive heart disease, NR = not reported. Corresponding quantitative results are reported in Supplemental Table S6-4 (U.S. EPA, 2018).

Figure 6-3 Results of studies of short-term ambient $PM_{2.5}$ concentrations and hospital admissions and emergency department visits for heart failure.

In summary, recent multicity studies, along with studies published in the 2009 PM ISA, provide continued evidence for an association between short-term $PM_{2.5}$ exposure and ED visits and hospital admissions for heart failure, including among study populations with generally lower $PM_{2.5}$ concentrations than those in the previous ISA (Table 6-3). Several studies conducted exposure assessment using a single monitor or an average of fixed-site monitors, which restricts the study population to people living near monitors, and may result in exposure misclassification due to spatial variation of $PM_{2.5}$;

however, consistent positive associations across multicity and single-city studies continues to provide strong evidence for an association between short-term $PM_{2.5}$ and CHF that is unlikely to be driven by chance or systemic bias.

6.1.3.2 Controlled Human Exposure Studies of Impaired Heart Function

In the 2009 PM ISA, there were no CHE studies examining the effect of short-term exposure to $PM_{2.5}$ on impaired heart function. Since the publication of that document, Vieira et al. (2016b) have reported that in both exercising heart failure and control patients, short-term exposure to DE results statistically significant ($p < 0.05$) decreases in estimates of left ventricular stroke volume (i.e., the amount of blood the left ventricle pumps per beat). The authors also reported that particle filtration of DE attenuated this effect in both groups. More information on studies published since the 2009 ISA can be found in Table 6-4 below.

Table 6-4 Study-specific details from controlled human exposure (CHE) studies of short-term $PM_{2.5}$ exposure and impaired heart function.

Study	Population	Exposure Details	Endpoints Examined
(Vieira et al., 2016b)	Healthy adults n = 8 M, 7 F; 45 ± 10 yr; 7 with a history of smoking HF patients n = 16 M, 10 F; 51 ± 9 yr; 19 white; 17 with a history of smoking	325 ± 31 µg/m^3 $PM_{2.5}$ DE generated from a diesel engine and conditioned through a refrigerated metal retainer 25 ± 6 µg/m3 $PM_{2.5}$ filtered DE 21 min total exposure, 15 at rest and 6 while walking	O_2 pulse as a surrogate for stroke volume during 6 min walking exposure

DE = diesel Exhaust, F = female, HF = heart failure, M = male, n = number, O_2 = Oxygen SD = standard deviation.

6.1.3.3 Toxicology Studies of Impaired Heart Function

In the 2009 PM ISA (U.S. EPA, 2009), a study found decreased contractility after exposure to carbon black in mice (Yan et al., 2008). Since the 2009 PM ISA, Kurhanewicz et al. (2014) demonstrated that in mice, short-term $PM_{2.5}$ exposure statistically significantly decreased ($p < 0.05$) LVDP and contractility compared to filtered air controls. However, a separate study did not report cardiac gene expression consistent with cardiac damage (Aztatzi-Aguilar et al., 2015) following short-term $PM_{2.5}$ exposure in rats. Taken together, there is some additional evidence from more recent toxicological studies

that short-term exposure to $PM_{2.5}$ may result in impaired heart function in mice. More information on studies published since the 2009 ISA can be found in Table 6-5 below.

Table 6-5 Study-specific details from toxicological studies of short-term $PM_{2.5}$ exposure and impaired heart function.

Study	Population	Exposure Details	Endpoints Examined
(Kurhanewicz et al., 2014)	C57BL/6 mice; F, n = 5−8 per treatment group	Inhalation of 190 µg/m^3 $PM_{2.5}$ for 4 h from Research Triangle Park, NC	LVDP and contractility 24 h post
(Aztatzi-Aguilar et al., 2015)	Adult Sprague-Dawley rats, M, n = 4 per treatment group	Inhalation of 178 µg/m^3 $PM_{2.5}$ for 5 h/day for 3 days from a high traffic and industrial area north of Mexico City in early summer	Gene expression consistent with cardiac damage (Acta1 and Col3a1) in heart tissue collected 24 h post

Acta1 = skeletal alpha-actin, Col3a1 = collagen Type 3 alpha, d = day, f = female, h = hour, M = male, n = number, LVDP = left ventricular developed pressure.

6.1.4 Cardiac Electrophysiology, Arrhythmia, and Cardiac Arrest

In epidemiologic studies, the effect of short-term $PM_{2.5}$ exposure on arrhythmia is generally evaluated using ICD codes for ED visits, HA, and out-of-hospital cardiac arrests (OHCA) that typically result from ventricular arrhythmia. In addition, there is a body of epidemiologic studies that examine arrhythmias recorded on implantable cardiodefibrillators.

Experimental and epidemiologic panel studies typically use surface ECGs to measure electrical activity in the heart resulting from depolarization and repolarization of the atria and ventricles. The *P* wave of the ECG represents atrial depolarization, while the QRS represents ventricular depolarization and the T wave, ventricular repolarization. Because the ventricles account for the largest proportion of heart mass overall and thus are the primary determinants of the electrical activity recorded in the ECG, ECG changes indicating abnormal electrical activity in the ventricles are of greatest concern. Such endpoints denoting ventricular electrical activity include QTc interval, transmural dispersion (Tp-Te) duration, and T-wave shape. Changes in QTc, RT, and/or Tp-Te duration as wells as changes in T-wave shape and amplitude may be indicative of abnormal impulse propagation in the ventricles. Effects on these endpoints are plausible given that exposure to PM is associated with changes in cardiac autonomic tone and systemic inflammatory responses that may in turn influence cardiac ion channels, adrenergic and cholinergic receptors and gap junction proteins, all of which contribute to normal impulse conduction in heart muscle (Brook et al., 2004). Cardiac arrhythmias can vary in severity from the benign to the potentially lethal as in cardiac arrest, which causes loss of heart function and results from an electrical disturbance that disrupts the heart's pumping action.

In the 2009 PM ISA, results from studies of arrhythmia-related hospitalizations was limited. Since the publication of the 2009 PM ISA, evidence of arrhythmia-related hospitalizations remains limited. However, there is some evidence from epidemiologic panel studies of an association between short-term $PM_{2.5}$ exposure and potential indicators of arrhythmia. Moreover, both CHE and animal toxicological studies provide some evidence that $PM_{2.5}$ exposure influences the electrical activity of the heart.

With respect to OHCA, the 2009 PM ISA reviewed a handful of small studies examining the association between $PM_{2.5}$ exposure and OHCA. Each of these studies reported no evidence of an association between short-term $PM_{2.5}$ exposure and OHCA. Since the publication of the 2009 PM ISA, additional ED visit and hospital admissions studies with substantially larger populations have evaluated the relationship between short-term $PM_{2.5}$ exposure and OHCA. In contrast to the studies from the previous review, recent studies have reported generally positive associations between short-term $PM_{2.5}$ exposure and OHCA. That being said, potential copollutant confounding remains an uncertainty in these studies.

6.1.4.1 Emergency Department Visits and Hospital Admissions for Arrhythmia and Out-of-Hospital Cardiac Arrest

A number of studies based on administrative databases have sought to evaluate the association between short-term $PM_{2.5}$ exposure and HAs for cardiac arrhythmias (also known as dysrhythmias). In these studies, a primary discharge diagnosis of ICD-9 427 has typically been used to identify hospitalized patients. ICD-9 427 includes a heterogeneous group of arrhythmias including paroxysmal ventricular or supraventricular tachycardia, atrial fibrillation and flutter, ventricular fibrillation and flutter, cardiac arrest, premature beats, and sinoatrial node dysfunction.

6.1.4.1.1 Arrhythmias

In the 2009 PM ISA, studies of arrhythmia-related hospital admissions reported inconsistent results and most studies provided little evidence of an association. The multicity U.S. MCAPS study observed a modest increase (0.6% [95% CI: 0.0−1.2%]) in hospital admissions for the combined outcome of cardiac arrhythmias and conduction disorders (Dominici et al., 2006). However, a multicity study in Australia and New Zealand (Barnett et al., 2006) and a study in Atlanta, GA (Metzger et al., 2004) observed null associations between arrhythmia ED visits and hospital admissions and $PM_{2.5}$ exposure. Since the publication of the 2009 PM ISA, recent studies continue to provide inconsistent evidence of an association between $PM_{2.5}$ and arrhythmia-related hospital admissions (Table 6-6).

Table 6-6 Epidemiologic studies of short-term $PM_{2.5}$ exposure and cardiac arrhythmia hospital admission and emergency department visits.

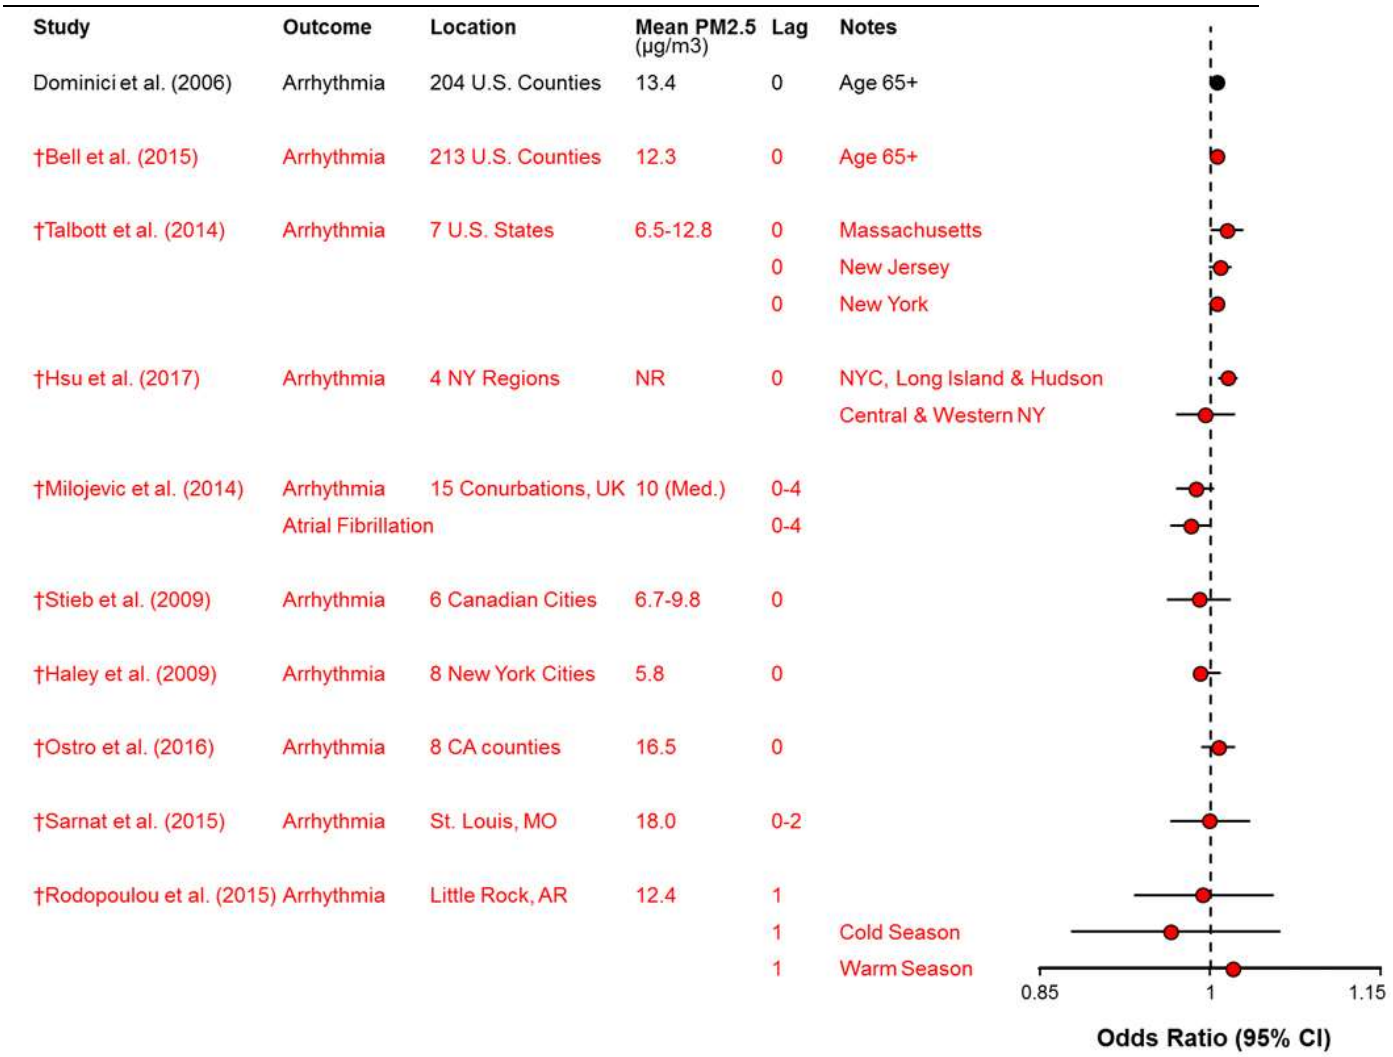
†Studies published since the 2009 PM ISA. For the included epidemiologic studies, the focus is on those studies conducted in areas where mean $PM_{2.5}$ concentrations are <20 µg/m³ or in the case of a multi-city study where more than half of the cities have concentrations <20 µg/m³. Other studies maybe be included if they contribute to evaluating important uncertainties (see Preface).

Several multicity studies in the U.S., Canada, and Europe examined the relationship between $PM_{2.5}$ exposure and arrhythmia-related ED visits and hospital admissions and observed inconsistent associations (Figure 6-4). Similar to the U.S. MCAPS study by Dominici et al. (2006), Bell et al. (2015) reported a positive increase (0.6% [95% CI: 0.3−1.0%]) in risk of hospitalization for heart rhythm disturbance (ICD 426, 427) among Medicare beneficiaries. Talbott et al. (2014) also examined hospital admissions for arrhythmias in seven U.S. states and, though they did not pool their results, they observed evidence of positive associations on the same day in Massachusetts, New Jersey, and New York. Another large administrative data study in New York, using a hybrid estimation of $PM_{2.5}$ exposure combining monitor data and model predictions, reported a positive association with arrhythmia hospital admissions in the NYC region, but null and imprecise associations (i.e., wide 95% CI; Figure 6-4) in the other three NY regions (Hsu et al., 2017). Conversely, Milojevic et al. (2014) considered arrhythmia HAs in England and Wales and observed negative associations with $PM_{2.5}$ concentrations. However, it's possible that the examined lag period (lag 0−4) was long, and could have diluted any immediate effect, as the authors conducted a sensitivity analysis and reported that arrhythmia hospital admissions were positively associated with $PM_{2.5}$ exposure at lag 0−1 (quantitative results not presented). Additional multicity studies in Canada Stieb et al. (2009), New York (Haley et al., 2009), and California (Ostro et al., 2016) also reported null or negative associations.

Results from single-city studies in the U.S. were also inconsistent, with some studies reporting generally null associations (Rodopoulou et al., 2015; Sarnat et al., 2015), while another study observed a positive association (quantitative results not presented (Bunch et al., 2011)). In whole, recent evidence continues to provide inconsistent evidence of an association between short-term in $PM_{2.5}$ exposure and ED visits and hospital admissions for arrhythmias.



Note: †Studies published since the 2009 PM ISA. NR = not reported. Corresponding quantitative results are reported in Supplemental Table S6-6 (U.S. EPA, 2018).

Figure 6-4 Results of studies of short-term $PM_{2.5}$ exposure and hospital admissions and emergency department visits for arrhythmia.

6.1.4.1.2 Out-of-Hospital Cardiac Arrest

The majority of out-of-hospital cardiac arrests (OHCA) are due to cardiac arrhythmias. The 2009 PM ISA reviewed several studies examining the association between $PM_{2.5}$ and OHCA (Rosenthal et al., 2008; Sullivan et al., 2003; Levy et al., 2001). Two of these studies were conducted in Seattle and reported no evidence of an association between $PM_{2.5}$ and OHCA (Sullivan et al., 2003; Levy et al., 2001). The third, a study in Indianapolis, Indiana did not observe an association with $PM_{2.5}$ (Rosenthal et al., 2008). However, Rosenthal et al. (2008) did find a positive association between hourly $PM_{2.5}$ and the subset of events that were witnessed by bystanders, which potentially reduces misclassification of

outcome in regard to cause and timing. Since the publication of the 2009 PM ISA, a number of additional studies have been published on $PM_{2.5}$ and OHCA. The recent literature reports consistent, positive associations between short-term exposure to $PM_{2.5}$ and risk of OHCA (Table 6-7).

†Studies published since the 2009 PM ISA. For the included epidemiologic studies, the focus is on those studies conducted in areas where mean $PM_{2.5}$ concentrations are <20 µg/m^3 or in the case of a multi-city study where more than half of the cities have concentrations <20 µg/m^3. Other studies maybe be included if they contribute to evaluating important uncertainties (see Preface).

A number of recently published studies report positive associations between $PM_{2.5}$ exposure and OHCA in the United States, Europe, and Australia. In the U.S., Ensor et al. (2013) and Silverman et al. (2010) observed positive associations in Houston, Texas (lag 0−1, lag 1−2) and New York City (lag 0−1), respectively (see Table 6-7). In Australia, Dennekamp et al. (2010) reported an 8.7% (95% CI: 3.1, 14.6%) increase in OHCA in Melbourne, while Straney et al. (2014) also observed a positive association in Perth (OR: 1.11, 95% CI: 1.01, 1.20; lag 0−48 hours). European studies also observed positive associations in Copenhagen, Denmark (e.g., RR: 1.090, 95% CI: 1.004, 1.184; lag 3) (Wichmann et al., 2013) and Helsinki, Finland (e.g., OR: 1.09, 95% CI: 1.00, 1.20; lag 0) (Rosenthal et al., 2013) (see Table 6-7). However, a study in Stockholm, Sweden found no evidence of an association (quantitative results not presented) (Raza et al., 2014). The study by Rosenthal et al. (2013) in Helsinki additionally considered whether associations differ depending on the type of OHCA, specifically comparing those due to myocardial infarction to those due to other cardiac causes. They found that $PM_{2.5}$ was more strongly associated with OHCA presumed to be due to myocardial infarction.

In summary, the current state of the literature provides evidence for an association between short-term $PM_{2.5}$ exposure and OHCA. This association is typically observed with $PM_{2.5}$ concentrations averaged over the past 0 to 2 days, although associations with $PM_{2.5}$ concentrations as far back as 4 days prior to the event have been reported. Additionally, all of the studies in this section relied on a single monitor or an average of fixed-site monitors to estimate $PM_{2.5}$ exposure, which restricts the study population to people living near monitors, a limitation identified in the 2009 PM ISA, that persists when the recent body of evidence is included.

6.1.4.2 Panel Epidemiologic Studies for Arrhythmia and Conduction Abnormalities

The body of evidence examining the relationship between ventricular arrhythmias and short-term exposures to $PM_{2.5}$ is small and limited to studies that were evaluated in the 2009 PM ISA (U.S. EPA, 2009). These studies included patients with implantable cardioverter defibrillators (ICDs) and examined associations between ICD-detected arrhythmic events and $PM_{2.5}$ exposures. Generally, there were inconsistent results across study cohorts, with some evidence for positive associations in studies conducted in Boston using 1 or 2-day averages of $PM_{2.5}$. However, results from other studies did not demonstrate a consistent relationship between short-term $PM_{2.5}$ exposures and ventricular arrhythmias.

No recently published panel studies are available to inform the relationship between ventricular arrhythmia and $PM_{2.5}$ exposures; however, there is new evidence for other types of arrhythmic measures including ectopy and atrial fibrillation. Several panel studies used ECG measurements to examine for the presence of ectopic beats or tachycardia, which are often benign but can indicate greater risk for more serious arrhythmias, particularly when heart disease is present.

As in the 2009 PM ISA (U.S. EPA, 2009), recent studies have generally found positive associations between ectopic measures and short-term PM2.5 exposures (Table 6-8). Among a large cohort of older men in the Boston, MA area included in the Normative Ageing Study, positive associations were observed between 2- and 4-day averages of $PM_{2.5}$ predictions, obtained from a geospatial model incorporating AOD observations and surface monitoring $PM_{2.5}$ data, and arrhythmia measured as ventricular ectopy (bigeminy, trigeminy or couplet episodes) (OR of 1.45 (95% CI: 1.08, 1.96) and 1.79 [95% CI: 1.22, 2.59]) (Zanobetti et al., 2014a). Similarly, in a study of nursing home residents with coronary artery disease in Los Angeles, CA, ventricular tachycardia was associated with exposure to $PM_{2.5}$ in the prior 24-hour period [29% higher daily rate (95% CI: 1, 63)] (Bartell et al., 2013). Another measure of ectopy, premature ventricular contractions, was positively associated with 30-minute personal exposures to $PM_{2.5}$ in a large panel of healthy, nonsmoking adults in central Pennsylvania (He et al., 2011). Characteristics of cardiac rate and rhythm including measures of supraventricular or ventricular ectopic runs were also associated with $PM_{2.5}$ exposures in a study conducted in Ottawa, Canada in patients having ECGs for clinical purposes; however, confidence intervals around these associations were large (Cakmak et al., 2014). In addition, Cakmak et al. (2014) reported strong, positive associations with heart block, or the failure of the SA signal to move through the AV node.

Atrial fibrillation has also been examined with $PM_{2.5}$ exposures in a few recent studies. This arrhythmic disorder in the atria can cause symptoms such as fatigue, palpitations, shortness of breath and anxiety. Atrial fibrillation also greatly increase risk for stroke, dementia, congestive heart failure and premature mortality (Kwok et al., 2011; Paquette et al., 2000; Benjamin et al., 1998). As described in the 2009 PM ISA, Rich et al. (2006b) found positive, but imprecise associations between atrial fibrillation and 24-hour $PM_{2.5}$ exposures in a cohort of patients with ICDs. A recent study, also conducted in Boston, MA observed associations between $PM_{2.5}$ over the subsequent 0−24 hours and higher risk of atrial fibrillation in a cohort of patients with ICDs (26% (95% CI: 8, 47), but associations in this study were strongest for subdaily averaging times (e.g., 2 or 6 hours) (Link et al., 2013). This study also found that associations were stronger when analyses were limited to study participants residing within 25 km of the monitoring station compared to those residing within a 50 km radius (Link et al., 2013). Similar results were observed by Liao et al. (2011) in a panel study in Pennsylvania as associations with atrial fibrillation were observed for $PM_{2.5}$ exposures 30 minutes to 2 hours prior. In contrast, other studies examining atrial fibrillation or premature atrial contractions found weak or null associations with 24-hour $PM_{2.5}$ exposures (Cakmak et al., 2014; He et al., 2011).

In summary, there is recent evidence of an association with measures of ectopy and atrial fibrillation with short-term exposure to $PM_{2.5}$.

6.1.4.2.1 Conduction Abnormalities

Electrocardiograms register the electrical activity of the whole heart across time using skin surface electrodes. Depolarization and repolarization of the ventricles occurs during the QT interval. Electrical impulse (i.e., action potential) propagation involves a complex interplay of sodium, potassium and calcium channels. Disturbances in depolarization and repolarization can be measured by QRS width, QT prolongation (or QTc corrected for heart rate) T-wave width and T-wave complexity and are associated with increased risks of ventricular arrhythmias (Castro-Torres et al., 2015).

A limited number of studies was available in the 2009 PM ISA (U.S. EPA, 2009) that considered the association between PM and ECG markers of repolarization. These publications all used the same panel of study participants with ischemic heart disease from Erfurt, Germany and demonstrated associations between higher 5-hour levels of $PM_{2.5}$ and lower T-wave amplitude, higher T-wave complexity and longer QT duration.

A number of additional studies have been published since the 2009 PM ISA that examine associations between short-term $PM_{2.5}$ concentrations and ventricular depolarization and repolarization changes, but there is considerable variability in the ECG endpoints studied and findings across these studies are inconsistent. These results are summarized below and in Table 6-9.

Short-term $PM_{2.5}$ exposure and repolarization disturbances related to QTc prolongation, T-wave amplitude or T-wave width were examined in several studies (Rich et al., 2012; Baja et al., 2010; Hampel et al., 2010; Liao et al., 2010; Zhang et al., 2009). In a large cross-sectional analysis from the national Women's Health Initiative, authors reported associations between $PM_{2.5}$ concentrations (lag 0−2) and a 5% increase in the relative odds of a T-wave abnormality in post-menopausal women in addition to associations with reduced T-wave amplitude (Zhang et al., 2009). However, strong positive associations between $PM_{2.5}$ concentrations averaged over the previous 0−23 hours and T-wave amplitude were reported in a panel study of ischemic heart disease participants from Augsburg, Germany [3.3% increased T-amplitude (95%CI 0.2, 6.3)] (Hampel et al., 2010). Similarly, QTc prolongation, a more well-studied risk marker for ventricular arrhythmias, was associated with 0 to up to 5-day averages of $PM_{2.5}$ concentrations in this panel of MI survivors [e.g., 0.5% (95% CI 0.0, 1.0), 24−47 hour average of $PM_{2.5}$] (Hampel et al., 2010). Positive associations between short-term $PM_{2.5}$ exposure and QTc prolongation were also observed in a panel of healthy adults in Pennsylvania (Liao et al., 2010), but not among adults in Boston, MA (Baja et al., 2010). No associations were observed between $PM_{2.5}$ levels and QTc prolongation or time between T-wave peak and T-wave end in cardiac rehabilitation patients in New York (Rich et al., 2012). Although evidence from recent studies is inconclusive, taken together these studies indicate a potential for cardiac depolarization and repolarization disturbances by $PM_{2.5}$. These disturbances may increase the risk for malignant ventricular arrhythmias that could result in cardiac arrest.

6.1.4.3 Controlled Human Exposure Studies for Arrhythmia and Conduction Abnormalities

In prior reviews, there were a limited number of controlled human exposure studies examining the relationship between short-term $PM_{2.5}$ exposure and ventricular arrhythmia. The 2004 ACQD included one study reporting that healthy adults exposed to $PM_{2.5}$ CAPs displayed no significant changes in ECG (Gong et al., 2000). These results remained consistent when this experiment was repeated with additional subjects exposed to a similar concentration of $PM_{2.5}$ (Gong et al., 2003). However, Gong et al. (2004) did report that ectopic heartbeats (i.e., a type of arrhythmia) increased in healthy subjects, but decreased in COPD subjects.

Recent CHE studies expand our knowledge of the relationship between $PM_{2.5}$ and indicators of possible ventricular arrhythmia. In healthy adults, there was little change and no statistically significant differences in T-wave amplitude (Kusha et al., 2012) or Tp-Te (Sivagangabalan et al., 2011) when exposure to $PM_{2.5}$ CAP was compared to control exposures. In contrast, in the same study, Sivagangabalan et al. (2011) reported QTd dispersion (Max QT interval-Min QT interval) increased ($p = 0.008$) following $PM_{2.5}$ CAP exposure when compared to FA. Moreover, in a double-blind dietary intervention study of healthy middle-aged adults, participants were supplemented with either fish oil or olive oil for 28-days prior to FA (Day 1) and then, CAP exposure (Day 2). Results indicated that the duration of the QTc interval was statistically significantly ($p < 0.05$) increased 20 h after exposure in the olive oil group only. In contrast, relative to FA exposure, Tp-Te was increased significantly ($p < 0.05$) in

the fish oil group only. The authors concluded that fish oil blocked CAP-induced QTc prolongation, but not Tp-Te prolongation (Tong et al., 2012).

Taken together, and similar to the previous review, these more recent CHE studies show some evidence that short-term exposure to $PM_{2.5}$ can result in abnormal electrical activity in the heart. For more information on these recently published studies, see Table 6-10 below.

Table 6-10 Study-specific details from controlled human exposure (CHE) studies of short-term $PM_{2.5}$ exposure and arrhythmia and conduction abnormalities.

Study	Population	Exposure Details	Endpoints Examined
(Tong et al., 2012)	Healthy adults n = 8 M 21 F; 50−72 yr 57.4 ± 1.4	278 ± 19 µg/m^3 CAP for 2 h at rest CAPS from Chapel Hill, NC Effect of 28-day supplementation pre-exposure with fish oil or olive oil	QTc and Tp-Te pre, and 20 h post

(Sivagangabalan et al., 2011)	Healthy adults n = 11 M, 14 F; 18−50 yr	150 µg/m^3 CAP from Toronto	QT and Tp-Te: throughout the exposure

c = corrected for heart rate, CAP = concentrated ambient particle, ECG = electrocardiogram, F = female, M = male, n = number, QT = time interval between from beginning of the Q-wave, to end of the T-wave, SD = standard deviation, Tp-Te = time interval from peak to end of the T-wave.

6.1.4.4 Toxicology Studies for Arrhythmia and Conduction Abnormalities

In the 2009 PM ISA, Wellenius et al. (2006) reported that inhalation of $PM_{2.5}$ decreased incidence of supraventricular arrhythmia in a rat model of acute myocardial infarction. In contrast, Nadziejko et al. (2004) found that in male rats that develop spontaneous arrhythmias, inhalation exposure to $PM_{2.5}$ increased ($p < 0.05$) the frequency of irregular and delayed heart beats.

Since the publication of the 2009 PM ISA, there is additional evidence that short-term exposure to $PM_{2.5}$ can result in conduction abnormalities that may be indicative of arrhythmias. In rats, Ghelfi et al. (2010) reported that short-term exposure to $PM_{2.5}$ significantly increased ($p < 0.05$) *P* wave duration and the RTp interval, while decreasing Tp-Te ($p = 0.02$). Of note, these authors also reported that blocking

synthesis of the hormone angiotensin (see Section 6.1.6.4.1) reversed these effects. Similarly, in SH rats Farraj et al. (2015) reported a statistically significant decrease ($p < 0.05$) in the duration of the PR interval during short-term exposure to $PM_{2.5}$ in summer, but not winter. These authors also demonstrated that short-term exposure to summer but not winter $PM_{2.5}$ increased sensitivity to triggered cardiac arrhythmia.

In contrast to the results presented above, Ghelfi et al. (2010) did not find a statistically significant effect of short-term $PM_{2.5}$ exposure on the QRS complex and Ghelfi et al. (2010) and Farraj et al. (2015) both reported no change in the QT interval in response to short-term exposure to $PM_{2.5}$. In addition, in female mice Kurhanewicz et al. (2014) did not find statistically significant indicators of conduction abnormalities in response to short-term $PM_{2.5}$ exposure.

Taken, the current ISA provides evidence that short-term $PM_{2.5}$ exposure may increase the potential for developing an arrhythmia. Most studies found at least some indication of conduction abnormalities as measured by ECG. There is also some evidence that these conduction abnormalities may be dependent upon the season in which $PM_{2.5}$ was collected. More information on studies published since the 2009 ISA can be found in Table 6-11 below.

Table 6-11 Study-specific details from toxicological studies of short-term $PM_{2.5}$ exposure and arrhythmia and conduction abnormalities.

Study	Study Population	Exposure Details	Endpoints Examined
(Farraj et al., 2015)	Adult SH rats (12 weeks) M, n = 6/group	Inhalation of 168.7 µg/m^3 summer or 78.5 µg/m^3 winter $PM_{2.5}$ CAPs collected from Durham NC. Exposed for 4 h	QTc and PR in the time period immediately post to 6 h post arrhythmia development using aconitine infusion one-day post.
(Ghelfi et al., 2010)	Adult Sprague Dawley rats, n = 80 total	Inhalation of 510 µg/m^3 $PM_{2.5}$ some groups pretreated with valsartan or benazepril Exposed for 5 h	PR, QT, QRS, RTp, Tp-Te, and Pdur measured continuously during exposure
(Kurhanewicz et al., 2014)	Adult, C57BL/6 mice, f, n = 5−8/group	Inhalation of 190 µg/m^3 $PM_{2.5}$ from Research Triangle Park, NC Exposed for 4 days, 4 h/day.	QRS, QTc, *P*-wave, Tp-Te ST, and RT measured continuously pre- to post exposure

c = corrected for heart rate, CAPs = concentrated ambient particles, d = day, ECG = electrocardiogram, F = female, h = hour, M = male, n = number, post = after-exposure, pre = before exposure, Pdur = time interval of a complete *P*-wave, PR = time interval between the beginning of the *P*-wave to the peak of the *R*-wave, QRS = time interval between the beginning of the Q-wave and the peak of the S-wave, QT = time interval between from beginning of the Q-wave, to end of the T-wave, RTp = time interval between the beginning of *R*-wave and peak of the T-wave, SH = spontaneously hypertensive, ST = beginning of S-wave to end of T-wave, Tp-Te = time interval from peak to end of the T-wave.

6.1.5 Cerebrovascular Disease and Stroke

Cerebrovascular disease (CBVD) typically includes conditions classified under ICD10 codes I60−I69 (ICD 9: 430−438) such as hemorrhagic stroke, cerebral infarction (i.e., ischemic stroke) and occlusion of the precerebral and cerebral arteries. Ischemic stroke results from an obstruction within a blood vessel that supplies oxygen to the brain, potentially leading to infarction, and accounts for 87% of all strokes (Goldberger et al., 2008). Hemorrhagic stroke is less common, but results in a disproportionate number of fatalities. The hemorrhagic stroke subtype results from a brain aneurysm or leaking vessel in the brain and can be further categorized by brain region (e.g., intracerebral or subarachnoid). Older age, female sex, smoking, obesity and prior stroke are known risk factors for stroke and should be considered in epidemiologic analysis. Comorbidities that increase stroke risk but may also be associated with $PM_{2.5}$ exposure include hypertension, diabetes and CHD and atrial fibrillation.

In the 2009 PM ISA, inconsistent results were found in several epidemiologic studies that considered the relationship between short-term $PM_{2.5}$ exposure and ED visits and hospital admissions for CBVD. Similarly, results from studies published since the last review for CBVD or all stroke outcomes have been largely inconsistent, with most studies reporting a lack of an association.

6.1.5.1 Emergency Department Visits and Hospital Admissions

The 2009 PM ISA reviewed several epidemiologic studies of short-term $PM_{2.5}$ exposure and ED visits and hospital admissions for CBVD and reported inconsistent results across studies. For example, the U.S. MCAPS study observed a modest increase (0.8% [95% CI: 0.3−1.4%]) in hospital admissions for CBVD (Dominici et al., 2006); however, a multicity study in Australia and New Zealand observed a null association (Barnett et al., 2006). This section first reviews recent studies that have considered all strokes or CBVD as a composite endpoint, and subsequently considers those studies focusing specifically on ischemic or hemorrhagic strokes. Results from recent studies examining CBVD or all stroke outcomes, as well as those examining more specific stroke outcomes, have been largely inconsistent. Study details and results are presented in Table 6-12.

Table 6-12 Epidemiologic studies of short-term $PM_{2.5}$ exposure and cerebrovascular and stroke-related hospital admission and emergency department (ED) visits.

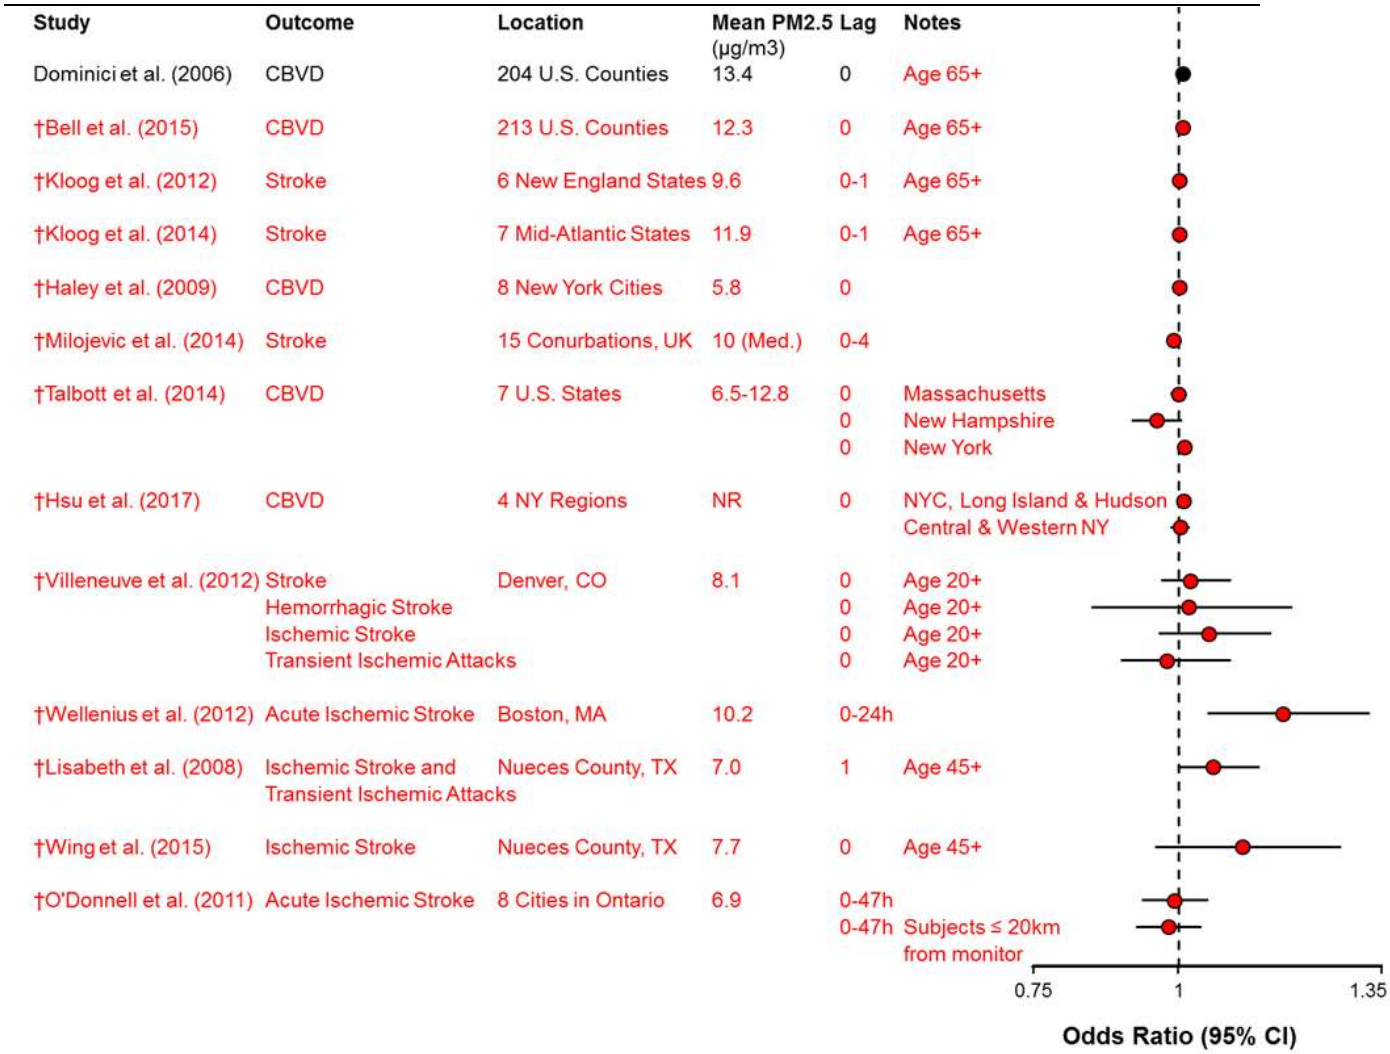
†Studies published since the 2009 PM ISA. For the included epidemiologic studies, the focus is on those studies conducted in areas where mean $PM_{2.5}$ concentrations are <20 µg/m³ or in the case of a multi-city study where more than half of the cities have concentrations <20 µg/m³. Other studies maybe be included if they contribute to evaluating important uncertainties (see Preface).

Recent multicity studies examining the composite endpoint of all strokes or CBVD in relation to short-term $PM_{2.5}$ exposure have generally reported the lack of a positive association, although a few studies have found small but precise associations. The results of Bell et al. (2015) provide modest evidence for a positive association between $PM_{2.5}$ and CBVD in the Medicare study (0.7% [95% CI: 0.3, 1.0%] at lag 0), and are consistent with the results of Dominici et al. (2006), included in the 2009 PM ISA. In contrast, several additional multicity studies primarily observed null or negative associations across study regions using novel $PM_{2.5}$ exposure metrics that combine measured and modeled $PM_{2.5}$ concentrations (Hsu et al., 2017; Kloog et al., 2014; Talbott et al., 2014; Kloog et al., 2012) or measured $PM_{2.5}$ concentrations from monitors (Milojevic et al., 2014; Haley et al., 2009). Positive associations were reported in certain regions of some studies, such as New York state (Talbott et al., 2014) and the New York City metro area (Hsu et al., 2017). Single-city studies in the U.S. and Canada tended to report null associations (Rodopoulou et al., 2015; Kim et al., 2012; Villeneuve et al., 2012). Overall, recent epidemiologic evidence for an association between short-term $PM_{2.5}$ exposure and composite CBVD

endpoints continues to be inconsistent, though studies have generally reported null or low-magnitude associations (Figure 6-5).



Note: †Studies published since the 2009 PM ISA. CBVD = cerebrovascular disease, NR = not reported. Corresponding quantitative results are reported in Supplemental Table S6-7 (U.S. EPA, 2018).

Figure 6-5 Results of studies of short-term $PM_{2.5}$ exposure and hospital admissions and emergency department visits for cerebrovascular disease.

Emergency Department Visits and Hospital Admissions Visits for Stroke Subtypes

Cerebrovascular disease and stroke ED visits and hospital admissions can be further classified as ischemic strokes, hemorrhagic strokes, transient ischemic attacks (TIAs), and a number of other, less

well-defined clinical syndromes resulting from derangements in the cerebral circulation. Studies focused specifically on ischemic stroke have yielded inconsistent results (Figure 6-5). The observed variability in results among these studies may be due to the majority of the studies being conducted in single cities and having smaller sample sizes due to the focus on a more specific outcome. Several U.S. based single-city studies reported positive associations for ischemic stroke in Boston, MA (Wellenius et al., 2012a) and Nueces County, Texas (Wing et al., 2015; Lisabeth et al., 2008). Conversely, other single-city studies have reported null or negative associations in Edmonton, Canada (Chen et al., 2014b; Villeneuve et al., 2012) and southern Israel (Yitshak Sade et al., 2015). Additionally, a null association (OR: 0.99, 95% CI: 0.94, 1.05) was observed in Ontario, Canada (O'Donnell et al., 2011) using data from a stroke registry, which is thought to have reduced outcome misclassification compared to administrative data sets.

Fewer studies have focused specifically on the association between $PM_{2.5}$ and the risk of hemorrhagic stroke, in part because hemorrhagic strokes are much less common than ischemic strokes. Several recent studies provide contrasting results, including null associations observed in small studies in Edmonton, Canada (Villeneuve et al., 2012) and southern Israel (Yitshak Sade et al., 2015). Overall, the recent epidemiologic evidence for an association between short-term $PM_{2.5}$ and various stroke subtypes continues to remain inconsistent and limited.

6.1.6 Blood Pressure and Hypertension

The pressure on blood vessel walls from circulating blood is referred to as BP. Persistently elevated BP is referred to as hypertension. Increases in BP can lead to a number of cardiovascular endpoints including IHD, HF, and arrhythmia (Section 6.1.1). BP is tightly regulated through numerous homeostatic mechanisms including through the renal system (Section 6.1.6.4.1). Thus, in addition to discussing the effect of $PM_{2.5}$ exposure on changes in systolic blood pressure (SBP), diastolic blood pressure (DBP), mean arterial pressure (MAP), and pulse pressure, this section also presents evidence for potential $PM_{2.5}$-induced changes in BP through the renal system.

In the 2009 PM ISA, there were no epidemiologic studies examining the relationship between short-term $PM_{2.5}$ exposure and ED visits and hospital admissions for hypertension. However, there was some evidence from CHE and animal toxicological studies for a relationship between short-term $PM_{2.5}$ exposure and increases in BP.

The evidence relating short-term $PM_{2.5}$ exposure and increases in BP or to hypertension has increased since the last review. Although more recent ED visit and hospital admissions studies for hypertension are largely inconsistent (i.e., some studies show positive associations while others do not), evidence from CHE and animal toxicological studies generally show changes in some measure of BP following short-term $PM_{2.5}$ exposure. Notably, results from animal toxicological studies also suggest that diet and genetics may be influential factors in BP changes following short-term $PM_{2.5}$ exposure (Section 6.1.6.4).

6.1.6.1 Emergency Department Visits and Hospital Admissions

Patients with a primary discharge diagnosis related to hypertension are likely have a documented history of hypertension and present to EDs because they are experiencing asymptomatic blood pressure elevations, severe hypertension accompanied by concerning symptoms, or a hypertension-related emergency (Bender et al., 2006). In interpreting the results of these studies it is important to note that patients experiencing an acute cardiovascular event (e.g., acute coronary event or stroke) would be expected to have a primary discharge diagnosis related to the acute cardiovascular event, even if hypertension was believed to be a proximal cause (Szyszkowicz et al., 2012).

The 2009 PM ISA did not review any epidemiologic studies of ambient $PM_{2.5}$ and ED visits and hospital admissions for hypertension. This section focuses on the few available recent studies providing limited and inconsistent evidence of an association between hypertension and short-term $PM_{2.5}$ exposure (Table 6-13).

CMAQ = Community Multiscale Air Quality Modeling System, CO = carbon monoxide, HR = hazard ratio, max = maximum, NO_2 = nitrogen dioxide, NR = not reported, OR = odds ratio, PM_{10} = particulate matter with mean aerodynamic diameter 10 µm, $PM_{10-2.5}$ = particulate matter with mean aerodynamic diameter between 2.5 µm and 10 µm, $PM_{2.5}$ = particulate matter with mean aerodynamic diameter 2.5 µm, RR = relative risk, SO_2 = sulfur dioxide.

†Studies published since the 2009 PM ISA. For the included epidemiologic studies, the focus is on those studies conducted in areas where mean $PM_{2.5}$ concentrations are <20 µg/m³ or in the case of a multi-city study where more than half of the cities have concentrations <20 µg/m³. Other studies maybe be included if they contribute to evaluating important uncertainties (see Preface).

A study of hypertension ED visits and hospital admissions in New York State using a hybrid method to estimate $PM_{2.5}$ exposure from monitor and modeled data over the years 1991−2006 (Hsu et al., 2017) reported a 1.93% (95% CI: 0.69, 3.18%) increased risk of ED visits on the concurrent day (lag 0) near New York City; however, Hsu et al. (2017) observed no associations in the remaining regions of the state. Hsu et al. (2017) did not present pooled results across the state, but the differing results across the state provide evidence of potential regional heterogeneity in risk estimates. In contrast, a single-city study in Little Rock, Arkansas, reported a negative association for the risk of ED visits (−1.03%, 95% CI: −2.69%, 0.67%; lag 1) (Rodopoulou et al., 2015). The observed association was attenuated but remained negative in a copollutant model adjusting for O_3 (−0.58%, 95% CI: −2.34%, 1.21%; lag 1). Rodopoulou et al. (2015) reported a positive association in the cold season, indicating that a negative association in the warm season is driving the overall results. Similarly, a two-city Canadian study in Edmonton and Calgary observed positive associations in the cold season (Brook and Kousha, 2015). The authors did not report quantitative results for the warm season, but they stated that there were "no statistically significant positive results". In a study in Edmonton, Canada, Szyszkowicz et al. (2012) observed a positive year-round association between short-term $PM_{2.5}$ concentrations and hypertension. Additionally, a single-city study examined emergency calls for hypertensive crisis in Leipzig, Germany across multiple lag periods. Franck et al. (2011) reported generally negative or null associations across lag periods (lag 1 to 7).

In summary, there is limited and inconsistent evidence for a year-round association between short-term $PM_{2.5}$ exposure and ED visits and hospital admissions for hypertension. Studies reported evidence of seasonal differences, with positive associations in the cold season and negative or null associations in the warm season (Brook and Kousha, 2015; Rodopoulou et al., 2015); however, among these studies only Rodopoulou et al. (2015) examined the potential for copollutant confounding, which remains an important limitation for both year-round and seasonal analyses.

6.1.6.2 Panel Epidemiologic Studies of Changes in Blood Pressure (BP)

Studies of short-term $PM_{2.5}$ exposure and blood pressure included in the 2009 PM ISA (U.S. EPA, 2009) were limited in size and number and results were not consistent across studies. While the majority of studies supported associations between $PM_{2.5}$ and higher systolic blood pressure (SBP) and diastolic blood pressure (DBP), other studies reported lower BP or no association. Several studies have since been published investigating associations between short-term $PM_{2.5}$ concentrations and blood pressure, but overall, the recent evidence is similar to that in that last review in providing mixed evidence for associations (Table 6-14).

Since the publication of the 2009 PM ISA, there are a number of quasi-experimental studies available. As noted previously, these studies are advantageous in that they include well-characterized exposures across a range of $PM_{2.5}$ concentrations. Across these studies, results generally did not show associations between short-term $PM_{2.5}$ exposures and changes in SBP or DBP. Kubesch et al. (2014) and Weichenthal et al. (2014a) conducted similar randomized crossover studies with participants exposed for 2 hours to ambient $PM_{2.5}$ in a high or low exposure site. While Kubesch et al. (2014) reported positive associations for BP and $PM_{2.5}$ during the exposure period and up to five hours after, Weichenthal et al. (2014a) reported null associations with $PM_{2.5}$ during the exposure period and SBP or DBP. Chung et al. (2015) similarly observed no associations with BP in a study examining $PM_{2.5}$ from traffic exposures and BP measurements from individuals residing in communities near highways and other residing in urban background locations.

Liu et al. (2014b) and Morishita et al. (2015a) also conducted studies utilizing ambient gradients of $PM_{2.5}$ concentrations by transporting study participants to specific locations to reflect differences in $PM_{2.5}$ concentrations. Liu et al. (2014b) monitored BP during 5-day exposures near a steel mill (daily average $PM_{2.5}$ 11.0 $\mu g/m^3$) and on a college campus (daily average $PM_{2.5}$ 9.4 $\mu g/m^3$), and Morishita et al. (2015a) transported study participants from a rural Michigan community to an urban area over 5 days; neither study reported an association between $PM_{2.5}$ and changes in BP.

The relationship between short-term $PM_{2.5}$ exposures and BP has also been examined in well-established cohorts including the Multi-Ethnic Study of Atherosclerosis (MESA), the Normative Aging Study (NAS), the Detroit Exposure and Aerosol Research Study (DEARS), and the Detroit Healthy Environments Partnership (DHEP) study. While Hicken et al. (2013), Mordukhovich et al.

(2009), and Wilker et al. (2009) did not find associations in participants from the MESA or NAS with 1-hour to 1-month concentrations of $PM_{2.5}$, Dvonch et al. (2009), Hicken et al. (2014), and Brook et al. (2011) found some evidence of a relationship in studies conducted in Detroit. While Brook et al. (2011) and Hicken et al. (2014) found positive associations between SBP and 1-day lag $PM_{2.5}$ concentrations or 48-hour averages, respectively, Dvonch et al. (2009) reported negative associations for SBP. Taken together, results from these panel studies in healthy populations do not provide strong support for a consistent relationship between BP and short-term exposures to $PM_{2.5}$.

In contrast, panel studies including older adult populations report consistent evidence for a relationship between $PM_{2.5}$ and BP, particularly studies including participants living in nursing homes or senior communities, allowing for improved exposure assessment. Jacobs et al. (2012) examined BP in nursing homes residents and found positive associations between 24-hour $PM_{2.5}$ concentrations and SBP, but only in participants on antihypertensive medication. No associations were found for DBP. Liu et al. (2009) and Wellenius et al. (2012b) also examined BP in nursing home residents or community dwelling seniors, respectively, and also reported positive associations between $PM_{2.5}$ and BP. While Liu et al. (2009) found increases in SBP relative to 24-hour $PM_{2.5}$ levels, Wellenius et al. (2012b) reported positive associations for both SBP and DBP across averaging times ranging from 1 to 28 days with the strongest associations for 7 and 14 day averages. In addition to older adult populations, Rich et al. (2012) examined associations between BP and $PM_{2.5}$ exposures in a panel of cardiac rehabilitation patients; positive associations were reported for SBP and the $PM_{2.5}$ levels in the preceding 6 hours.

Recent evidence is similar to that evaluated in the 2009 PM ISA (U.S. EPA, 2009) and studies continue to demonstrate inconsistent results across a variety of study designs. There is, however, some indication of associations between short-term exposures to $PM_{2.5}$ and changes in BP in subpopulations including older adults and individuals with pre-existing cardiovascular disease.

6.1.6.3 Controlled Human Exposure Studies of Changes in Blood Pressure (BP)

Previous work in the 2004 AQCD reported decreased SBP in asthmatics and increased SBP in healthy subjects after exposure to $PM_{2.5}$ CAPS from Los Angeles while exercising (Jr et al., 2003). The same study found no significant change in DBP. In the 2009 PM ISA (U.S. EPA, 2009), a single study associated increases in DBP in healthy adults with $PM_{2.5}$ carbon content, but not with $PM_{2.5}$ mass (Urch et al., 2005). In the previous review, it was suggested that longer follow-up times may be needed after a CHE study to capture a response to slower activated BP control mechanisms. Thus, it is important to note that some of the CHE studies discussed in this review measured for potential changes in BP up to 24-hours post $PM_{2.5}$ exposure.

A few recent CHE studies have expanded our understanding of the relationship between exposure to $PM_{2.5}$ and changes in BP. Bellavia et al. (2013) reported significant elevations in SBP ($p = 0.001$), and an increase in DBP that was not statistically significant in healthy adults after exposure to fine CAP from Toronto, Canada relative to FA. Similarly, Brook et al. (2009) examined the effect of $PM_{2.5}$ CAP exposure on BP in healthy adults in Toronto, Canada. The authors reported that DBP increased linearly during the exposure resulting in a significant 2.9 mm Hg increase (CAPs; $p = 0.002$) upon completion of the exposure. A trend toward elevated SBP with CAP exposure was also reported. Tong et al. (2015) also found an association between $PM_{2.5}$ CAP exposure and BP. Adults in their upper 50s were randomization into either fish oil, olive oil, or naïve groups for a 28-day supplementation period. In the naïve group at 30 min post exposure, DBP increased by 2.1 mm hg relative to filtered-air exposure ($p = 0.04$). This same relative increase was observed 60 min after exposure in the fish oil ($p = 0.008$) and olive oil ($p = 0.03$) supplemented groups. Increases in SBP that were not statistically significant were also reported in all treatment groups.

In contrast to the studies described above, Lucking et al. (2011) found no differences in BP post DE, particle filtered DE, or FA exposure in healthy men. Similarly, in older overweight, but healthy participants, Hemmingsen et al. (2015b) found no significant changes in BP after exposure to filtered, or nonfiltered traffic related air pollution (TRAP) from Copenhagen, Denmark using a relatively low $PM_{2.5}$ exposure concentration (Table 6-15). Direct changes in blood pressure were also not reported in the FILTER-HF CHE study (Vieira et al., 2016b). This study tested whether introducing a respiratory filter could attenuate the cardiovascular effects of acute DE-exposure in patients with HF, or in healthy individuals. When the FILTER-HF patients and healthy controls exercised for 6 minutes, BP increased with exercise but there were no statistically significant differences with DE exposure with or without filtration, although it was noted that assessing changes in blood pressure in the HF group is difficult given beta-blocker use.

A few CHE studies in the current review indicate that $PM_{2.5}$ CAP has an effect on BP. However, these studies are not entirely consistent with respect to reporting changes in SBP versus DBP. That being said, it is notable that in studies where increases in one measure of BP (e.g., SBP), but not the other (e.g., DBP) was found to be statistically significant, that other measure of BP usually trended toward statistical significance. There is also some evidence that changes in blood pressure may be associated with the endotoxin present in the PM samples (Zhong et al., 2015). Taken as a whole, there is some evidence that short-term $PM_{2.5}$ exposure can result in changes in blood pressure following CAPS but not DE exposure. More information on studies published since the 2009 ISA can be found in Table 6-15 below.

Table 6-15 Study-specific details from CHE studies of short-term $PM_{2.5}$ exposure and BP.

6.1.6.4 Toxicological Studies of Changes in Blood Pressure (BP)

In the 2009 PM ISA, studies generally reported an increase in some measure of BP following short-term $PM_{2.5}$ exposure to CAPs (Bartoli et al., 2009; Ito et al., 2008; Chang et al., 2004). Since the publication of the 2009 PM ISA, Wagner et al. (2014b) reported statistically significant changes ($p < 0.05$) in SBP, DBP, and MAP in SH rats in three of four independent experiments compared to control animals. In an earlier study, this group similarly reported that Sprague Dawley rats with cardio-metabolic syndrome fed a high fructose diet had a statistically significant decrease ($p < 0.05$) in SBP, DBP and MAP during $PM_{2.5}$ exposure relative to control exposed animals (Wagner et al., 2014a). More information on studies published since the 2009 ISA can be found in Table 6-16 below.

Table 6-16 Study specific details from toxicological studies of short-term $PM_{2.5}$ exposure and blood pressure (BP).

Study	Study Population	Exposure Details	Endpoints Examined
(Wagner et al., 2014b)	Adult SH rats, M, n = 8/treatment group	Inhalation of $PM_{2.5}$ CAPs from Dearborn, MI collected in summer, four independent experiments $PM_{2.5}$ concentrations were 415 ± 99; 642 ± 294; 767 ± 256; and 364 ± 58 $\mu g/m^3$ respectively., 8 h/day for 4 days to air or CAPs.	BP during exposure
(Wagner et al., 2014a)	Adult Sprague-Dawley rats, M, n = 4−8 per treatment group, fed either a normal diet or a high-fructose diet. BP = blood pressure, CAP = concentrated ambient particle, h = hour, M = male, n = number, week = week.

6.1.6.4.1 Renin-Angiotensin System

Renin is secreted by the juxtaglomerular apparatus of the kidney and converts angiotensinogen to angiotensin 1 (Ang1). In the lung, kidney, and vascular endothelium, angiotensin-converting enzyme (Ace) cleaves Ang1 to release AngII. AngII can bind the angiotensin type 1 receptor (At1r) and causes vasoconstriction and a subsequent increase in blood pressure. It can also stimulate the release of aldosterone, which also increases blood pressure. Given this direct link between changes in the renin-angiotensin system and increases in blood pressure, the effect of short-term $PM_{2.5}$ inhalation on this system was evaluated.

The 2009 ISA for PM included no short-term studies on the renin-angiotensin system following short-term exposure to $PM_{2.5}$ CAPS. Since the 2009 PM ISA, a study in rats has demonstrated that short-term exposure to $PM_{2.5}$ increased ($p < 0.05$) plasma Ang II levels (Ghelfi et al., 2010). In an additional study, Aztatzi-Aguilar et al. (2015) found a statistically significant increase ($p < 0.05$) in At1r, but not Ace mRNA in the heart. These authors also found a statistically significant increase ($p < 0.05$) in mRNA expression of the receptor B1r in the heart; this is interesting given that increases in this receptor are indicative of vasodilation rather than vasoconstriction. Taken together, there is some evidence that short-term $PM_{2.5}$ exposure can lead to changes in multiple pathways involved in the regulation of vasoconstriction/vasodilation, and thus, blood pressure. More information on studies published since the 2009 ISA can be found in Table 6-17 below. In summary, studies published since the conclusion of the 2009 PM ISA with respect to changes in BP measurements and the renin-angiotensin system provide some additional evidence that short-term exposure to $PM_{2.5}$ can result in changes in BP. These studies

also provide some evidence that genetic or dietary factor may influence the effect of $PM_{2.5}$ exposure on BP.

Table 6-17 Study-specific details from animal toxicological studies of the renin-angiotensin system.

Study	Study Population	Exposure Details	Endpoints Examined
(Ghelfi et al., 2010)	Adult Sprague Dawley rats, n = 80 total	Inhalation of 390 µg/m^3 $PM_{2.5}$ some groups pretreated with valsartan or benazepril 5 h exposure	Plasma angiotensin II immediately post
(Aztatzi-Aguilar et al., 2015)	Adult Sprague-Dawley rats, m, n = 4 per treatment group	Inhalation of 178 µg/m^3 $PM_{2.5}$ for 5 h/day for 3 days from a high traffic and industrial area north of Mexico City in early summer	Angiotensin and bradykinin system gene expression in heart tissue collected 24 h post

CAPs = concentrated ambient particles, d = day, h = hour, m = male, n = number, post = after-exposure.

6.1.7 Peripheral Vascular Disease, Venous Thromboembolism, Pulmonary Embolism

Thrombosis refers to the formation of a blood clot inside a blood vessel, while a blood clot that breaks free and travels from its initial site of formation is known as an embolus. This mass can then become lodged and occlude blood flow, thus resulting in an embolism. Thrombi typically form in the deep (i.e., popliteal, femoral, iliac) veins of the lower extremities and can give rise to emboli that lodge in the pulmonary arteries. These deep vein thromboses (DVTs) and pulmonary emboli (PE) are the most common subtypes of venous thromboembolism (VTE).

In the 2009 PM ISA, there were two hospital admission studies looking at the relationship between short-term $PM_{2.5}$ exposure and PVD. One of these studies found a positive association between hospital admissions for PVD and short-term $PM_{2.5}$ exposure while the other study observed a negative association. Thus, there was only limited evidence of an association between $PM_{2.5}$ exposure and PVD hospital admissions in the last review.

Some epidemiologic studies published since the 2009 PM ISA provide additional evidence that short-term $PM_{2.5}$ exposures may be associated with increased risk of hospital admissions for PVD. However, considerable uncertainties remain with respect to the potential for copollutant confounding given that copollutant analyses were generally lacking in these studies. That being said, the lack of copollutant analyses in epidemiologic studies is at least partially mitigated by CHE and animal toxicological studies that provide biological plausibility for these associations by demonstrating changes

in hemodynamics (e.g., an increase in coagulation factors) following short-term $PM_{2.5}$ exposure (Section 6.2.1). Nonetheless, the relationship between ED visit and hospital admissions studies for PVD and short-term $PM_{2.5}$ exposure is still considered to be uncertain.

6.1.7.1 Emergency Department (ED) Visits and Hospital Admission

The 2009 PM ISA reviewed a limited number of studies examining the association between $PM_{2.5}$ and peripheral vascular disease (PVD). The MCAPS study among U.S. Medicare beneficiaries by Dominici et al. (2006) reported a positive association between hospital admissions for PVD and $PM_{2.5}$ concentrations on the same day (lag 0). Conversely, a single-city study in Toronto observed a negative association between PVD and $PM_{2.5}$ (Burnett et al., 1999). Several recent studies evaluating $PM_{2.5}$ exposure and PVD, venous thromboembolism (VTE), pulmonary embolism, and deep vein thrombosis are now available, and provide emerging evidence that $PM_{2.5}$ may be associated with specific forms of PVD, but there is still a limited evidence base (Table 6-18).

Table 6-18 Epidemiologic studies of short-term $PM_{2.5}$ concentrations and hospital admission and emergency department visits for peripheral vascular disease.

†Studies published since the 2009 PM ISA.

For the included epidemiologic studies, the focus is on those studies conducted in areas where mean $PM_{2.5}$ concentrations are <20 $\mu g/m^3$ or in the case of a multi-city study where more than half of the cities have concentrations <20 $\mu g/m^3$. Other studies maybe be included if they contribute to evaluating important uncertainties (see Preface).

Bell et al. (2015) considered PVD hospital admissions among U.S. Medicare beneficiaries in 140 U.S. counties. The authors observed a 1.26% (95% CI: 0.48, 2.05%) increase in hospital admissions associated with $PM_{2.5}$ concentrations on the same day (lag 0). This association was consistent with the results of the Dominici et al. (2006) MCAPS study reviewed in the 2009 PM ISA, and also a recent Medicare-based study in eight New York cities (Haley et al., 2009). A study of 7 U.S. states also reported an association in New York and in New Jersey, but did not observe an association in five other participating states (Talbott et al., 2014).

In addition to studies evaluating the association between $PM_{2.5}$ and PVD, a few recent studies specifically evaluated VTE, and related outcomes of deep vein and pulmonary embolism. With regard to VTE, studies reported inconsistent results. In Santiago, Chile, Dales et al. (2010) observed a positive association between hospital admissions for VTE and $PM_{2.5}$ concentrations at lag 0−1 (OR: 1.02 [95% CI: 1.01, 1.03]). However, a U.S. Women's Health Initiative study did not report evidence of a positive association (Shih et al., 2011).

Studies examining deep vein thrombosis and pulmonary embolism provide inconsistent evidence of an association. In a study of Medicare beneficiaries in the northeastern U.S. using spatiotemporal monitoring that incorporates land use variables and AOD to estimate $PM_{2.5}$ concentrations, Kloog et al. (2015) observed that $PM_{2.5}$ concentrations were associated with a 0.59% (95% CI: 0.07, 1.11%) higher risk of pulmonary embolism at lag 0−2 and a 0.64% (95% CI: 0.03, 1.25%) higher risk of hospital admissions for deep vein thrombosis at lag 0−1. In Santiago, Chile, Dales et al. (2010) also observed an association between $PM_{2.5}$ and pulmonary embolism. On the other hand, in a large study from England and Wales, (Milojevic et al., 2014) reported a decrease in risk of hospital admissions for pulmonary embolism at lag 0−4 (−4.11%, 95% CI: −7.29, −0.71%).

In summary, there is limited, but generally consistent evidence that short-term $PM_{2.5}$ exposure is associated with increased hospital admissions for PVD. However, the number of studies available for review is still limited and considerable uncertainties remain. Specifically, none of the reviewed studies evaluated potential copollutant confounding. Evidence regarding specific forms of PVD (i.e., VTE, deep vein thrombosis, and pulmonary embolism) is inconsistent and insufficient to determine the presence of an association.

6.1.8 Emergency Department Visits and Hospital Admission Studies of Combined Cardiovascular-Related Effects

In addition to individual cardiovascular diseases, epidemiologic studies examined cardiovascular diseases in aggregate where, in some cases, the aggregate represented all cardiovascular diseases while, in others, a specific combination of cardiovascular diseases was represented. For example, many epidemiologic studies consider hospital admissions and ED visits for combined cardiovascular-related effects, including diseases of the circulatory system. This endpoint encompasses ED visits and hospital admissions for ischemic heart disease, MI, PVD, heart failure, arrhythmia, CBVD and stroke, and diseases of pulmonary circulation. Fewer studies examine the endpoint of cardiac diseases, a subset of CVD that excludes hospitalizations for cerebrovascular disease, peripheral vascular disease, and other circulatory diseases not involving the heart or coronary circulation. The 2004 PM AQCD discussed time-series studies examining the association between ambient $PM_{2.5}$ concentrations and CVD ED visits and HA. The 2009 PM ISA further reviewed studies providing strong evidence of an association from multicity studies of adults ages 65 years and older (Bell et al., 2008; Host et al., 2008; Barnett et al.,

2006). A number of single-city studies also generally supported the presence of an association between $PM_{2.5}$ and CVD ED visits and HA. Recent studies tend to focus on overall CVD visits and continue to add to the available evidence supporting the presence of an association of daily changes in $PM_{2.5}$ with ED visits and hospital admissions for CVD. Study details and results are presented in Table 6-19.

Table 6-19 Epidemiologic studies of short-term $PM_{2.5}$ concentrations and cardiovascular-related hospital admission and emergency department (ED) visits.

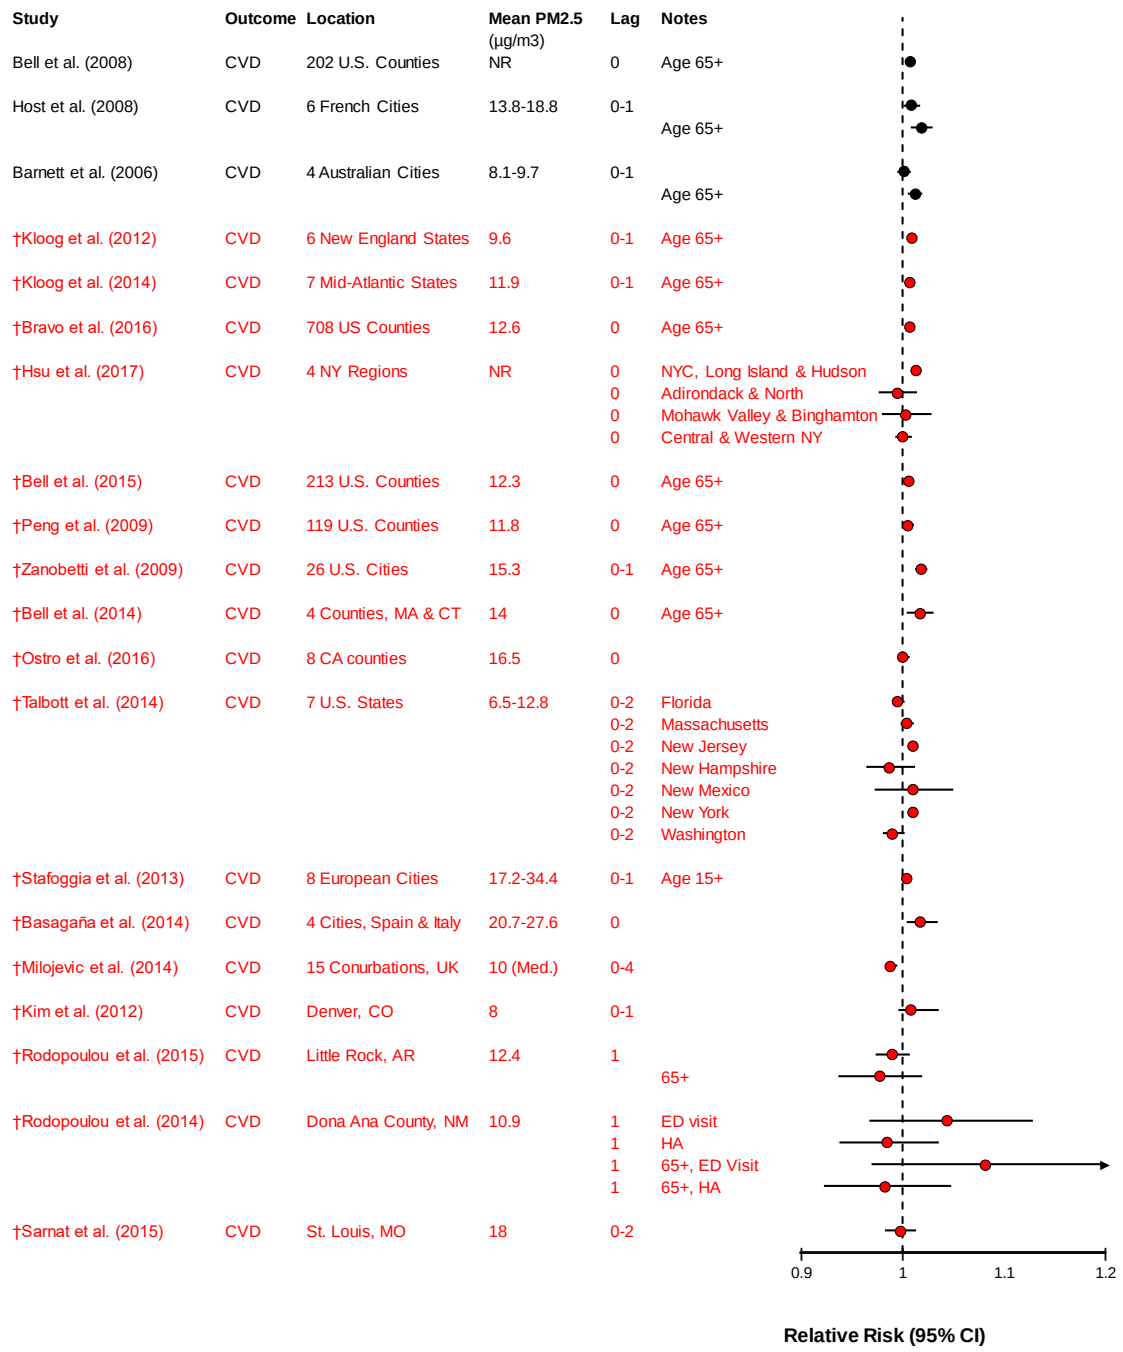
CMAQ = Community Multiscale Air Quality Modeling System, CVD = cardiovascular disease, CO = carbon monoxide, HR = hazard ratio, max = maximum, NR = not reported, NO_2 = nitrogen dioxide, OR = odds ratio, PM^{10} = particulate matter with mean aerodynamic diameter 10 µm, $PM_{10-2.5}$ = particulate matter with mean aerodynamic diameter between 2.5 µm and 10 µm, $PM_{2.5}$ = particulate matter with mean aerodynamic diameter 2.5 µm, RR = relative risk, SO_2 = sulfur dioxide.

For the included epidemiologic studies, the focus is on those studies conducted in areas where mean $PM_{2.5}$ concentrations are <20 µg/m^3 or in the case of a multi-city study where more than half of the cities have concentrations <20 µg/m^3. Other studies maybe be included if they contribute to evaluating important uncertainties (see Preface).

†Studies published since the 2009 PM ISA.

Epidemiologic studies that examined the effect of $PM_{2.5}$ on CVD ED visits and hospital admissions generally observed evidence of consistent positive associations. Several recent multicity studies in the U.S. and Europe provide additional support for positive associations between short-term $PM_{2.5}$ exposure and CVD ED visits and hospital admissions (Figure 6-6). While most studies of ED visits and hospital admissions rely on fixed-site monitoring, several recent studies assigned $PM_{2.5}$ exposure using spatiotemporal models of $PM_{2.5}$ concentration incorporating land use variables, AOD observations, and surface measurements. Studies utilizing Medicare hospital admissions in the Northeast and Mid-Atlantic reported a 1.03% (95% CI: 0.69, 1.45%) and 0.78% (95% CI: 0.54, 1.01%) increase in CVD

admissions over the previous two days (lag 0−1), respectively (Kloog et al., 2014; Kloog et al., 2012). A similar study of 708 urban and rural U.S. counties also reported a 0.79% (95% CI: 0.62, 0.97%) increased risk of CVD-related hospital admissions associated with $PM_{2.5}$ exposure over the previous two days (Bravo et al., 2017). Additionally, a study of seven U.S. states reported positive associations in Massachusetts, New Jersey, and New York, but did not observe a positive association in the other four states (Talbott et al., 2014), while a study of New York state observed a positive association near New York City at lag 0, but nulls results across the remaining regions of the state (Hsu et al., 2017).



Note: †Studies published since the 2009 PM ISA. CVD = cardiovascular disease, NR = not reported. Corresponding quantitative results are reported in Supplemental Table S6-8 (U.S. EPA, 2018).

Figure 6-6 Results of studies of short-term $PM_{2.5}$ exposure and hospital admissions and emergency department visits for cardiovascular-related effects.

There have been a number of recent multicity studies in the U.S. using $PM_{2.5}$ concentrations measured from single monitors or averaged across monitors to assign $PM_{2.5}$ exposure. The majority of these studies examined Medicare populations in cities across the U.S. Studies utilizing Medicare hospital admissions records for CVD in 213 (Bell et al., 2015), 119 (Peng et al., 2009), and 26 (Zanobetti et al., 2009) geographically diverse U.S. counties all reported increases in risk ranging from 0.6% to 1.9% (Figure 6-6). A Medicare study in four Northeastern counties also observed evidence of a positive association (Bell et al., 2014). In non-Medicare populations, a study of eight California counties reported a positive increase in risk with $PM_{2.5}$ at lag 2 (0.61%, 95% CI: −0.18%, 1.49%) (Ostro et al., 2016).

Multicity studies in Europe also provide generally consistent evidence of a positive association between short-term $PM_{2.5}$ exposure and cardiovascular-related ED visits and HA. The MED-PARTICLES study performed in eight southern European cities reported a 0.51% (95% CI: 0.12%, 0.90%) higher rate of cardiovascular-related hospital admissions for $PM_{2.5}$ concentrations averaged over the same and previous days (lag 0−1) (Stafoggia et al., 2013b). A four-city MED-PARTICLES study in Spain and Italy also observed a positive, but less precise (i.e., wider 95% CIs) association between $PM_{2.5}$ exposure and cardiovascular-related hospital admissions (1.18%, 95% CI: 0.32%, 2.04%) (Basagaña et al., 2015). On the other hand, Milojevic et al. (2014) considered cardiovascular-related hospital admissions in England and Wales and reported a negative association for PM2.5 concentrations at lag 0−4. Results from a number of single-city studies tended to be inconsistent, likely due to their generally smaller sample size and focus on a single location (Sarnat et al., 2015; Rodopoulou et al., 2014; Kim et al., 2012; Ito et al., 2011; Lall et al., 2011).

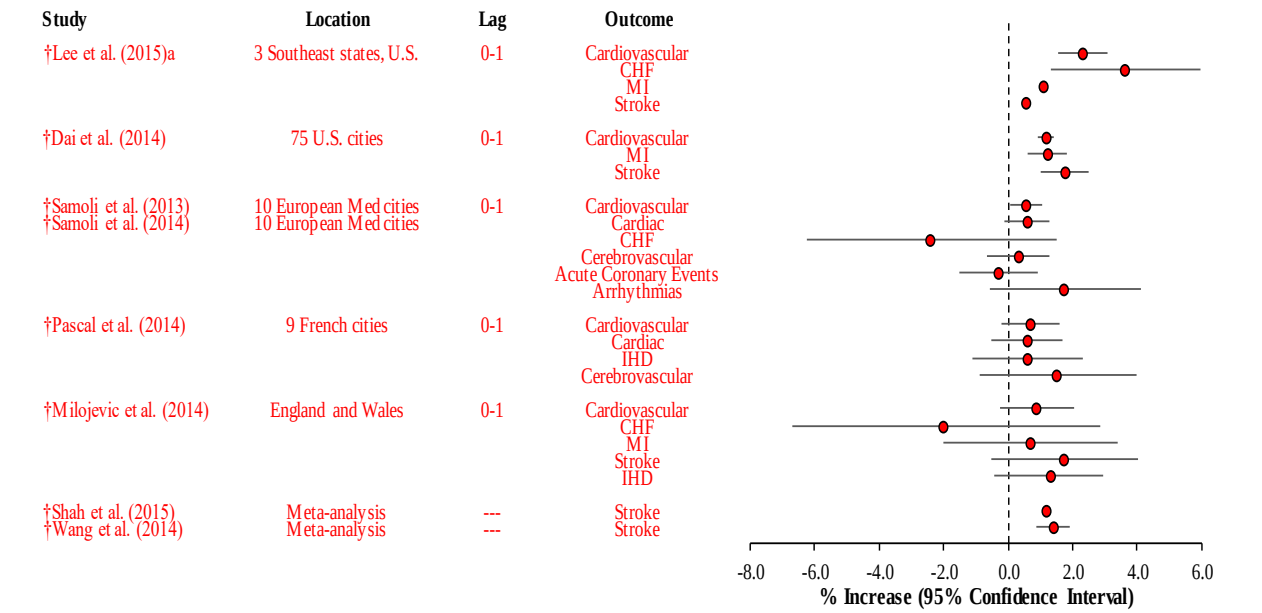
In summary, recent studies continue to provide evidence of a positive association between $PM_{2.5}$ exposure and cardiovascular-related ED visits and HA. Evidence of this association is provided by a number of multicity studies conducted across the U.S. and Europe. Single-city studies offer less consistent evidence.

6.1.9 Epidemiologic Studies of Cardiovascular Mortality

Studies that examine the association between short-term $PM_{2.5}$ exposure and cause-specific mortality outcomes, such as cardiovascular mortality, provide additional evidence for $PM_{2.5}$-related cardiovascular effects, specifically whether there is evidence of an overall continuum of effects. The multicity epidemiologic studies evaluated in the 2009 PM ISA provided evidence of consistent positive associations, ranging from 0.47–0.94% for a 10 $\mu g/m^3$ increase in 24-hour average $PM_{2.5}$ concentrations, between short-term $PM_{2.5}$ exposure and cardiovascular mortality (U.S. EPA, 2009). Across studies, the $PM_{2.5}$ effect on cardiovascular mortality was observed to be immediate with associations occurring in the range of lag 0 to 1 day(s). A limitation within the evidence was that multicity studies did not extensively examine potential copollutant confounding, but evidence from single city studies suggested that the $PM_{2.5}$-cardiovascular mortality relationship was not confounded by gaseous copollutants. In addition,

evidence from animal toxicological and controlled human exposure studies provided coherence and biological plausibility for the $PM_{2.5}$-related cardiovascular mortality associations reported in epidemiologic studies (U.S. EPA, 2009).

Recent multicity epidemiologic studies provide additional evidence of consistent positive associations between short-term $PM_{2.5}$ exposure and cardiovascular mortality at lags consistent with the 2009 PM ISA (i.e., lags 0 to 1 day) (Figure 6-7). Unlike the studies evaluated in the 2009 PM ISA, some recent studies have also further evaluated the $PM_{2.5}$-cardiovascular mortality relationship by examining cause-specific cardiovascular mortality outcomes (e.g., stroke, heart failure) (Figure 6-7). Across multicity studies there is evidence of a positive association for some of these cardiovascular mortality outcomes; however, the overall evidence is not as consistent as that observed when examining all cardiovascular mortality as detailed in Figure 6-7. This pattern of associations across cardiovascular mortality outcomes is also reflected in a single-city study conducted in Pittsburgh, PA that focused only on copollutant models including O_3 (i.e., authors did not report results of single pollutant models), but reported mean $PM_{2.5}$ concentrations similar to those observed in the multicity studies (i.e., 13.9 $\mu g/m^3$) (Dabass et al., 2016a). The difference in results across cardiovascular mortality outcomes can likely be attributed to the smaller number of mortality events observed when examining some cause-specific cardiovascular mortality outcomes, which results in unstable estimates with larger uncertainty. As a result, those studies included in the discussion of policy-relevant considerations in Section 6.1.14, specifically potential copollutant confounding, lag structure of associations, and effect modification by season and temperature focus on the combination of all cardiovascular mortality outcomes.



Note: †Studies published since the 2009 PM ISA. CHF = congestive heart failure; MI = myocardial infarction; IHD = ischemic heart disease. a = Lee et al. (2015b) did not provide 95% confidence intervals for the MI and stroke results. Corresponding quantitative results are reported in Supplemental Table S6-9(U.S. EPA, 2018).

Figure 6-7 Percent increase in cause-specific cardiovascular mortality outcomes for a 10 μg/m^3 increase in 24-hour average $PM_{2.5}$ concentrations observed in multicity studies and meta-analyses.

6.1.10 Heart Rate (HR) and Heart Rate Variability (HRV)

Heart rate (HR), a key prognostic indicator, is modulated at the sinoatrial node of the heart by both parasympathetic and sympathetic branches of the autonomic nervous system. In general, increased sympathetic activation increases HR, while enhanced activation of parasympathetic, vagal tone, decreases HR, but HR does not, however, provide direct information on the relative contribution of each arm of the autonomic nervous system (Lahiri et al., 2008). Heart rate variability (HRV) represents the degree of difference in the inter-beat intervals of successive heartbeats and is an indicator of the relative balance of sympathetic and parasympathetic tone to the heart and their interaction (Rowan III et al., 2007). Low HRV is associated with an increased risk of cardiac arrhythmia (Corey et al., 2006) and an increased risk of mortality in people with previous myocardial infarction (Fauchier et al., 2004; Bigger et al., 1992),). In general, the two most common ways for measuring HRV are time domain measures of variability and frequency domain analysis of the power spectrum. With respect to time domain measures, the standard deviation of NN intervals (i.e., normal-to-normal or the interval between consecutive normal beats; SDNN) reflects total heart rate variability and root mean square of successive differences in NN intervals (rMSSD) reflect parasympathetic influence on the heart. In terms of frequency domain, high frequency (HF) domain is widely thought to reflect cardiac parasympathetic activity while the low frequency (LF) domain has been posited as an indicator of the interaction of the sympathetic and parasympathetic

nervous systems (Billman, 2013)although its linkage with sympathetic tone is controversial and uncertain (Notarius et al., 1999).

In the 2009 PM ISA (U.S. EPA, 2009), numerous epidemiologic panel studies observed positive associations between short-term $PM_{2.5}$ and changes in HRV indices. Some studies also reported stronger HRV decreases in individuals with pre-existing disease. In addition, CHE studies reported changes in HRV following $PM_{2.5}$ exposures more consistently in older adults.

Since the publication of the 2009 PM ISA, there have been a number of studies across disciplines indicating a relationship between short-term exposure to $PM_{2.5}$ and changes in HRV. A number of epidemiologic panel studies using quasi-experimental designs suggest that short-term exposure to $PM_{2.5}$ can elicit a change in HRV. In agreement with these panel studies is limited evidence from CHE studies reporting a shift toward sympathetic predominance following exposure to $PM_{2.5}$. Finally, there is also limited evidence for $PM_{2.5}$ effects on HRV that may be modified by seasonal/dietary/genetic factors from animal toxicological studies. Thus, in the current review there is additional evidence across disciplines that short-term exposure to $PM_{2.5}$, can lead to changes in HRV.

With respect to HR, in the current review epidemiologic panel studies generally reported inconsistent results across a handful of studies. That is, while some studies showed a change in HR following short-term exposure to $PM_{2.5}$, other panel studies did not. In addition, there was no evidence of changes in HR from CHE studies, but some evidence from animal toxicological studies indicating that short-term $PM_{2.5}$ exposure can result in changes in HR. Taken together, evidence for changes in HR in response to short-term $PM_{2.5}$ exposure is considered to be limited across disciplines.

6.1.10.1 Epidemiologic Panel Studies of Heart Rate (HR) and Heart Rate Variability (HRV)

The epidemiologic panel study evidence in the 2009 PM ISA (U.S. EPA, 2009) included numerous studies that observed associations between short-term $PM_{2.5}$ concentrations over hours to days and decreases in HRV (Table 6-20). Most of the studies reported associations between higher concentrations of $PM_{2.5}$ averaged over 24−48 hours and lower SDNN, rMSSD and HF. Some studies also reported stronger HRV decreases among individuals with pre-existing diabetes, glucose intolerance, ischemic heart disease, or hypertension and in subgroups defined by genetic polymorphisms in oxidative stress related genes, lower intake of dietary methyl nutrients and genetic polymorphisms of methionine metabolism and chronic lead exposure. The $PM_{2.5}$ associations with HRV were less marked in individuals on prescription beta-blocker medication or those who reported taking omega-3-fatty acid supplements. There were no epidemiologic panel studies that examined HR evaluated in the 2009 PM ISA.

Several panel studies published since the last review demonstrate the potential for $PM_{2.5}$ exposures to elicit a rapid change in HRV. These studies used quasi-experimental designs to evaluate the

relationship between HRV indices and well-defined $PM_{2.5}$ exposures primarily related to traffic. Weichenthal et al. (2014a) specifically evaluated effects related to 2-hour exposures in high and low traffic settings and found that time-domain measures of HRV (rMSSD and pNN50) were reduced in the 3 hours following exposures, but estimates for SDNN, LF, HF, and LF/HF were imprecise (i.e., wide confidence intervals around effect estimates). Another study evaluating traffic exposures monitored participants over the course of a day and examined 5-minute HRV measures relative to concurrent and up to very short lags of $PM_{2.5}$ concentrations with consideration of time spent commuting. In this study, (Hampel et al., 2014) observed consistent decreases in rMSSD and SDNN with concurrent and up to 30-minute lags of ambient $PM_{2.5}$ concentrations in nontraffic environments (−1.03% change in SDNN 95%CI (−1.61, −0.44); −1.37% change in rMSSD 95%CI (−2.03, −0.72) per 5.4 µg/m3, 15−19-minute lag), but generally found increases in SDNN with $PM_{2.5}$ concentrations during traffic exposures and varied estimates for rMSSD. Nyhan et al. (2014) and Liu et al. (2015b) conducted studies examining HRV in young healthy participants during different modes of commuting (e.g., subway, bus, cars, walking, cycling); however, results from these studies were not consistent. While Nyhan et al. (2014) did not observe associations between SDNN or rMSSD and ambient $PM_{2.5}$ concentrations, Liu et al. (2015b) reported consistent decreases in SDNN and rMSSD with increases in $PM_{2.5}$ concentrations for all commuters, with the strongest associations for walking commutes.

In two related studies, Brook et al. (2013b) and Morishita et al. (2015a) examined exposures to traffic-related $PM_{2.5}$ in Detroit. In both of these studies, 25 healthy rural residents in Michigan were transported to urban locations on a daily basis under controlled conditions so as to minimize ambient exposures for 5 consecutive days for 4−5 hours. 5-day averaged $PM_{2.5}$ exposures measured at home residence and the urban site were associated with 13 ms lower SDNN (95% CI: −25, −0.9) in the first published study (Brook et al., 2013b) whereas nonsignificant estimates were reported for same-day averaged $PM_{2.5}$ in a second publication (Morishita et al., 2015a).

Other recently available studies focused on associations between $PM_{2.5}$ exposure and changes in HRV in specific subpopulations, including those with pre-existing cardiovascular disease and older adults. Zanobetti et al. (2010) found decreases in rMSSD and HF with increases in PM averaged over 30 minutes up to five days in adults with ischemic heart disease. Furthermore, this study observed even larger reductions with traffic exposures in the two hours preceding HRV measures [−15.2% RMSSD (95% CI: −24.8, −4.4); −39.2% HF (95% CI: −58.0, −12.0)]. While Schneider et al. (2010) also found evidence for reductions in rMSSD and pNN50 with increasing $PM_{2.5}$ concentrations [−3.75% rMSSD (95% CI: −7.98, 0.68); −10.20% pNN50 (95% CI: −21.47, 0.25)], other studies conducted in panels with pre-existing cardiovascular disease did not find associations between $PM_{2.5}$ and SDNN, rMSSD, or pNN50 for averaging periods ranging from 1-hour up to 5-days (Bartell et al., 2013; Rich et al., 2012). In a panel of individuals with diabetes or glucose intolerance in Augsburg, very short averaging periods calculated from fixed-site monitors including concurrent time of ECG recording up to 6-hour lags of hourly averages were associated with 2−5% lower SDNN per 12.3 µg/m3 $PM_{2.5}$. Concurrent $PM_{2.5}$ was also associated with 7% lower rMSSD (95% CI: −12, −2) (Hampel et al., 2012). In a follow-up analysis, a

3.3% lower SDNN (95% CI: −5.8, −0.7) and 6.9% lower rMSSD (95% CI: −11.7, −1.7) were associated with 1-hour averages $PM_{2.5}$ per 12.3 µg/m3 (Peters et al., 2015).

HRV has also been examined in studies conducted with well-established cohorts including the MESA and the NAS. In the MESA, the strongest associations for HRV were reported between 2-day average $PM_{2.5}$ and reductions in rMSSD in repeated 10 second ECGs [−2.06% rMSSD (95% CI: −4.02, 0.0)] (Park et al., 2010). Similar associations were observed for SDNN (Park et al., 2010). Consistent with these results, the NAS used 7 minute ECGs and reported reductions in SDNN, LF, and HF [−3.8% (95% CI: −0.2, −7.4), −7.8% (95% CI: −0.4, −15.3), and −10.6% (95% CI: −1.8, −19.4)] for 2-day $PM_{2.5}$ exposures (Ren et al., 2010).

Changes in HR related to short-term exposures to $PM_{2.5}$ were generally inconsistent across the studies examining associations. While Lee et al. (2014) found decreases in HR associated with increases in 1-day lag $PM_{2.5}$ concentrations, Liu et al. (2009) found increases in HR with increasing 24-hour $PM_{2.5}$ concentrations. Increases in HR were also observed in a panel of adults with personal monitoring in Detroit relative to 1−10 hour averages of $PM_{2.5}$ exposure, but no associations were observed for 10−20 hour averages of $PM_{2.5}$ exposure or for a 1-day lag (Brook et al., 2011; Brook et al., 2010b). Morishita et al. (2015a) reported positive associations between HR and $PM_{2.5}$ in a quasi-experimental study in healthy adults transported to an urban exposure site for 5 consecutive days.

6.1.10.2 Controlled Human Exposure Studies of Heart Rate (HR) and Heart Rate Variability (HRV)

In the 2009 PM ISA, a study examined healthy adults and adults with asthma exposed for two hours to $PM_{2.5}$ (Jr et al., 2003) and found significant increases in HR in both groups. With respect to HRV, in the 2009 PM ISA decreases in HRV in response to short-term $PM_{2.5}$ exposure were observed more consistently in CHE studies of older adults (Gong et al., 2004; Devlin et al., 2003).

Since the 2009 PM ISA, a few CHE studies have examined the effect of $PM_{2.5}$ on HR. Sivagangabalan et al. (2011) and Brook et al. (2009) reported that exposure to $PM_{2.5}$ CAP did not result in a significant difference in HR relative to FA. Similarly, in heart failure patients and healthy subjects, the FILTER-HF study indicated that HR was not significantly changed with exposure to DE or filtered DE when compared to clean air exposure. When the FILTER-HF patients exercised for 6 minutes, heart rate increased with exercise, but there were no significant differences with air pollution exposure with or without filtration (Vieira et al., 2016b).

Recent CHE studies have reported changes in indices of HRV following short-term $PM_{2.5}$ exposure. In Copenhagen, Denmark, Hemmingsen et al. (2015b) exposed older overweight, but healthy men and women to TRAP that was nonfiltered or particle filtered. HFn was statistically significantly decreased ($p < 0.05$) and LF was statistically significantly increased ($p = 0.027$) when nonfiltered TRAP was compared to particle filtered after 5 hours of exposure. In addition, SDNN was transiently reduced by 13% ($p = 0.045$) after first entering the nonfiltered TRAP chamber, but notably, this effect did not persist. Similarly, Brook et al. (2009) reported that exposure to $PM_{2.5}$ CAP resulted in significant reductions ($p < 0.05$) in both time and frequency domains of HRV. In a dietary intervention study, Tong et al. (2012) found that after a 28-day supplementation period with olive oil, there was a lower HF/LF ratio immediately after CAP exposure in older adults. This reflected an immediate increase in LF that persisted

20 hours post exposure. There were no changes in HRV time domain measurements in this study. In an additional CAP study, Huang et al. (2012) found no difference in measures of time or frequency domains of HRV when CAP exposure was compared to clean air, but noted that CAP concentrations were lower than those used in previous studies where cardiovascular effects were reported.

As previously noted, the FILTER-HF CHE study examined whether introducing a respiratory filter could attenuate the cardiovascular effects of acute DE-exposure in patients with heart failure. Results indicated that time and frequency metrics of HRV were not significantly changed with exposure to DE or filtered DE when compared to clean air exposure (Vieira et al., 2016a).

Considered as a whole, the CHE studies discussed above provide some evidence of a change in HRV following $PM_{2.5}$ CAP exposure, but not following exposure to DE. Moreover, there is no evidence from the studies discussed above since the 2009 PM ISA for changes in heart rate following short-term exposure to $PM_{2.5}$. More information on studies published since the 2009 ISA can be found in Table 6-21 below.

Table 6-21 Study specific details from controlled human exposure (CHE) studies of short-term $PM_{2.5}$ exposure and Heart Rate (HR) and Heart Rate Variability (HRV).

Study	Population	Exposure Details	Endpoints Examined
(Brook et al., 2009) Toronto Cohort	Healthy adults n = 16 M; 15 F 27 ± 8	148.5 ± 54.4 µg/m^3 $PM_{2.5}$ CAPs for 2 h CAPs from Toronto	HR: during exposure HRV time and frequency domains: pre- and just before end of exposure
(Hemmingsen et al., 2015b)	Healthy overweight older adults n = 25 M, 35 F; 55−83 yr	24 ± 13 µg/m^3 (nonfiltered) 3.0 ± 1.2 µg/m^3 (filtered) $PM_{2.5}$ for 5 h at rest PM collected from a busy street in central Copenhagen, Denmark	HRV: ≤1 h post
(Huang et al., 2012)	Healthy adults n = 7 M, 8 F; 20−36 yr	89.5 ± 10.7 µg/m^3 $PM_{2.5}$ CAPs for 2 h. During exposure, subjects completed 4 cycles of 15 minutes each rest or exercise.	HRV time-domain endpoints: 18 h post HRV frequency domain: 1 and 18 h post
(Tong et al., 2012)	Healthy adults n = 8 M 21 F; 50−72 yr 57.4 ± 1.4	278 ± 19 µg/m^3 CAP for 2 h at rest CAPs from Chapel Hill, NC Effect of supplementation with fish oil or olive oil	HRV frequency and repolarization metrics: 105 min pre, and 2 h, 20 h post HRV time domain: Holter device was wore for entire 48 period calculated from two 24-h periods

6.1.10.3 Toxicology Studies of Heart Rate (HR) and Heart Rate Variability (HRV)

In the 2009 PM ISA (U.S. EPA, 2009) there was some animal toxicological evidence for changes in HR following short-term exposure to $PM_{2.5}$ CAPS. Since the 2009 PM ISA, using data collected every 30 seconds or integrated over 8 hours, Rohr et al. (2011) reported that winter ($p < 0.05$), but not summer month short-term $PM_{2.5}$ exposure resulted in a statistically significant increase in HR in SH rats. Similarly, Farraj et al. (2015) also reported that during winter, but not summer $PM_{2.5}$ CAPs exposure statistically significantly decreased ($p < 0.05$) HR in SH rats compared to controls. Wagner et al. (2014b) also found a statistically significant increase in HR in two of four independent experiments in SH rats. In a separate study that evaluated diet, Wagner et al. (2014a) reported a statistically significant decrease ($p < 0.05$) in HR in Sprague Dawley rats fed a normal or high fructose chow following $PM_{2.5}$ exposure when compared to controls. However, Kurhanewicz et al. (2014) found no change in HR following $PM_{2.5}$ exposure in mice when compared to filtered air controls.

Considered as a whole, there is some evidence that exposure to $PM_{2.5}$ could lead to changes in HR, although the direction of these HR changes are not entirely consistent. This could be due to differences in study parameters such as species, strain, diet, or the season in which the $PM_{2.5}$ was collected. More information on studies published since the 2009 ISA can be found in Table 6-22 below.

6.1.10.3.1 Heart Rate Variability (HRV)

The 2009 PM ISA provided some evidence of changes in HRV following short-term $PM_{2.5}$ CAPs exposure in SH rats, but not in wild-type or $ApoE^{-/-}$ mice (U.S. EPA, 2009). Since the publication of the 2009 PM ISA, Rohr et al. (2011) collected $PM_{2.5}$ data every 30 minutes during exposure and reported that in the summer, there was a statistically significant reduction in SDNN ($p = 0.003$), but not rMSSD in SH rats, whereas a statistically significant change ($p = 0.027$) in rMSSD, but not SDNN was reported in the winter. Interestingly, these authors also reported no significant effects on rMSSD or SDNN in summer or winter using 8-hour integrated $PM_{2.5}$ measurements. In addition, Wagner et al. (2014a) found that changes in HRV metrics in Sprague Dawley rats were dependent upon diet; that is, SDNN and rMSSD both increased ($p < 0.05$) following short-term exposure to $PM_{2.5}$ CAPs in animals fed a high fructose diet. However, SDNN and rMSSD both decreased ($p < 0.05$) in normal chow fed rats (Wagner et al., 2014a) following short-term $PM_{2.5}$ exposure.

In addition to the studies presented above, Kurhanewicz et al. (2014)and Farraj et al. (2015) reported that short-term $PM_{2.5}$ exposure did not alter time or frequency measures of HRV. Similarly, in SH rats exposed to $PM_{2.5,}$ Wagner et al. (2014b) found no statistically significant change in rMSSD in four independent experiments and no statistically significant changes in SDNN in three of four of these experiments.

Taken together, there is at least some evidence from animal toxicology studies that short-term exposure to $PM_{2.5}$ may lead to changes in HRV. Moreover, these studies demonstrate that changes in HRV may be dependent upon the season in which $PM_{2.5}$ is collected and the diet of the animal being exposed. More information on studies published since the 2009 ISA can be found in Table 6-22 below.

Table 6-22 Study specific details from toxicological studies of short-term $PM_{2.5}$ exposure and heart rate (HR) and heart rate variability (HRV).

Study	Population	Exposure Details	Endpoints Examined
(Farraj et al., 2015)	Adult SH rats (12 weeks) M, n = 6/group	Inhalation of 168.7 µg/m^3 summer or 78.5 µg/m^3 winter $PM_{2.5}$ CAPS collected from Durham NC. 4 h exposure	HR, HRV time and frequency domains, in the time period immediately post to 6 h post
(Kurhanewicz et al., 2014)	Adult, C57BL/6 mice, F, (10−12 weeks), n = 5−8/group	Inhalation of 190 µg/m^3 $PM_{2.5}$ from Research Triangle Park, NC Exposed for 4 days, 4 h/day.	HR, HRV time and frequency domains continuously pre- to post exposure

Table 6-22 (Continued): Study specific details from toxicological studies of short-term $PM_{2.5}$ exposure and heart rate (HR) and heart rate variability (HRV).

Study	Population	Exposure Details	Endpoints Examined
(Rohr et al., 2011)	SH rats, male, 13−14 weeks old, n = 8 per treatment group	Inhalation of 518 µg/m^3 and 357 µg/m^3 $PM_{2.5}$ CAPs in the summer and winter, respectively from Detroit, Mi, 8 h/day for 13 days	HR, HRV time and frequency domains during exposure
(Wagner et al., 2014b)	Adult SH rats, m n = 8/treatment group	Inhalation of $PM_{2.5}$ CAPs from Dearborn, MI collected in summer, four independent experiments $PM_{2.5}$ concentrations were 415 ± 99; 642 ± 294; 767 ± 256; and 364 ± 58 µg/m^3 respectively., 8 h/day for 4 days to air or CAPs	HR, HRV time domains during exposure
(Wagner et al., 2014a)	Adult Sprague-Dawley rats, M, n = 4−8 per treatment group, fed either a normal diet or a high-fructose diet	Inhalation of 356 µg/m^3 $PM_{2.5}$ CAPs from Dearborn, MI; 8 h/day for 9 consecutive weekdays	HR, HRV time domains during exposure and during nonexposure times in the evening and weekend

CAPs = concentrated ambient particles, d = day, F = female, h = hour, HR = heart rate, HRV = heart rate variability, M = male, n = number, SH = spontaneously hypertensive.

6.1.11 Systemic Inflammation and Oxidative Stress

As discussed in detail above (Section 6.1.1), systemic inflammation has been linked to a number of CVD-related outcomes. For example, circulating cytokines such as IL-6 can stimulate the liver to release inflammatory proteins (e.g., CRP) and coagulation factors that can ultimately increase the risk of thrombosis and embolism. Similarly, oxidative stress can result in damage to healthy cells and blood vessels and further increase the inflammatory response. Thus, this section discusses the evidence for changes in markers of systemic inflammation and oxidative stress following short-term $PM_{2.5}$ exposures.

In the 2009 PM ISA (U.S. EPA, 2009), the evidence for systemic inflammation following short-term exposure to $PM_{2.5}$ was limited. This remains the case in the current ISA. That is, while some epidemiologic panel, CHE, and animal toxicological studies report changes in markers of inflammation such as IL-6 and inflammatory proteins such as CRP following short-term exposure to $PM_{2.5}$, other studies do not show changes in these and other markers of inflammation. However, it should be noted that markers of systemic inflammation such as cytokines are often transiently expressed, thus making it difficult to consistently find changes across studies using a variety of methodological approaches.

With respect to oxidative stress, in the 2009 PM ISA there were a few animal toxicological studies that provided mostly positive evidence of an effect of short-term $PM_{2.5}$ CAP exposure on markers of oxidative stress. Since the 2009 PM ISA, there are a couple of additional toxicological studies in animals reporting changes in measures of oxidative stress following short-term $PM_{2.5}$ exposure. Thus, there is additional evidence for oxidative stress following short-term exposure to $PM_{2.5}$, that adds to similar evidence from the previous review.

6.1.11.1 Epidemiologic Panel Studies of Systemic Inflammation and Oxidative Stress

There are numerous recently published epidemiologic studies examining associations between inflammatory biomarkers in circulation and short-term exposure to $PM_{2.5}$ (Table 6-23), but overall, across study designs and populations, results are inconsistent. Strak et al. (2013a) and Steenhof et al. (2014) provide some evidence of positive associations in healthy populations in a study of healthy volunteers in Utrecht, the Netherlands that were exposed to five different sites that differed appreciably in $PM_{2.5}$ concentrations. Results demonstrate that increases in $PM_{2.5}$ concentrations were associated with increased CRP as well as higher white blood count, particularly neutrophils (Steenhof et al., 2014).

However, contrary to the results just discussed, in the Heinz Nixdorf Recall study from the Ruhr Area in Germany, associations were not observed between $PM_{2.5}$ and CRP. The study included almost 4,000 population-based participants and used a chemistry transport model with a spatial resolution of 1 × 1 km grid to estimate $PM_{2.5}$ exposures Hertel et al. (2010 2010, 1075921) also observed null associations between $PM_{2.5}$ and CRP in healthy individuals in Utah based on measurements taken on days with low, moderate, and high $PM_{2.5}$ concentrations. Karottki et al. (2014) conducted a study including 78 adults from 58 homes and found that 48-hour average concentrations of $PM_{2.5}$ were associated with increased CRP. Null associations were observed for IL-6, IL1B, IL-8, white blood counts or IFN-γ (Karottki et al., 2014).

Several studies focused on populations with pre-existing cardiovascular disease, which provide some evidence for $PM_{2.5}$-associated changes in inflammatory biomarkers. Huttunen et al. (2012) conducted a study with 52 older adults with ischemic heart diseases, and found that bi-weekly measures of IL12 and CRP for a 6-month period were associated with ambient $PM_{2.5}$. Other, well-conducted studies demonstrated similar associations between $PM_{2.5}$ and inflammatory IL6 and TNF in a panel of older adults, with the strongest associations being observed for 5-day averages (Wittkopp et al., 2013; Delfino et al., 2009b). However, other studies in panels of older adults, including some with pre-existing cardiovascular conditions, did not find evidence for associations with inflammatory markers. In a panel of patients with recent myocardial infarction or unstable angina participating in a cardiac rehabilitation program in Rochester, New York, null associations were observed between CRP and $PM_{2.5}$ levels averaged over 5 hours up to 5 days (Wang et al., 2016; Rich et al., 2012), with the exception of a positive association with 72−95 hour lag concentrations. Short-term $PM_{2.5}$ exposure was not associated with CRP

or myeloperoxidase, markers of systematic inflammation, in a panel of adults with acute coronary syndrome or nonemergent cardiac catheterization (Croft et al., 2017). Similarly, Liu et al. (2009) conducted a repeated measures study with a panel of older adults residing in three nursing homes and did not observe evidence for associations between $PM_{2.5}$ and markers for inflammation and oxidative stress. $PM_{2.5}$ was also not associated with CRP, IL6, or serum amyloid A in a study of 115 postmenopausal women residing in the Seattle, WA area (Williams et al., 2011).

6.1.11.2 Controlled Human Exposure Studies of Short-Term $PM_{2.5}$ Exposure and Systemic Inflammation and Oxidative Stress

In the 2004 PM AQCD, exposure to $PM_{2.5}$ CAPs was not found to effect IL-6, TNF-α, WBC count, or CRP (Ghio et al., 2003). In addition, exposure to $PM_{2.5}$ CAPs was found to not effect serum amyloid A levels (Jr et al., 2003). However, Gong et al. (2004) reported the number of peripheral basophils increased in healthy, but not in COPD subjects after short-term exposure to $PM_{2.5}$.

A few CHE studies published since the 2009 PM ISA found at least some evidence of inflammation following short-term exposure to $PM_{2.5}$. Behbod et al. (2013) reported that exposure to $PM_{2.5}$ CAP resulted in healthy adults having increased blood leukocytes and neutrophils at 24 hours, but not 3-hour post exposure due in part to the endotoxin content of the sample. Similarly, Brook et al. (2009) reported that blood neutrophils and total white blood cells, but not TNF-α were higher immediately after ($p < 0.01$ vs. pre-exposure value for the same visit), but not 24-hour post CAP exposure. Notably however, these changes were not statistically significant when compare to FA exposure (Brook et al., 2009). In an additional study, Urch et al. (2010) used two different $PM_{2.5}$ CAP exposure levels and reported a statistically significant increase ($p < 0.05$) in blood IL-6 levels for the higher CAP (140 ± 6 μg/m^3) condition ($p < 0.0001$) at 3-hour, but not immediately after or the day after exposure. In addition, no significant effects were observed at the lower CAP level (64 ± 3 μg/m^3).

Although the studies mentioned above include some evidence for increases in inflammatory markers following short-term exposure to $PM_{2.5}$, some of these and other studies also reported no statistical change in a number of inflammatory markers (Vieira et al., 2016a; Hemmingsen et al., 2015a; Liu et al., 2015a; Tong et al., 2015; Behbod et al., 2013; Hazucha et al., 2013; Tong et al., 2012; Lucking et al., 2011; Urch et al., 2010). For example, relative to baseline Tong et al. (2015) reported no statistical difference in serum levels of CRP, ICAM-1, VCAM-1, IL-6, and TNF-α following $PM_{2.5}$ exposure.

Similarly, Liu et al. (2015a) did not report a statistically significant change in Il-6 or CRP and Hemmingsen et al. (2015a) did not report an increase in CRP or inflammatory cells following short-term $PM_{2.5}$ exposure.

Overall, the evidence presented above is inconsistent. This is not unexpected however, given the variability in design and subjects across these studies (Table 6-24). Thus, it can still be concluded that the studies presented above provide limited evidence that short-term exposure to $PM_{2.5}$ can result in an increase in inflammation. Moreover, these results also provide evidence that the amount of endotoxin present in $PM_{2.5}$ exposure appreciably contributes to inflammatory potential.

With respect to markers of oxidative stress, Liu et al. (2015a) reported increased levels ($p < 0.05$) of the lipid peroxidation biomarker malondialdehyde (MDA) in urine, but not blood following short-term exposure to $PM_{2.5}$. However, in the same study there was little post-exposure change in urine levels of the DNA oxidative damage biomarker OHdG. Similarly, Hemmingsen et al. (2015a) did not report changes in blood markers of oxidative stress when $PM_{2.5}$ exposure was compared to FA exposure. Thus, there is little evidence from CHE studies of a relationship between markers of oxidative stress and $PM_{2.5}$. However, given the potential transient nature for markers of oxidative stress, results of these studies may have been different if additional time points had been selected for blood and urine collection. More information on studies published since the 2009 ISA can be found in Table 6-24.

Table 6-24 Study-specific details from controlled human exposure (CHE) studies of short-term $PM_{2.5}$ exposure and inflammation and oxidative stress.

Study	Population	Exposure Details	Endpoints Examined
(Behbod et al., 2013)	Healthy adults N = 19 M; 16 F 18−60 yr old	~250 µg/m^3 fine CAP (0.1 to 2.5 microns) ~200 µg/m^3 course CAP (2.5 to 10 microns) For 130 min CAP from busy Toronto street Correlated effects with presence of endotoxin	Inflammatory cells and markers of inflammation ~45 pre- and 3 h and 24 h after start of each exposure
(Brook et al., 2009) Toronto Cohort	Healthy adults n = 16 M; 15 F 27 ± 8	148.5 ± 54.4 µg/m^3 $PM_{2.5}$ CAP for 2 h CAP from Toronto	Markers of inflammation: pre, post, and 24 h post

6.1.11.3 Toxicology Studies of Systemic Inflammation and Oxidative Stress

2 Toxicological studies in the 2009 PM ISA (U.S. EPA, 2009) that evaluated inflammation reported
3 inconsistent results. Although Kodavanti et al. (2005) reported no increase in WBCs after short-term

$PM_{2.5}$ exposure, an additional study reported a significant decrease in WBC following short-term $PM_{2.5}$ exposure (Kooter et al., 2006).

Since the 2009 PM ISA, Xu et al. (2013) investigated the pulmonary and systemic inflammatory effects of $PM_{2.5}$ in mice at 5, 14, and 21 days post-exposure. PM statistically significantly increased ($p < 0.05$) monocyte chemoattractant protein-1 levels at 5 days only, while TNF-α, and IL-12 were not statistically significantly altered. However, short-term $PM_{2.5}$ exposure significantly ($p < 0.05$) increased leukocyte ($p < 0.05$) adhesion (14 day) and rolling (21 day) in the mesenteric microvasculature compared to FA. Davel et al. (2012) also reported that pulmonary arterial tissue TNF-α protein statistically significantly increased ($p < 0.05$), while IL-1-β and IL-6 protein were not modified following $PM_{2.5}$ exposure in rats. They also reported no statistically significant differences in plasma levels of TNF-α, IL-1β, and IL-6, nor did they report appreciable differences in a number of inflammatory cell types between $PM_{2.5}$ exposed and control animals. Taken together, there is at least some evidence from toxicological studies of an effect of short-term $PM_{2.5}$ exposure on markers of systemic inflammation and the ability to observe these effects are likely highly influenced by study design (e.g., exposure duration and sample collection times post-exposure). More information on these studies and their design can be found in Table 6-25.

6.1.11.3.1 Oxidative Stress

The 2009 PM ISA (U.S. EPA, 2009) evaluated the effects of short-term $PM_{2.5}$ CAPs exposure on markers of oxidative stress in animal toxicological studies and generally reported increases in these markers (Ghelfi et al., 2008; Rhoden et al., 2005; Gurgueira et al., 2002). Since the publication of the 2009 PM ISA, Davel et al. (2012) used hydroethidine fluorescence (a probe that detects superoxides) to show that short-term exposure to $PM_{2.5}$ can induce oxidative stress in pulmonary arteries of rats when compared to FA control. Similarly, Ghelfi et al. (2010) found that short-term exposure to $PM_{2.5}$ resulted in changes in markers of oxidative stress. Thus, there is limited additional evidence that short-term exposure to $PM_{2.5}$ can result in oxidative stress.

Table 6-25 Study-specific details from toxicological studies of short-term $PM_{2.5}$ exposure and systemic inflammation and oxidative stress.

Study	Population	Exposure Details	Endpoints Examined
(Xu et al., 2013)	Adult C57Bl/6 mice, lacking Adrb1, Adrb2, both, or neither	Inhalation of 143.8 µg/m^3 $PM_{2.5}$ CAPs, for 6 h/day, 5 days/week for 5, 14, and 21 days from Columbus, OH	Leukocyte rolling post 14 and 21 days exposure and blood markers of inflammation post 5, 14, and 21 days exposure
(Davel et al., 2012)	3-mo old Wistar rats, M	Inhalation of 600 µg/m^3 $PM_{2.5}$ CAPs for 3 h/day for two weeks from Sao Paulo City, Brazil	Protein markers of inflammation in the pulmonary artery post exposure Markers of inflammation in the blood post-exposure Detection of superoxide in the pulmonary artery using hydroethidine fluorescence
(Ghelfi et al., 2010)	Adult Sprague Dawley rats, n = 80 total	Inhalation of $PM_{2.5}$ some groups pretreated with valsartan or benazepril 5 h exposure	Markers of oxidative stress measured by chemiluminescence and TBARS

CAPs = concentrated ambient particle, d = day, DE = diesel exhaust, h = hour, M = male, TBARS = thiobarbituric acid reactive substances, week = week.

6.1.12 Coagulation

Coagulation refers to the process by which blood changes from a liquid to a semi-solid state in order to form a clot. Increases in coagulation factors (e.g., fibrinogen, thrombin) or decreases in factors that promote fibrinolysis such as tissue plasminogen activator (tPA) can promote clot formation, and thus, increase the potential for an embolism.

In previous reviews, evidence from epidemiologic panel, CHE, and animal toxicological studies were inconsistent, with some studies showing changes in markers of coagulation following $PM_{2.5}$ exposure while other studies did not. In general, this remains to be the case in the current review. In epidemiologic panel studies, the evidence for associations with fibrinogen was limited across studies, and the evidence for other biomarkers was similarly limited. Likewise, CHE studies provide inconsistent evidence across these studies of an effect of short-term $PM_{2.5}$ exposure on indicators for thrombosis and coagulation. Notably however, there was some evidence for changes in markers of coagulation following short-term exposure to $PM_{2.5}$ from toxicological studies in mice, but not rats. Specifically, these studies provide evidence from genetic mouse models that activation of the β-adrenergic pathway or the sympathetic nervous system contributes to changes in markers of coagulation following short-term $PM_{2.5}$ exposures (Chiarella et al., 2014). When considered as a whole, these recent studies do provide additional evidence that short-term exposure to $PM_{2.5}$ can promote clot formation. Although in some cases evidence

for increases or decreases in clotting factors is inconsistent across studies, this is largely expected given the differences in study design and the transient nature of clotting factor expression.

6.1.12.1 Panel Epidemiologic Studies of Coagulation

Several recently available studies have examined associations between short-term exposures to $PM_{2.5}$ and biomarkers related to coagulation, with fibrinogen being the most commonly studied (Table 6-26). As in the 2009 PM ISA (U.S. EPA, 2009), the evidence for associations for fibrinogen with short-term exposures to $PM_{2.5}$ remains inconsistent across studies, and the evidence for other biomarkers remains limited.

Of the recent studies, one was quasi-experimental in design. Strak et al. (2013a) conducted a study with 31 healthy volunteers in Utrecht, the Netherlands where participants were assigned in random order to five locations to capture distinct pollutant exposures including two traffic sites, an underground train station, a farm, and an urban background site. In two-pollutant models, 5-hour exposures to $PM_{2.5}$ at outdoor sites were associated with increases in vWF and platelet counts but not fibrinogen or tPA/PAI-1 complex (Strak et al., 2013a). In a follow-up analysis using an alternative determination of coagulation status, null associations were observed for $PM_{2.5}$ concentrations and FXII-mediated (intrinsic) thrombin generation (Strak et al., 2013b).

O'Toole et al. (2010) conducted a study designed to capture gradients in $PM_{2.5}$ concentrations. Blood samples were collected from young, healthy adults on a day with high $PM_{2.5}$ concentrations, a day with moderate concentrations, and two days with low concentrations. Results from this study demonstrated an increase in platelet-monocyte aggregates with increasing $PM_{2.5}$ concentrations; however, associations were not observed for pro-coagulation factor fibrinogen.

Other studies have evaluated associations for fibrinogen, lipoprotein-associated phospholipase A2, and vWF in panels with pre-existing cardiovascular conditions. Results across these studies are inconsistent (Croft et al., 2017; Wang et al., 2016; Huttunen et al., 2012; Rich et al., 2012; Brüske et al., 2011; O'Toole et al., 2010; Peters et al., 2009). Croft et al. (2017) reported positive associations between fibrinogen and 1, 12, and 24-hour lags of $PM_{2.5}$ exposure, but found no evidence of associations for d-Dimer or vWF in a panel of adults with acute coronary syndrome or nonemergent cardiac catheterization. Huttunen et al. (2012), Rich et al. (2012), Brüske et al. (2011), and Peters et al. (2009) did not observe associations for fibrinogen or other biomarkers examined.

Overall these panel studies do not provide strong support for associations between short-term $PM_{2.5}$ exposures and fibrinogen. Similarly, studies for other biomarkers of coagulation remain limited, as was the case in the last review. More information on these studies can be found in Table 6-26.

6.1.12.2 Controlled Human Exposure Studies of Coagulation

Previous reviews described multiple CHE studies that evaluated the potential for thrombosis and coagulation following exposure to fine particles. Studies exposed healthy adults to $PM_{2.5}$ CAP and reported increased levels of fibrinogen (a marker for increased tendency for blood to coagulate) in both studies (Ghio et al., 2003; Ghio et al., 2000). However, in an additional study Jr et al. (2003) did not find an increase in fibrinogen, or two other coagulation markers: factor VII, or vWF. A later study by the same group in the same location evaluated older adults with COPD and also reported no associations between these coagulation indices and $PM_{2.5}$ exposure (Gong et al., 2004).

Recent studies have also examined the relationship between short-term $PM_{2.5}$ exposure and the potential for increased coagulation. Lucking et al. (2011) exposed healthy young men to FA, DE, and DE filtered using a particle trap (filtered DE). Results indicated no statistically significant difference in platelet levels. Results also indicated no statistically significant difference in tPA release (i.e., an anticoagulant) when comparing DE to FA exposures in response to the blood vessel dilator bradykinin. However, exposure to filtered DE revealed enhanced tPA release in response to bradykinin when compared to unfiltered DE ($P = 0.03$), suggesting that $PM_{2.5}$ from DE can suppress tPA release.

In the same study, Lucking et al. (2011) also performed ex vivo analyses using a Badimon chamber model 2 hours after each exposure. The procedure was designed to mimic the rheological conditions of people with mild coronary artery disease (low-shear) and more severe coronary stenosis (high-shear). When study participant's blood was pumped from the antecubital vein through the low-shear, and then the high-shear chambers, there was thrombus formation after unfiltered DE exposure compared to FA exposure in both stress chambers: 21.8% (low); $P = 0.001$ and 14.8% (high); $P = 0.02$. Exposure to filtered DE significantly reduced thrombus formation in the low-shear chamber by 15.7% ($P = 0.023$), thereby indicating that particles were at least partially responsible for thrombus formation under low-shear conditions.

In contrast to the results presented above, following $PM_{2.5}$ exposure Hazucha et al. (2013) found no change in plasminogen, vWF, tPA, D-dimer, or PAI-1 relative to pre-exposure levels in adults who currently or previously smoked. Similarly, in a dietary supplementation study, Tong et al. (2015) reported no difference in plasminogen, vWF, or fibrinogen levels immediately after, or 20 hour post exposure in naïve or subjects supplemented with olive or fish oil for four weeks prior to $PM_{2.5}$ exposure. However, these authors also reported that in volunteers supplemented with olive oil that there was a statistically significant ($p < 0.05$) increase in tPA and a decrease in D-dimer levels relative to baseline (Tong et al., 2015). In a prior dietary intervention study, these authors (Tong et al., 2012) also reported no changes in platelets immediately after or 20 hour post $PM_{2.5}$ exposure in groups supplemented with olive or fish oil. Finally, Vieira et al. (2016a) also did not report that exposure to DE or filtered DE increased platelets or other indicators of coagulation.

Taken together, the recent evidence from CHE studies appears to be inconsistent with respect to an effect of $PM_{2.5}$ exposure on indicators of thrombosis and coagulation. However, this is not particularly unexpected given variability in study design and subjects across these studies (Table 6-27). Thus, it can be concluded from the information presented above that there is some evidence that short-term exposure to $PM_{2.5}$ can result in changes in coagulation/fibrinolysis factors that can promote thrombosis. More information on studies published since the 2009 ISA can be found in Table 6-27.

Table 6-27 Study-specific details from controlled human exposure (CHE) studies of short-term $PM_{2.5}$ exposure and coagulation.

Study	Population	Exposure Details	Endpoints Examined
(Hazucha et al., 2013)	Current and ex-smokers; n = 11; 3 M, 8 F 35−74 yr	108.7 ± 24.8 µg/m^3 $PM_{2.5}$ for 2 h at rest	Markers of coagulation: 3 h and 22 h post

6.1.12.3 Toxicology Studies of Coagulation and Thrombosis

In the 2009 PM ISA, (Sun et al., 2008a) reported that $PM_{2.5}$ increased tissue factor (TF) expression in aortas and in the atherosclerotic plaques of $ApoE^{-/-}$ mice fed a high-fat diet compared to filtered air controls.

Since the publication of the 2009 ISA, additional rodent studies have specifically measured the effects of CAPs on hemostasis and thrombosis. In rats, exposure to ambient $PM_{2.5}$ did not alter fibrinogen, platelet counts, partial thromboplastin time to activation, or prothrombin time (Davel et al., 2012). In mice however, Budinger et al. (2011) reported that short-term $PM_{2.5}$ exposure increased ($p < 0.05$) the formation of thrombin-anti-thrombin complexes in the plasma of wild type, but not $IL\text{-}6^{-/-}$ mice. In a follow-up mechanistic study, Chiarella et al. (2014) found that in mice, $PM_{2.5}$-induced increases in plasma thrombin-antithrombin complexes were reduced in the presence of the catecholamine transport inhibitor reserpine, whereas treatment with the β2-agonist albuterol exacerbated PM-dependent indicators of thrombosis. Furthermore, these $PM_{2.5}$ mediated effects were lost by pharmacological inhibition or genetic

loss of the β2-adrenergic receptor in murine alveolar macrophages. In summary, there is additional animal toxicological evidence in the current review that short-term exposure to $PM_{2.5}$ can result in an increase of factors consistent with coagulation and thrombosis in mice, but not rats. Moreover, a mechanistic study provides evidence that the β-adrenergic receptor is involved in this process in mice. More information on studies published since the 2009 ISA can be found in Table 6-28.

Table 6-28 Study-specific details from toxicological studies of short-term $PM_{2.5}$ exposure and coagulation.

Study	Population	Exposure Details	Endpoints Examined
(Budinger et al., 2011)	Adult, C57BL/6 and $IL6^{-/-}$ mice, M	Inhalation of 88.5 μg/m^3 $PM_{2.5}$ CAPs for 8 hours/day for 3 days	Formation of thrombin anti thrombin complexes post 3 days exposure
(Chiarella et al., 2014)	Adult, C57BL/6, and $Adrb1^{-/-}$, $Adrb2^{-/-}$, or Adrb1 and $Adrb^{-/-}$mice	Inhalation $PM_{2.5}$ CAP (109 μg/m^3), exposed for 8 h/day for 3 days	Plasma thrombin-anti-thrombin and thrombus formation time, TF mRNA levels post 3 days exposure
(Davel et al., 2012)	3-mo old Wistar rats, M	Inhalation of 600 μg/m^3 $PM_{2.5}$ CAPs for 3 h/day for 2 weeks from Sao Paulo City, Brazil	Hematological variables, coagulation outcomes, post 15-day exposure

CAP = concentrated ambient particle, d = day, F = female, h = hour, M = male, n = number, SD = standard deviation, TF = tissue factor

6.1.13 Endothelial Dysfunction and Arterial Stiffness

Endothelial dysfunction is the physiological impairment of the inner lining of blood vessels. Endothelial dysfunction is typically measured by flow mediated dilation percent (FMD%). It is a noninvasive technique involving measurement of the percent change in brachial artery diameter (BAD) after reactive hyperemia (increased blood flow following removal of an artery-occluding blood pressure cuff) (Thijssen et al., 2011) or pharmacological challenge. In addition to measuring FMD or BAD, experimental studies often examine biomarkers that may be indicative of endothelial dysfunction or vascular damage. These biomarkers include endothelin 1 (ET-1), and changes in the number of circulating endothelial progenitor cells (EPCs).

In the previous review, there was limited evidence from animal toxicological studies for a relationship between short-term $PM_{2.5}$ exposure and increased molecular markers of endothelial dysfunction, but a single CHE study did not show a relationship between short-term $PM_{2.5}$ exposure and clinical measures of endothelial dysfunction (e.g., BAD). In contrast, there is considerable and consistent recent evidence of endothelial dysfunction following short-term PM2.5 exposure. Specifically, there is at

least some evidence from more recent epidemiologic panel studies and consistent evidence from CHE and animal toxicological studies of endothelial dysfunction or markers of endothelial dysfunction following short-term exposure to $PM_{2.5}$.

Arterial stiffness is associated with a variety of cardiovascular risk factors and outcomes (Laurent et al., 2006). Carotid-femoral pulse wave velocity (PWV) is used to directly and noninvasively measure arterial stiffness. PWV measures the velocity at which the pulse generated by the heart travels through the arteries, typically measured by the foot-to-foot method (end diastole of the wave in the carotid artery to end diastole of the wave in the femoral artery). There is no recent evidence that short-term exposure to $PM_{2.5}$ can result in changes in arterial stiffness.

6.1.13.1 Panel Epidemiologic Studies of Impaired Vascular Function

Several epidemiologic studies examined the relationship between ambient $PM_{2.5}$ and vasomotor function, particularly for brachial artery diameter and flow-mediated or nitroglycerin-mediated dilation (Table 6-29).

A series of analyses were done using the Detroit Exposure and Aerosol Research Study (DEARS) data focused on personal measures of $PM_{2.5}$ and vascular measurements in nonsmoking adults. In these studies, positive associations were observed between 2-hour $PM_{2.5}$ and vasoconstriction, as indicated by brachial artery diameter (BAD); however, vasodilation was observed relative to $PM_{2.5}$ concentrations with a 2-day lag (Brook et al., 2011; Brook et al., 2010b). Flow-mediated dilation (FMD) and nitroglycerin-mediated dilation (NMD) were also measured in these studies, but associations were only observed for 2-hour averages of $PM_{2.5}$ and decreases in FMD. Other studies examining BAD, FMD, and NMD did not provide evidence of associations in either older or younger adults (Liu et al., 2014b; Liu et al., 2009).

6.1.13.1.1 Digital Vascular Function

By measuring the microvessel pulse-wave amplitude of the index finger in resting state and after cuff-induced occlusion, short-term $PM_{2.5}$ changes can be studied in relation to resting pulse-wave amplitude and to endothelium dependent reactive hyperemia. In roughly 2,400 participants of the Framingham Heart Study living in Boston, MA higher 1, 2, and 3-day averages of ambient $PM_{2.5}$ concentrations were associated with higher microvessel dilation (Ljungman et al., 2014). Another measure of microvascular function is central retinal arterial and venous diameter, where narrower arterial equivalents and wider venular equivalents are linked, with increased risk for more severe cardiovascular events including myocardial infarction and stroke. In the MESA study, preceding day $PM_{2.5}$ levels were associated with smaller central retinal arteriolar equivalents, and null associations were observed for venular equivalents (Adar et al., 2010).

6.1.13.1.2 Arterial Stiffness

Arterial stiffness can be measured using the augmentation index (Aix). Increases in this index indicate greater arterial stiffness and may represent increased risk of an adverse cardiovascular event. Stiffening of the elastic arteries has been associated with premature mortality and morbidity (Avolio et al., 2009; Laurent et al., 2001) plausibly increasing the cardiac load and leading to higher pulse pressure into the peripheral circulation and contributing to end-organ damage in the brain and kidneys (Mitchell, 2008). Several different measures of arterial stiffness are available including carotid femoral pulse wave velocity (CFPWV), augmentation index (AI), and aortic pulse pressure. CFPWV is generally considered to be the gold standard approach (Mitchell, 2009).

Morishita et al. (2015a) examined changes in AIX relative to ambient $PM_{2.5}$ in small panel of healthy adults and found no evidence of an association with same day $PM_{2.5}$ exposures.

6.1.13.1.3 Biomarkers of Endothelial Injury

Two studies reviewed in the 2009 PM ISA reported positive associations between short-term levels of PM and endothelial biomarkers (Delfino et al., 2008; O'Neill et al., 2007). Higher mean $PM_{2.5}$ during the preceding 1−6 days was associated with higher inter-cellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1) in 92 Boston residents with Type 2 diabetes (O'Neill et al., 2007). ICAM-1, VCAM-1, endothelial-leucocyte adhesion molecule (E-selectin) and *P*-selectin are specific markers of endothelial activation. Markers of vasodilation include vascular endothelial growth factor (VEGF), and markers of vasoconstriction include endothelin-1 (ET-1).

Other recently published studies have examined the relationship between short-term $PM_{2.5}$ concentration sand adhesion molecules. Madrigano et al. (2010) and Wilker et al. (2011) conducted analyses as part of the Normative Ageing Study from Boston, MA and examined 7-day and 2-day average $PM_{2.5}$ exposures, respectively. Results from these studies demonstrate that seven-day, but not 2-day, average level of $PM_{2.5}$ are associated with both higher VCAM-1 (6.0%, 95% CI 1.4, 10.9) and ICAM-1 (7.4%, 95% CI 3.8, 11.1).

Liu et al. (2009) also examined biomarkers related to vascular function in 28 nonsmoking seniors in nursing homes in Windsor, Ontario with residential monitoring. Positive associations were observed for personal $PM_{2.5}$ exposures and VEGF, but not for personal exposures and ET-1 or with ambient $PM_{2.5}$ concentrations (Liu et al., 2009).

In summary these studies overall indicate possible PM effects on adhesion molecules (VCAM-1 and ICAM-1), but the evidence base is limited. More information on these studies can be found in Table 6-29.

6.1.13.2 Controlled Human Exposure Studies of Short-Term $PM_{2.5}$ Exposure and Impaired Vascular Function

In the 2009 PM ISA (U.S. EPA, 2009), a CHE study examined the relationship between $PM_{2.5}$ exposure and vascular function. Bräuner et al. (2008) found no changes in vasoconstriction following a 24-hour exposure to unfiltered or particle filtered $PM_{2.5}$ urban traffic particles. In the current review, additional CHE studies have explored the relationship between exposure to $PM_{2.5}$ and vascular function.

As described below, these studies generally report decreases in vascular function following $PM_{2.5}$ CAP and unfiltered DE exposure.

Studies using ambient particles, Hemmingsen et al. (2015b), (Tong et al., 2015), and Brook et al. (2009) found at least some measure of impaired vascular function following $PM_{2.5}$ exposure. Hemmingsen et al. (2015b) reported a 12% significant decrease in brachial artery flow following nitroglycerin ($p = 0.033$) administration and a 5% decrease (not statistically significant) after reactive hyperemia when comparing nonfiltered to particle filtered air from Copenhagen, Denmark. Similarly, in a dietary supplementation study, healthy older adults were randomized to fish oil, olive oil, or naïve treatment groups for a 28-day supplementation period followed by exposure to FA then CAP (Tong et al., 2015). In response to reactive hyperemia, the authors reported significantly decreased FMD of the brachial artery immediately after CAP exposure in both the naïve; ($p = 0.03$) and fish oil ($p = 0.01$) groups relative to baseline measurement before treatment. Notably, at 20-hour post exposure, FMD for the fish oil group remained lower ($p = 0.01$). Finally, Brook et al. (2009) examined the effects of $PM_{2.5}$ from Toronto, Canada on vascular function in healthy adults. Immediately after exposure there was not a decrease in FMD or NMD, but the authors did report that FMD, but not NMD was statistically significantly decreased 24 hours after CAP exposure compared to baseline for the same visit ($p < 0.05$), but not relative to filter air exposure.

A PM effect on vascular function was also reported in a filtered DE study by Lucking et al. (2011). Healthy young men were exposed to FA, unfiltered DE, and filtered DE. When unfiltered DE was compared to FA, forearm blood flow was found to be impaired in response to the endothelium dependent vasoactive substances acetylcholine ($p = 0.01$) and bradykinin ($p = 0.009$), as well as the endothelium independent (and nitric oxide (NO) independent) vasoactive substance verapamil ($p = 0.03$). Importantly, there was not an impaired response when comparing filtered DE to FA, thereby indicating that it was likely the particles were responsible for the impaired blood flow following administration of the vasoactive agents. Finally, there was no statistically significant difference in forearm blood flow between DE and FA in response to the endothelial-independent vasodilator sodium nitroprusside (SNP), but interestingly, there was increased blood flow in response to SNP when comparing filtered DE to unfiltered DE ($p = 0.04$). Similarly, in the FILTER-HF study, healthy adult controls and HF patients were exposed to DE or filtered DE. A statistically significant 21% decrease in blood flow was demonstrated in the HF group only ($p < 0.05$) after reactive hyperemia, and this effect was almost completely attenuated ($p = 0.019$) with particle filtration (Vieira et al., 2016a).

With respect to biomarkers of endothelial dysfunction, Tong et al. (2015) did report a statistically significant ($p < 0.05$) increase in the vasoconstrictor ET-1 in blood 20 hours post-exposure in the naïve treatment group relative to baseline. In addition, Liu et al. (2015a) examined the potential for $PM_{2.5}$ CAP exposure to increase blood and urine levels of VEGF and ET-1. Statistically significant increases in ET-1 and VEGF were not found in the blood, but urine sampling revealed a statistically significant increase for VEGF at 1 hour, but not 21 hours (although still elevated). The authors also provided evidence that CAP

endotoxin content may contribute to the observed effects. Similarly, Zhong et al. (2015) reported that increases in VEGF in response to PM exposure are also associated with the amount of endotoxin present in the sample.

Taken together, recent CHE studies do show evidence of a $PM_{2.5}$ effect on vascular function. In contrast to the results reported in the single study from the previous review, all of the current studies report some effect of $PM_{2.5}$ ambient particles or DE particles on measures of blood flow. However, the timing of the response varied among studies. Studies were also not completely consistent with respect to the decreased blood flow response when comparing endothelial dependent to endothelial independent mechanisms. In addition, there was some evidence for an increase in markers associated with endothelial dysfunction in blood and urine.

6.1.13.2.1 Arterial Stiffness

Arterial stiffness can be measured using the augmentation index (Aix). Increases in this index indicate greater arterial stiffness and may represent increased risk of an adverse cardiovascular event. In the FILTER-HF study, HF and healthy control patients were exposed to FA, DE or filtered DE and decreases in Aix were not attenuated with particle filtration (Vieira et al., 2016a). Thus, DE-dependent decreased arterial stiffness in HF patients is related to exposure to the entire DE mixture and is not $PM_{2.5}$-dependent. Similarly, Lucking et al. (2011) examined the potential for arterial stiffness following FA, DE, and filtered DE exposure in healthy young men. There were no differences in indicators of arterial stiffness among any of the treatment groups. Thus, there is no evidence from CHE studies of a relationship between increased arterial stiffness and exposure to filtered DE. More information on studies published since the 2009 ISA can be found in Table 6-30.

6.1.13.3 Toxicology Studies of Impaired Vascular Function

Since the publication of the 2009 PM ISA, studies have evaluated the short-term effects of $PM_{2.5}$ exposure on endothelial dysfunction. Specifically, O'Toole et al. (2010) found that short-term $PM_{2.5}$ exposure reduced ($p < 0.05$) the level of circulating endothelial progenitor cells (EPCs). Haberzettl et al.

(2012) confirmed this finding, and identified that the reduction in circulation was not due to EPC death or tissue deposition. Instead, they found that CAP exposure increased ($p < 0.05$) the number of resident EPCs in the bone marrow and that this was at least in part due to impaired VEGF signaling resulting in decreased translocation into the blood. In an additional study, Davel et al. (2012) reported that short-term exposure to $PM_{2.5}$ impaired acetylcholine, but not NTP induced relaxation ($p < 0.05$) in pulmonary arterial rings from $PM_{2.5}$-exposed rats when compared to FA controls. Similarly, compared to control animal serum, Aragon et al. (2015) reported that treatment of naïve aortic rings with serum from mice exposed to the particle portion of mixed vehicle emissions (i.e., mixture of gas and diesel exhaust), but not $PM_{2.5}$ from road dust, resulted in impaired acetylcholine induced relaxation ($p < 0.05$). When considered as a whole, these toxicological studies report consistent evidence that short-term exposure to $PM_{2.5}$ can result in indicators of endothelial dysfunction. More information on studies published since the 2009 ISA can be found in Table 6-31.

6.1.14 Policy-Relevant Considerations

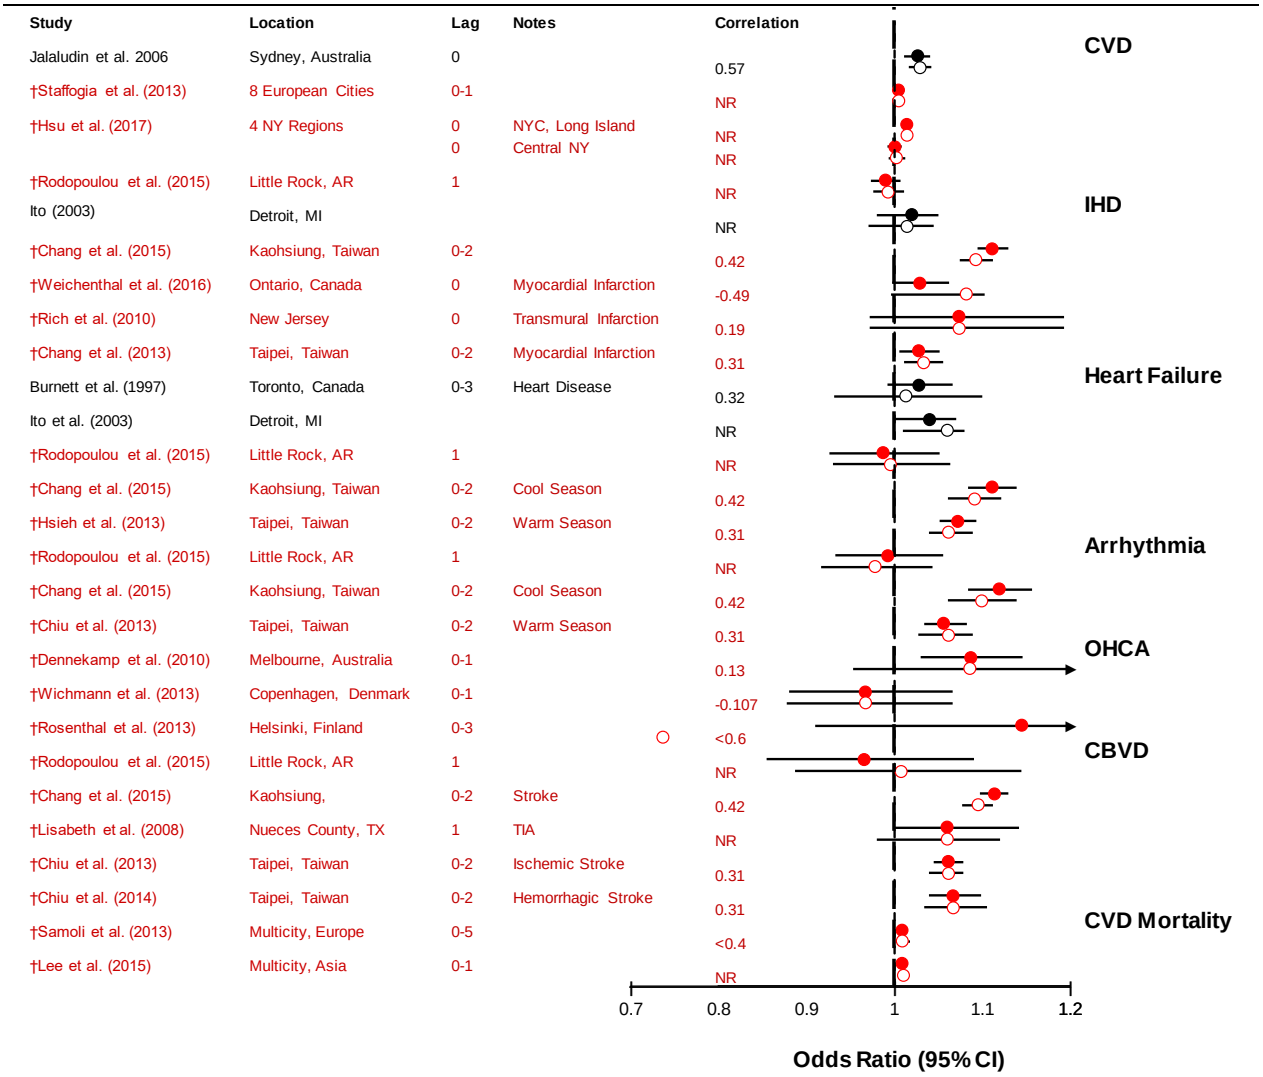
Epidemiologic studies that examined short-term $PM_{2.5}$ exposure and cardiovascular-related effects often conduct additional analyses to assess whether the associations observed are due to chance, confounding, or other biases. Within this section, evidence is evaluated across epidemiologic studies to further assess the association between short-term $PM_{2.5}$ exposure and cardiovascular-related effects, focusing specifically on those analyses that address policy-relevant issues: copollutant confounding

(Section 6.1.14.1), the role of season and temperature on $PM_{2.5}$ associations (Section 6.1.14.2), and lag structure (Section 6.1.14.3). The studies that inform these issues are primarily epidemiologic studies that conducted time-series or case-crossover analyses focusing on cardiovascular-related ED visits and hospital admissions and cardiovascular mortality. Studies examining additional endpoints, such as subclinical markers of a PM-related cardiovascular effect (e.g., heart rate variability, inflammation, etc.), may also examine some of these issues, but are not the focus of this evaluation.

6.1.14.1 Potential Copollutant Confounding of the $PM_{2.5}$-Cardio Vascular Disease (CVD) Relationship

In the examination of potential confounding effects of copollutants on the relationship between short-term $PM_{2.5}$ exposure and cardiovascular effects, it is informative to evaluate whether $PM_{2.5}$ risk estimates are changed in copollutant models. Compared to the evidence available at the time of the 2009 PM ISA, there are many additional studies that conducted analyses that inform the potential of confounding effects of copollutants. Recent studies have examined the potential for copollutant confounding by evaluating copollutant models that include O_3 (Figure 6-8), NO_2, (Figure 6-9), SO_2 (Figure 6-10), CO (Figure 6-11) and $PM_{10–2.5}$ (Figure 6-12). These recent studies address a previously identified data gap by informing the extent to which effects associated with exposure to $PM_{2.5}$ are independent of co-exposure to correlated copollutants. Generally, these studies provide evidence for a direct relationship between $PM_{2.5}$ exposure and cardiovascular-related health effects independent of other copollutants.

The results for associations between short-term $PM_{2.5}$ exposure and cardiovascular effects in single pollutant models and copollutant models adjusted for O_3 are shown in Figure 6-8. The correlations between $PM_{2.5}$ and O_3 exposures in the studies that conducted copollutant analyses were generally positive and low to moderate, ranging from $r = -0.49$ to 0.57. Across studies, the $PM_{2.5}$ effect estimates remained relatively unchanged in copollutant models adjusted for O_3. The trend persisted for aggregate CVD outcomes, as well as specific cardiovascular endpoints, such as IHD, heart failure, arrhythmia, cerebrovascular disease, and cardiovascular mortality. There were several exceptions to the trend. The effect of short-term $PM_{2.5}$ exposure on out-of-hospital cardiac arrest (Rosenthal et al., 2013) decreased substantially and became negative after adjusting for O_3 in the model. Conversely, the effect of short-term $PM_{2.5}$ exposure on MIs (Weichenthal et al., 2016b) increased after adjusting for O_3 in the model.

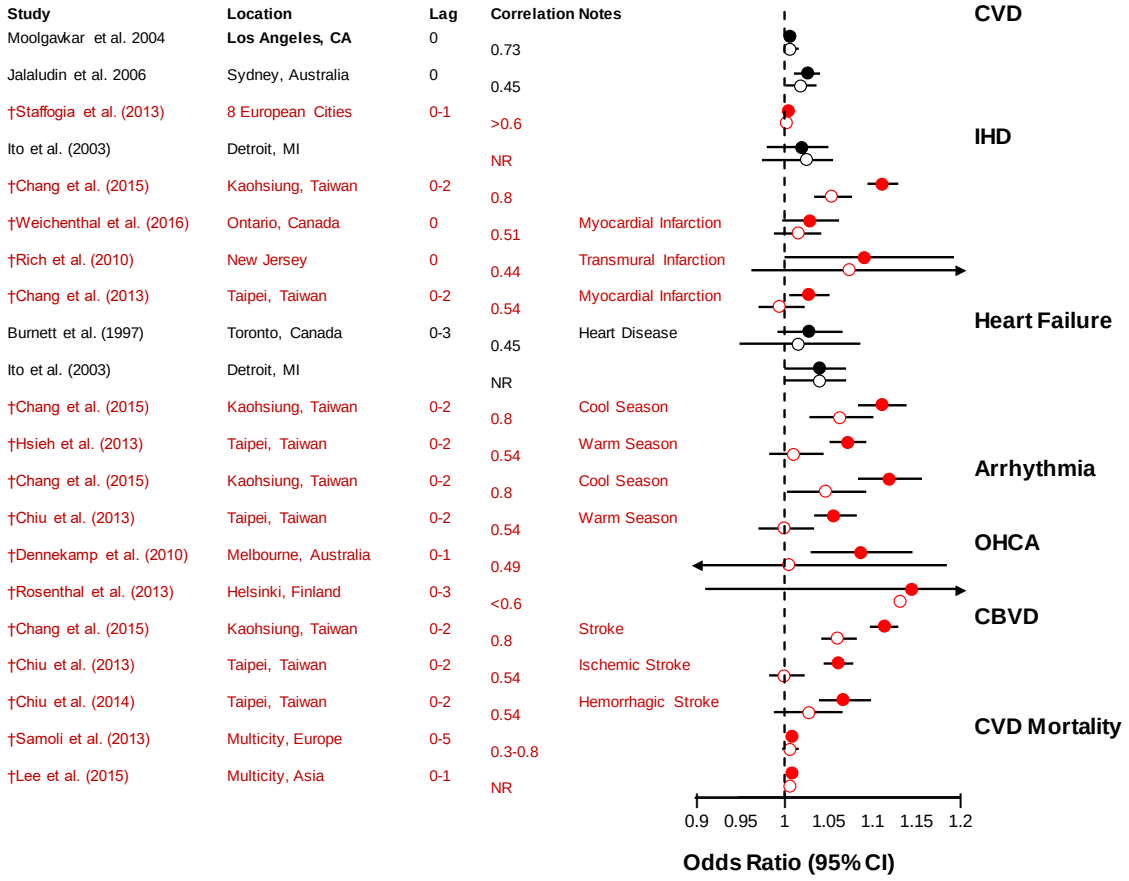


Associations are presented per 10 µg/m^3 increase in pollutant concentration. Circles represent point estimates; horizontal lines represent 95% confidence intervals for $PM_{2.5}$. Filled circles represent effect of $PM_{2.5}$ in single pollutant models, white circles represent effect of $PM_{2.5}$ adjusted for O_3. Supplemental Table S6-11 (U.S. EPA, 2018). TIA: transient ischemic attack; CVD: cardiovascular; IHD: ischemic heart disease; OHCA: out-of-hospital cardiac arrest; CBVD: cerebrovascular disease; NR: not reported. †Studies published since the 2009 PM ISA.

Figure 6-8 Associations between short-term exposure to $PM_{2.5}$ and cardiovascular effects in single pollutant models and models adjusted for O_3.

The results for associations between short-term $PM_{2.5}$ exposure and cardiovascular effects in single pollutant models and copollutant models adjusted for NO_2 are presented in Figure 6-9. For this pair of pollutants, the correlations were generally positive and moderate to high, ranging from $r = -0.45$ to 0.80. Generally, the $PM_{2.5}$ effect estimates remained relatively unchanged in copollutant models adjusted for NO_2 across CVD effects. However, there were several exceptions to the trend, and in each of these

cases the effect of short-term $PM_{2.5}$ exposure decreased after adjusting for NO_2 in the model (Chang et al., 2015; Chang et al., 2013; Chiu and Yang, 2013; Dennekamp et al., 2010). There were no instances when the inverse was observed (i.e., higher $PM_{2.5}$ associations after adjusting for NO_2).

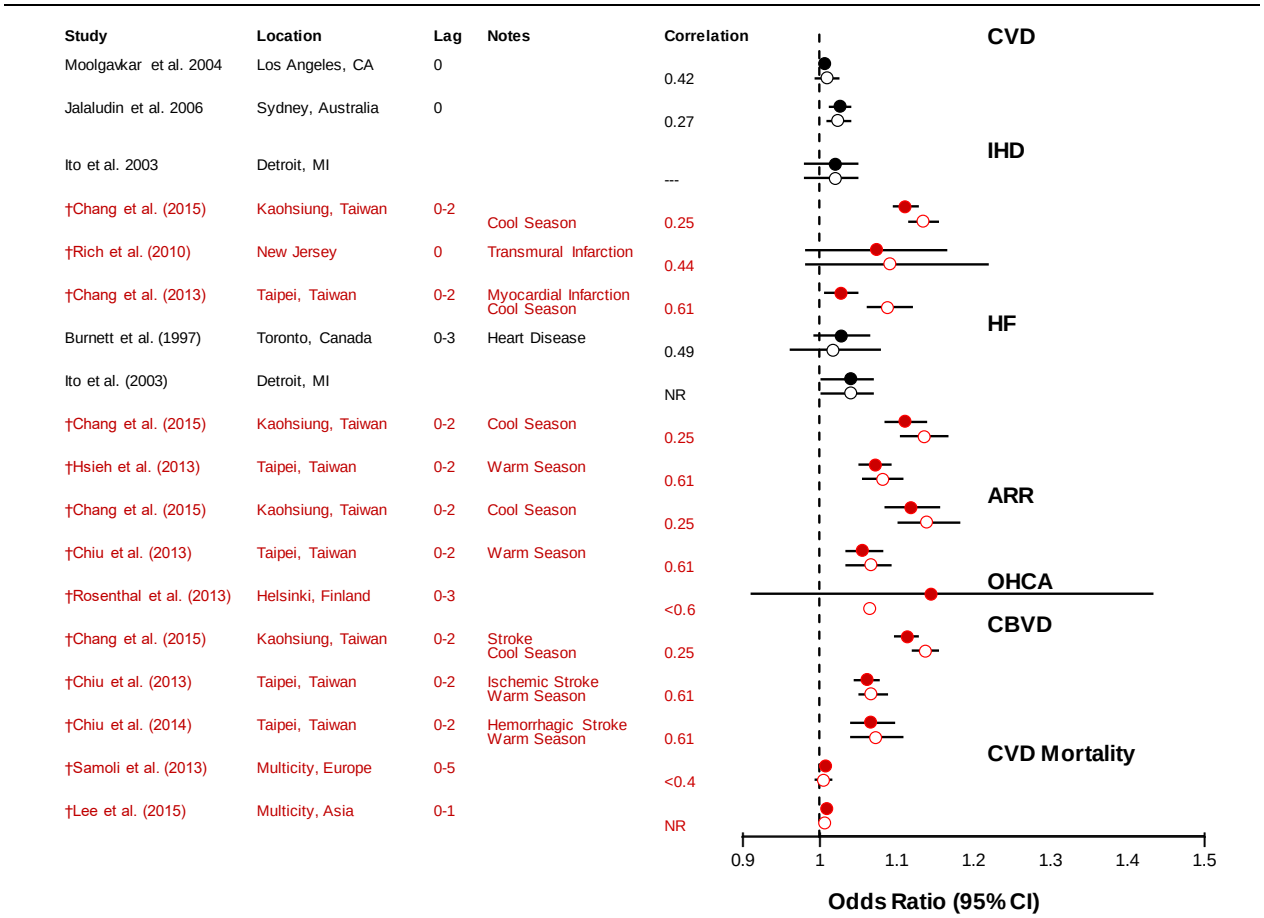


Associations are presented per 10 µg/m^3 increase in pollutant concentration. Circles represent point estimates; horizontal lines represent 95% confidence intervals for $PM_{2.5}$. Filled circles represent effect of $PM_{2.5}$ in single pollutant models, white circles represent effect of $PM_{2.5}$ adjusted for NO_2. Supplemental Table S6-12 (U.S. EPA, 2018). CVD: cardiovascular; IHD: ischemic heart disease; OHCA: out-of-hospital cardiac arrest; CBVD: cerebrovascular disease; NR: not reported. †Studies published since the 2009 PM ISA.

Figure 6-9 Associations between short-term exposure to $PM_{2.5}$ and cardiovascular effects in single pollutant models and models adjusted for NO_2.

The results for associations between short-term $PM_{2.5}$ exposure and cardiovascular effects in single pollutant models and copollutant models adjusted for SO_2 are presented in Figure 6-10. For this pair of pollutants, the correlations were generally positive and low to moderate, ranging from $r = -0.25$ to 0.61. Similar to ozone, the $PM_{2.5}$ effect estimates generally remained relatively unchanged in copollutant

models adjusted for SO_2 across CVD effects. In some instances, the magnitude of the $PM_{2.5}$ association increased slightly after adjusting for SO_2.

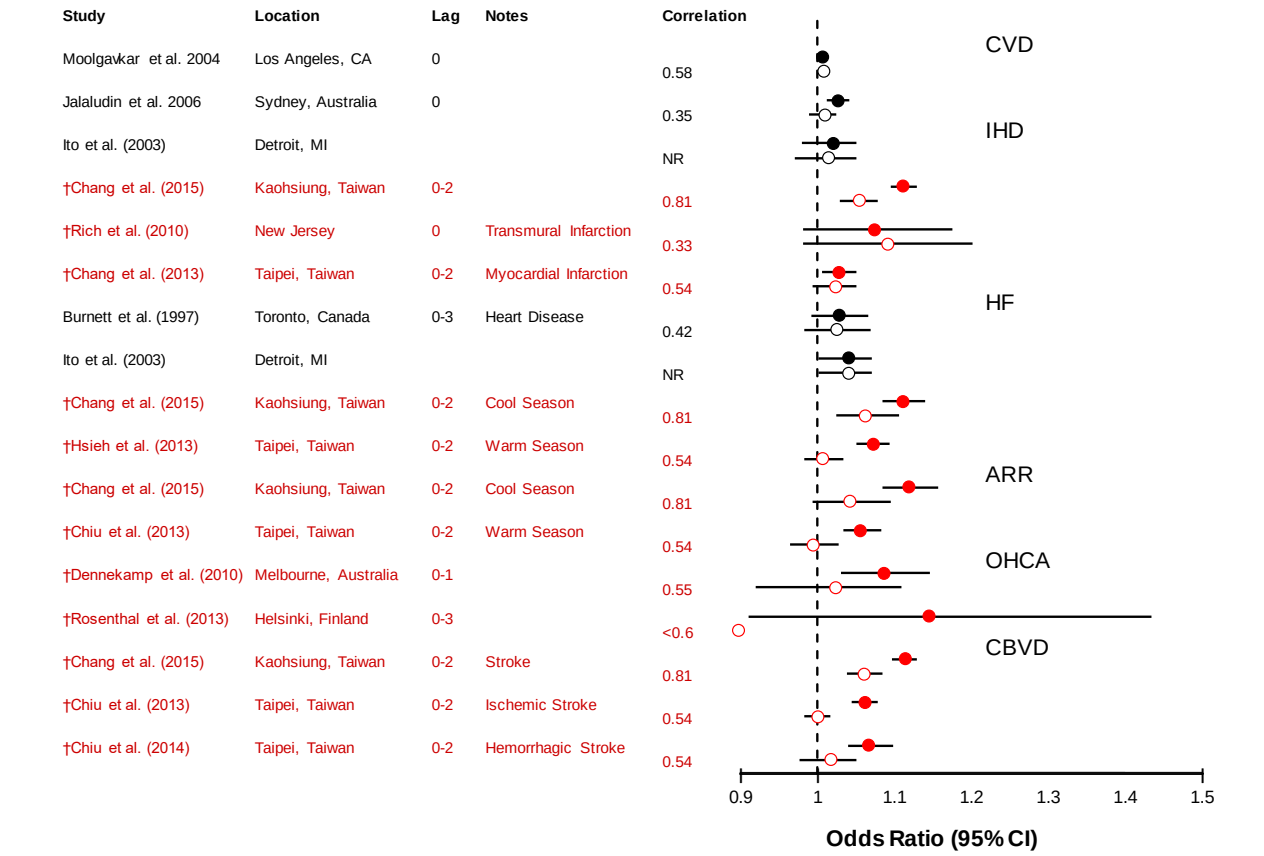


Associations are presented per 10 µg/m^3 increase in pollutant concentration. Circles represent point estimates; horizontal lines represent 95% confidence intervals for $PM_{2.5}$. Filled circles represent effect of $PM_{2.5}$ in single pollutant models, white circles represent effect of $PM_{2.5}$ adjusted for SO_2. Supplemental Table S6-13 (U.S. EPA, 2018). CVD: cardiovascular; IHD: ischemic heart disease; HF: heart failure; ARR: arrhythmia; OHCA: out-of-hospital cardiac arrest; CBVD: cerebrovascular disease; NR: not reported. †Studies published since the 2009 PM ISA.

Figure 6-10 Associations between short-term exposure to $PM_{2.5}$ and cardiovascular effects in single pollutant models and models adjusted for SO_2.

The results for associations between short-term $PM_{2.5}$ exposure and cardiovascular effects in single pollutant models and copollutant models adjusted for CO are presented in Figure 6-11. For this pair of pollutants, the correlations were generally positive and moderate to high, ranging from $r = -0.33$ to 0.81. Generally, the $PM_{2.5}$ effect estimates remained relatively unchanged in copollutant models adjusted

for CO across CVD effects. However, there were several exceptions to the trend. Similar to NO_2, there were several instances in which the effect of short-term $PM_{2.5}$ exposure decreased after adjusting for CO in the model (Chang et al., 2015; Chiu et al., 2014; Chiu and Yang, 2013; Hsieh et al., 2013; Dennekamp et al., 2010). There were no instances when the inverse was observed (i.e., higher $PM_{2.5}$ associations after adjusting for NO_2).

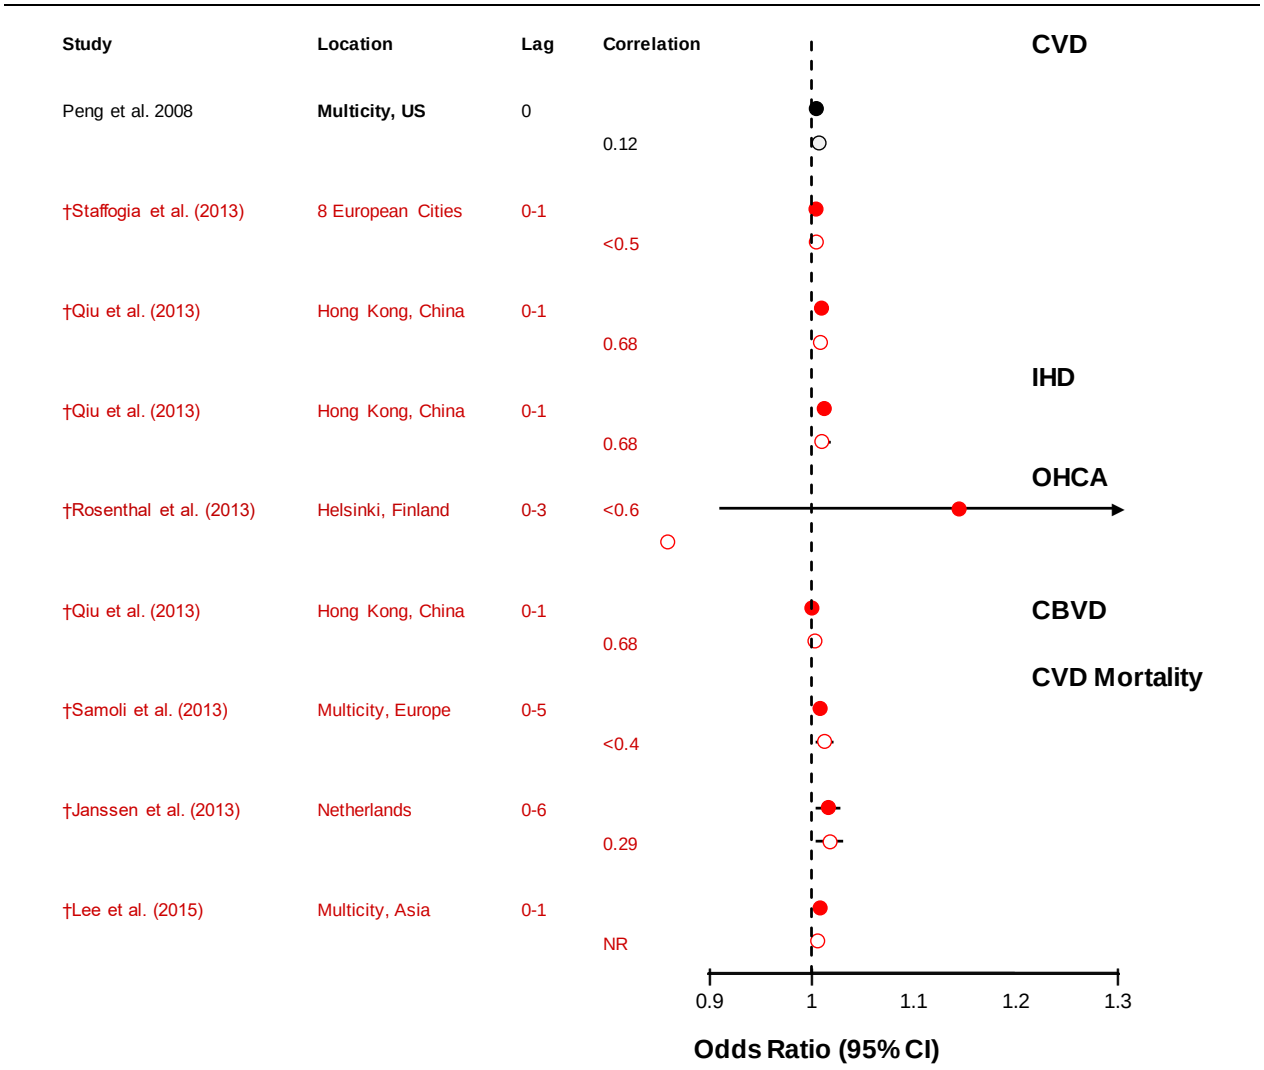


Associations are presented per 10 µg/m^3 increase in pollutant concentration. Circles represent point estimates; horizontal lines represent 95% confidence intervals for $PM_{2.5}$. Filled circles represent effect of $PM_{2.5}$ in single pollutant models, white circles represent effect of $PM_{2.5}$ adjusted for CO. Supplemental Table S6-14 (U.S. EPA, 2018). CVD: cardiovascular; IHD: ischemic heart disease; HF: heart failure; ARR: arrhythmia; OHCA: out-of-hospital cardiac arrest; CBVD: cerebrovascular disease; NR: not reported. †Studies published since the 2009 PM ISA.

Figure 6-11 Associations between short-term exposure to $PM_{2.5}$ and cardiovascular effects in single pollutant models and models adjusted for CO.

The results for associations between short-term $PM_{2.5}$ exposure and cardiovascular effects in single pollutant models and copollutant models adjusted for $PM_{10-2.5}$ are presented in Figure 6-12. For this

pair of pollutants, the correlations were generally positive and low to moderate, ranging from $r = -0.12$ to 0.68. Similar to ozone and SO_2, the $PM_{2.5}$ effect estimates generally remained relatively unchanged in copollutant models adjusted for SO_2 across CVD effects, except for in the study by (Rosenthal et al., 2013), for which the association was attenuated and became negative after adjusting for $PM_{10-2.5}$.



Associations are presented per 10 µg/m^3 increase in pollutant concentration. Circles represent point estimates; horizontal lines represent 95% confidence intervals for $PM_{2.5}$. Filled circles represent effect of $PM_{2.5}$ in single pollutant models, white circles represent effect of $PM_{2.5}$ adjusted for $PM_{10-2.5}$. Supplemental Table S6-15 (U.S. EPA, 2018). TIA: transient ischemic attack; CVD: cardiovascular; IHD: ischemic heart disease; OHCA: out-of-hospital cardiac arrest; CBVD: cerebrovascular disease; NR: not reported. †Studies published since the 2009 PM ISA.

Figure 6-12 Associations between short-term exposure to $PM_{2.5}$ and cardiovascular effects in single pollutant models and models adjusted for $PM_{10-2.5}$.

Overall, there are many more studies evaluating potential copollutant confounding using two-pollutant models than were available in the 2009 PM ISA. This new evidence generally demonstrates that the associations observed with $PM_{2.5}$ and cardiovascular effects in single pollutant models remain relatively unchanged in copollutant models, indicating that the observed associations with $PM_{2.5}$ are not artifacts due to confounding of another air pollutant. We did not observe any difference in the trend or pattern of these results across cardiovascular endpoints (e.g., aggregate CVD endpoints, IHD, heart failure, cardiovascular mortality). While the evidence is generally consistent across the copollutants evaluated, it was especially consistent for air pollutants that are not typically associated with traffic (i.e., ozone, SO_2, $PM_{10–2.5}$). While few, some inconsistencies were observed for the traffic-related pollutants (i.e., NO_2, CO), which generally had high correlations with $PM_{2.5}$ than the other copollutants. Due to these higher correlations, it is difficult to distinguish if any attenuation in $PM_{2.5}$ associations after adjusting for copollutants could be due to confounding, or if collinearity may play a role.

6.1.14.1.1 $PM_{2.5}$ within the Multipollutant Mixture

Although copollutant models are important in assessing potential copollutant confounding, it is well known that collinearity between pollutants can result in unstable estimates and that air masses are not limited to just two pollutants (Dominici et al., 2010). Therefore, in addition to copollutant models, studies that examine multipollutant exposures can provide additional information on the role of $PM_{2.5}$ within the complex air pollution mixture.

Analyses of pollutant mixtures use an array of statistical methods and pollutant combinations while examining cardiovascular-related effects, and were recently reviewed by (Luben et al., 2018). Luben et al. (2018) conducted a cross-disciplinary evaluation of the multipollutant effects on cardiovascular disease, integrating results from epidemiologic studies with controlled human exposure and animal toxicological studies. Overall, the review demonstrated a paucity of evidence available to characterize the multipollutant effects of air pollution on cardiovascular outcomes. Across the limited number of studies, the evidence neither consistently nor coherently indicated a stronger or weaker effect of combined exposure to $PM_{2.5}$ and another pollutant compared to exposure to a single pollutant alone.

6.1.14.2 The Role of Season and Temperature on $PM_{2.5}$ Associations

The examination of seasonal differences in $PM_{2.5}$ associations within studies that focus on cardiovascular-related hospital admissions and ED visits, as well as cardiovascular mortality, can provide information that could be used to assess whether specific sources that vary by season are contributing to the $PM_{2.5}$ associations observed in all-year analyses. Additional studies that examine potential modification of $PM_{2.5}$ associations by temperature can further elucidate the impact of season on observed associations. Studies evaluated in the 2009 PM ISA, demonstrated seasonal variability in $PM_{2.5}$

associations with cardiovascular-related effects, which is further supported by recent studies, while fewer studies have examined potential modification of $PM_{2.5}$ associations by temperature.

Different trends are observed when the role of season or temperature is evaluated across different cardiovascular endpoints (Figure 6-6). For example, among studies that evaluated short-term $PM_{2.5}$ exposure and ischemic heart disease, several studies observed no seasonal differences in associations (Rich et al., 2010; Szyszkowicz, 2009; Zanobetti et al., 2009), while Talbott et al. (2014) observed stronger associations during the cool season in some regions of New York. Similarly, there was no consistent trend for the effect of $PM_{2.5}$ on cerebrovascular disease across different seasons, with some studies observing stronger associations in the warm season (Chen et al., 2014b; Villeneuve et al., 2012), some studies observing strong associations in the cool season (Talbott et al., 2014), and others observing no seasonal differences in the association with $PM_{2.5}$ (O'Donnell et al., 2011).

Season had a more consistent effect on the relationship between short-term $PM_{2.5}$ exposure and other cardiovascular endpoints, such as heart failure, arrhythmias and aggregate cardiovascular disease (Figure 6-6). For both heart failure and arrhythmias, each of the limited number of studies reported stronger associations with short-term $PM_{2.5}$ exposure during the cool season. This general trend was also observed in studies evaluating aggregate CVD endpoints, with the majority of these studies observing stronger associations in the cool season. Conversely, the majority of studies evaluating the role of season or temperature on the effect of short-term $PM_{2.5}$ exposure on cardiovascular mortality observed stronger associations in the warm season. This trend was consistent across studies conducted in North America and Europe, whereas studies conducted in Asia tended to report stronger associations during the cool season or with lower temperatures.

Overall, there is no consistent role of season or temperature on the effect of short-term $PM_{2.5}$ exposure on cardiovascular morbidity or mortality. There is a limited number of studies that evaluate each of the different cardiovascular endpoints, and the evidence from these limited studies indicates inconsistent or no seasonal effects for some endpoints (i.e., ischemic heart disease, cerebrovascular disease), while the limited evidence more consistently indicates stronger associations during the cool season (for heart failure, arrhythmia, aggregate cardiovascular disease) or warm season (for cardiovascular mortality). In addition to the limited number of studies available to inform the role of season on the effect of short-term $PM_{2.5}$ exposure on cardiovascular effects, there are other factors the contribute uncertainty to this body of evidence. Variability in season-stratified results for different single-day lags make it difficult to draw inferences from this body of evidence. For example, Ito et al. (2011) observed no seasonal differences in the associations with CVD mortality for Lag day 1, but when evaluating Lag day 0, the authors reported strong positive associations in the warm season and strong negative associations during the cool season. Additionally, there is evidence of regional heterogeneity in the role of season on the effect of short-term $PM_{2.5}$ exposure on cardiovascular endpoints. Regional heterogeneity in results was observed both within studies that included multiple geographic study locations (e.g., (Talbott et al., 2014)) and across studies conducted in geographic locations (e.g., among

studies of CVD mortality, more likely to observe stronger associations in warm season for studies conducted in North America and Europe, but more likely to see stronger associations during cool season/cooler temperatures for studies conducted in Asia). Overall, the evidence across studies is inconclusive as to whether season or temperature modifies the association between short-term $PM_{2.5}$ exposure and cardiovascular endpoints.

6.1.14.3 The Effect of Lag Structure on Associations of Short-Term $PM_{2.5}$ Exposure and Cardiovascular Effects

An examination of the association between short-term $PM_{2.5}$ exposure and cardiovascular effects across different Lag days can inform whether $PM_{2.5}$ elicits an immediate, delayed, or prolonged effect on these endpoints, and whether the effect of $PM_{2.5}$ is consistent across cardiovascular endpoints. Recent studies provide evidence that allows for the comparison of immediate (single or multiday lags including lags 0−1), delayed (single or multiday lags including lags 2−5) or prolonged (multiday lags spanning at least four days, e.g., lag 0−5) exposure periods. Generally, evidence from studies that evaluate cardiovascular hospital admissions and ED visits indicates positive associations within the first few days after exposure, specifically for immediate single-day lags (i.e., Lag days 0 or 1) and multiday lags (i.e., Lag days 0−1, 0−2, or 0−3), with greater magnitude and precision of the association for multiday lags compared to single-day lags.

Generally, among studies that compared different single-day or multiday lag periods in evaluations of aggregate CVD hospital admissions and ED visits, stronger associations were observed for immediate Lag days, especially lag 0, compared to delayed or prolonged lag periods (Bell et al., 2014; Talbott et al., 2014; Qiu et al., 2013; Stafoggia et al., 2013a; Kim et al., 2012; Ito et al., 2011). For example, the left panel of Figure 6-13 (single day lag figure from Kim et al. 2012) demonstrates the stronger positive association for aggregate CVD hospital admissions with exposure on lag 0 compared to other single-day lags reported by Kim et al. (2012). Among studies that compared single-day lags and multiday lag periods, stronger associations were observed with multiday lag periods (e.g., lag 0−1, 0−2) and aggregate CVD hospital admissions and ED visits (Talbott et al., 2014; Qiu et al., 2013), though Bravo et al. (2017) observed generally similar effects for both single-day and multiday lag periods spanning immediate, delayed and prolonged exposure windows. Also, Milojevic et al. (2014) observed no difference in effects when examining immediate (i.e., 0−1) or prolonged (i.e., 0−4) multiday lags.

Similar to the results for studies focusing on aggregate CVD outcomes, comparison of lag periods in studies of several cause-specific CVD hospital admission and ED visits reported the strongest associations with immediate lag periods. Studies that examined the lag structure of associations between $PM_{2.5}$ and IHD (including MI and MI subtypes) largely provide evidence of immediate $PM_{2.5}$ effects with null or negative associations when examining delayed lags (Weichenthal et al., 2016b; Talbott et al., 2014; Kim et al., 2012; Rich et al., 2010; Haley et al., 2009; Stieb et al., 2009). For example, the right panel of Figure 6-13 demonstrates the stronger positive association for IHD hospital admissions with

exposure on lag 0 compared to other single-day lags reported by Kim et al. (2012). The observed risks were generally greater in magnitude for multiday lags (i.e., lag 0−1) compared to single-day lags (i.e., lag 0, lag 1). Similar results were observed for studies investigating short-term $PM_{2.5}$ exposure and heart failure (Talbott et al., 2014; Haley et al., 2009; Stieb et al., 2009), though Kim et al. (2012) observed positive associations for delayed lags (single day lags 2, 3, and 4) and a negative association for Lag day 0. Among recent studies evaluating the relationship between short-term $PM_{2.5}$ exposure and OHCA, authors generally observed the strongest associations for immediate lag periods (Ensor et al., 2013; Rosenthal et al., 2013; Dennekamp et al., 2010; Silverman et al., 2010), though some found delayed associations days (Wichmann et al., 2013).

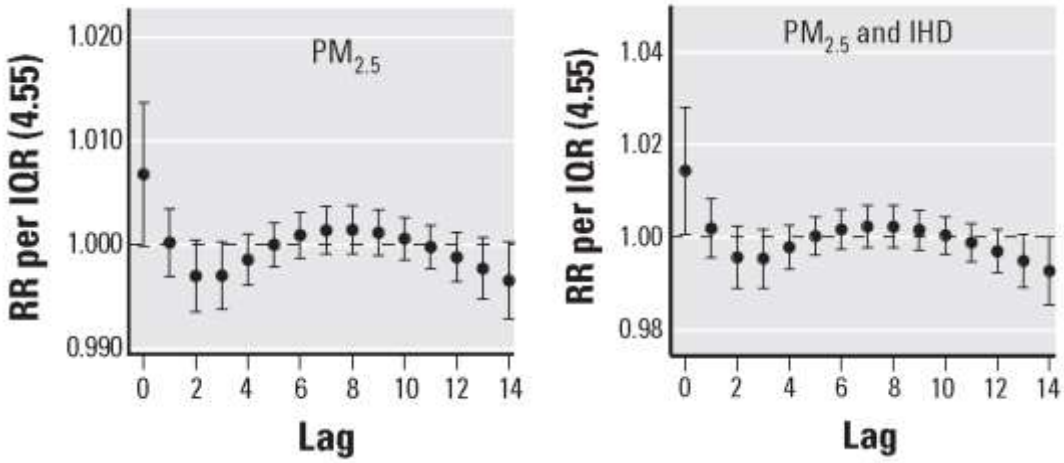


Figure 6-13 Pattern of RRs for single day lags 0−14 for aggregate cardiovascular disease (CVD) hospitalizations (left) and IHD hospitalizations (right) reported by Kim et al. (2012).

Most of the studies that examined multiple lag periods reported no evidence of a positive association between short-term $PM_{2.5}$ exposure and hospital admissions and ED visits for CBVD at any of the lag periods evaluated (Qiu et al., 2013; Kim et al., 2012; O'Donnell et al., 2011; Haley et al., 2009). However, when evaluating specific stroke subtypes, Lisabeth et al. (2008) and Wing et al. (2015) observed positive associations between $PM_{2.5}$ concentrations and ischemic stroke for immediate Lag days (lags 0 or 1), but not for delayed lags (single day lags 2, 3,4, 5). Limited evidence was inconsistent when comparing different lag periods in studies of ED visits and hospital admissions for arrhythmia. Talbott et al. (2014) reported positive associations for immediate lag periods (lag 0, 1, 0−1) with stronger associations observed for multiday lags compared to single-day lags. In contrast, Haley et al. (2009) observed negative associations for both immediate (i.e., 0,1) and delayed (i.e., 2, 3,4) single day lags in their evaluation of arrhythmia ED visits.

Recent multicity studies of short-term $PM_{2.5}$ exposure and cardiovascular mortality have conducted extensive examinations of the lag structure of associations. Of these studies, some only examined single-day lags (Lippmann et al., 2013c) or multi-day lags (Milojevic et al., 2014), while a few examined multi-day lags aimed at specifically addressing whether there is evidence of an immediate (lag 0−1 days), delayed (lag 2−5 days), or prolonged (lag 0−5 days) effect of $PM_{2.5}$ on cardiovascular mortality. Several studies provide evidence of an immediate $PM_{2.5}$ effect on cardiovascular mortality with associations largest in magnitude at lag 0 (Stafoggia et al., 2017; Janssen et al., 2013; Lippmann et al., 2013c; Samoli et al., 2013). Lanzinger et al. (2016a) and Samoli et al. (2013) provide some evidence indicating the potential for stronger associations with short-term $PM_{2.5}$ exposure averaged over delayed (e.g., lag 2−5) and prolonged (e.g., lag 0−5) lag periods and CVD mortality. Overall, recent multicity studies that examined the lag structure of associations, generally support the immediate effect of $PM_{2.5}$ on cardiovascular mortality, but also provide some evidence that associations may exist for exposures averaged over longer durations. However, the initial studies examining multi-day lags providing evidence of a delayed or prolonged effect are not supported when examining a series of single-day lags over the same duration.

Additionally, few studies examined subdaily averaging times, or exposures averaged over one or multiple hours during Lag day 0. In Rochester, New York, Gardner et al. (2014) observed positive associations between STEMI and $PM_{2.5}$ at lags of 0 hours and 0−2 hours, with evidence of positive associations for multi-hours lags up to 24 hours. Several studies investigating OHCA also examined subdaily averaging times, and generally observed positive associations, though the associations were consistently higher in magnitude for daily lags (single and multiday lags 0−4) compared to the subdaily lags (Straney et al., 2014; Ensor et al., 2013; Rosenthal et al., 2013). For example, Ensor et al. (2013) observed a small increase in risk of OHCA consistent with an increase in $PM_{2.5}$ concentrations in the hour preceding the OHCA event (1.84% [95% CI: −2.16, 5.90%]), but a larger magnitude association corresponding to an increase in 2-day moving average $PM_{2.5}$ (6.58% [95% CI: 0.83, 12.64%]). Wellenius et al. (2012a) considered subdaily averaging times when evaluating CBVD endpoints and observed positive associations for ischemic stroke at hourly lags ranging from 0 to 26 hours, with the largest magnitude of associations for lags from 8 to 20 hours. Overall, these evaluation of subdaily lags provide additional support for the immediate effect of short-term $PM_{2.5}$ exposure on cardiovascular hospital admissions, ED visits, and mortality.

In summary, there is evidence to support an immediate effect of short-term $PM_{2.5}$ exposure on hospital admissions and ED visits for aggregate CVD outcomes, IHD, HF and OHCA, as well as for cardiovascular mortality. This evidence comes from the evaluation of both single-day and multiday lags, as well as studies that evaluated subdaily lag periods. In contrast, the evidence was less consistent across studies, as well as across different lag periods within the same study, for associations between short-term $PM_{2.5}$ exposure and hospital admissions and ED visits for CBVD or arrhythmia. Overall, stronger associations were observed for immediate lags for most CVD outcomes, and the associations tended to be

stronger for immediate multiday lag periods (i.e., 0−1, 0−2) compared to immediate single-day lag periods (i.e., 0, 1).

6.1.15 Associations between $PM_{2.5}$ Components and Sources and Cardiovascular Effects

While many PM components are associated with a range of health effects, the 2009 PM ISA concluded that there was not sufficient evidence to differentiate between the PM components or sources that more closely related to health effects than $PM_{2.5}$ mass (U.S. EPA, 2009). However, there was some evidence for associations between increases in cardiovascular effects (e.g., hospital admissions and cardiovascular mortality) with sulfate particles and EC. In addition, several PM sources (i.e., crustal/soil/road dust and traffic) were associated with increased cardiovascular mortality and ST-segment changes. Generally, studies evaluated in the 2009 PM ISA that evaluated individual PM components and sources observed inconsistent results, with no apparent trend or pattern of effect across $PM_{2.5}$ components or across CVD endpoints.

Numerous recent studies examine short-term exposure to $PM_{2.5}$ sources or components and cardiovascular effects and the results are generally consistent with those reported in the 2009 PM ISA. To clearly illustrate the uncertainty in attributing cardiovascular effects to individual $PM_{2.5}$ components or sources versus $PM_{2.5}$ mass, this section is organized by component or source and discussed in the context of associations with $PM_{2.5}$ mass. In cases where studies examined short-term exposure to a $PM_{2.5}$ component or source and any cardiovascular health outcome, the evidence for the relationship is evaluated and synthesized below. This allows for integration across cardiovascular health endpoints in the evaluation of $PM_{2.5}$ components and sources. In each case, the evidence for the $PM_{2.5}$ component or source was evaluated in the context of the available evidence for the relationship with $PM_{2.5}$ mass.

The examination of the relationship between $PM_{2.5}$ components and CVD can generally be divided into two types of analyses: (1) those that examine whether specific components modify the $PM_{2.5}$-cardiovascular effects association, or (2) those that examine whether an individual component is associated with cardiovascular effects and potentially a better indicator of PM toxicity compared to PM mass. Although approach 1 is considered one of the techniques used to assess component toxicity as detailed in Mostofsky et al. (2012), these studies are often used to examine heterogeneity in $PM_{2.5}$-CVD risk estimates. As a result, the focus of this section is on those techniques that fall under approach 2, which includes assessing $PM_{2.5}$ component effect by component concentration or component concentration adjusted for $PM_{2.5}$ mass. Other techniques identified by Mostofsky et al. (2012) that would fall under approach 2 (i.e., component residual or $PM_{2.5}$ residual) were not used in the evaluation of $PM_{2.5}$ components and CVD health effects.

Taking this approach, the evidence does not demonstrate an individual PM component or source that is more consistently associated with CVD health endpoints. The largest body of evidence examining

the association with $PM_{2.5}$ components is for ED visits or hospital admissions for aggregate CVD, and these results are summarized in Figure 6-14 and Figure 6-15. Figure 6-14 provides a snapshot of the evidence from studies of aggregate CVD ED visits and hospital admissions that evaluated associations with both $PM_{2.5}$ and $PM_{2.5}$ components. The evidence varies among components, with some studies finding positive associations between almost all $PM_{2.5}$ components evaluated and various cardiovascular health outcomes. The figure demonstrates the most consistent, positive associations with $PM_{2.5}$ mass, though similar patterns of associations are observed with EC, OC and, though evaluated in fewer studies, several metals (e.g., V, Zn, Si, Ni). Overall, associations with aggregate CVD ED visits and hospital admissions are not more clearly linked to a particular $PM_{2.5}$ component compared with $PM_{2.5}$ mass, and within-study comparisons do not show a consistent difference in association between $PM_{2.5}$ mass and a particular component (Figure 6-14). While the number of studies is more limited for other CVD endpoints (e.g., cause-specific ED visits and hospital admissions, measures of blood pressure, HRV, vascular function, and biomarkers of inflammation and oxidative stress), similar trends in associations are observed within and across studies evaluating these endpoints. Several sources of uncertainty common among studies of $PM_{2.5}$ components and sources limit their ability to contribute to causal inference. These include measurement error due to spatiotemporal heterogeneity and poorly addressed potential confounding by other components in the $PM_{2.5}$ mixture. The evidence for $PM_{2.5}$ components and sources is detailed below.

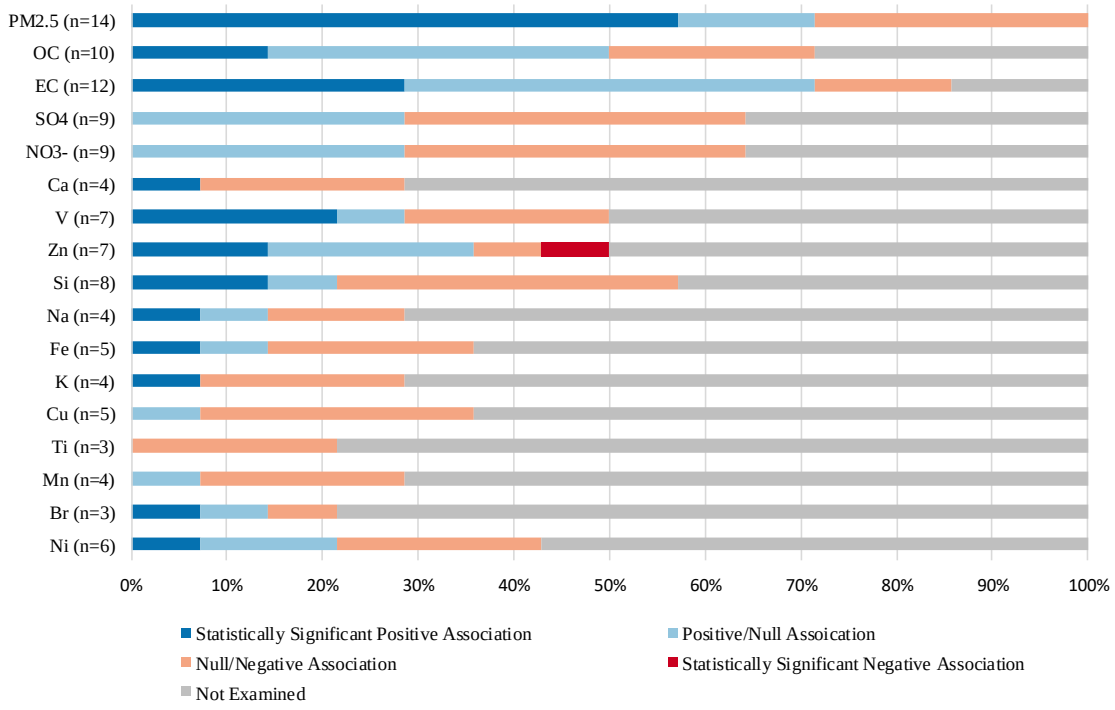
Note: Cells represent associations examined for studies of $PM_{2.5}$ mass and $PM_{2.5}$ components and aggregated cardiovascular hospital admissions or emergency department visits. Numbers within cells represent lag(s) at which association was observed. Dark blue = statistically significant positive association; light blue = positive association; light orange = null or negative association; red = statistically significant negative association; grey = component not examined. Only $PM_{2.5}$ components for which there were at least three studies available were included in the table. $PM_{2.5}$ = particulate matter with mean aerodynamic diameter 2.5 µm, OC = organic carbon, EC = elemental carbon, SO_4^{2-} = sulfate, NO_3^- = nitrate.

Figure 6-14 Heat map of associations observed between short-term $PM_{2.5}$ and $PM_{2.5}$ component exposure and hospital admissions and emergency department visits for cardiovascular-related effects.



Note: Bars represent the percent of associations across studies for $PM_{2.5}$ mass or $PM_{2.5}$ components for aggregated cardiovascular hospital admissions and emergency room visits where dark blue = statistically significantly positive, light blue = positive, light orange = null/negative, red = statistically significantly negative, and grey hatch = not examined. N = number of studies that provided an estimate. $PM_{2.5}$ = particulate matter with mean aerodynamic diameter 2.5 µm, OC = organic carbon, EC = elemental carbon, SO_4^{2-} = sulfate, NO_3^- = nitrate.

Figure 6-15 Distribution of associations for hospital admissions and emergency department visits for cardiovascular-related effects and short-term $PM_{2.5}$ and $PM_{2.5}$ components exposure in studies detailed in Figure 6-14.

6.1.15.1 Elemental and Black Carbon

In coronary artery disease patients in Boston, MA similar negative associations were observed between $PM_{2.5}$ and BC with rMSSD for 30-minute up to 5-day exposures (Zanobetti et al., 2010). Negative associations were also observed for HF, although associations were stronger for BC than $PM_{2.5}$ with averaging times from 2−5 days. No associations were observed in this panel for $PM_{2.5}$ exposures with SDNN, but BC exposures from 30-minutes up to 2-hours were reduced (Zanobetti et al., 2010). Associations were similar for BC and $PM_{2.5}$ in studies conducted with panels having pre-existing cardiovascular disease as Schneider et al. (2010) and Bartell et al. (2013) observed negative associations between BC and $PM_{2.5}$ with pNN50 and rMSSD, or HRV, respectively. Finally, Weichenthal et al. (2014a), in a quasi-experimental study that included women cycling on high and low traffic routes for 2-hours, found that associations between SDNN, LF, and LF/HF were similarly positive for both $PM_{2.5}$

and BC. However, negative associations observed between $PM_{2.5}$ and rMSSD and pNN50 were not observed for BC.

Several studies examined associations between measures of vascular function and ambient BC concentrations in addition to $PM_{2.5}$. While Madrigano et al. (2010) reported positive associations between VCAM-1 and BC that were not observed for $PM_{2.5}$, other studies did not find associations between BC and VCAM-1 or other biomarkers of vascular function including VEGF, ICAM-1, and ET-1 (Wilker et al., 2011; Liu et al., 2009). Ljungman et al. (2014) report evidence for associations between BC and pulse wave amplitude for 2 to 5-day averages in the Framingham Heart Study, which was consistent with results for $PM_{2.5}$.

In a quasi-experimental study conducted by Strak et al. (2013a), associations were null for fibrinogen and platelet counts with $PM_{2.5}$ and BC; however, positive associations were reported between $PM_{2.5}$ and vWF that were not observed for BC. Conversely, substantial reductions in lag time in FXII-mediated (intrinsic) thrombin generation were associated with BC exposures but not $PM_{2.5}$ exposures (Strak et al., 2013b). Croft et al. (2017) and Chen et al. (2017) also examined associations between BC and biomarkers related to coagulation in panels of adults with pre-existing cardiovascular conditions and observed positive associations between BC and fibrinogen and 12-hour up to 3-day lagged exposures; although associations with $PM_{2.5}$ were only observed by Croft et al. (2017) and 1−24 hour lags. Associations were not observed for D-dimer or vWF in these studies.

In a panel study including 31 young, healthy adults exposed to air pollution at five different sites with intermittent exercise, Steenhof et al. (2014) reported mixed results for associations between EC and WBC counts measured 2 and 18 hours post-exposure, though patterns in associations were very similar to those for $PM_{2.5}$. More specifically, positive associations were observed for WBC counts, neutrophils 2 hours post-exposure, and monocytes 18 hours post-exposure. In this same panel, positive associations were observed for both $PM_{2.5}$ and EC, but the magnitude of effect was smaller for EC (Strak et al., 2013a).

Liu et al. (2009) did not find evidence for associations between 24-hour outdoor BC or personal measurements of $PM_{2.5}$ and biomarkers for inflammation or oxidative stress (i.e., IL6, TNF-α, TBARS, 8-isoprostane) in a panel of older adults residing in retirement communities. Similar results were observed in studies conducted by Wittkopp et al. (2013) and Chen et al. (2017) in panels of adults with coronary artery disease or having risk factors for CVD as null associations were observed for CRP and up to 5-day averages of EC or 3-day lags for BC. In contrast, Croft et al. (2017) reported positive associations for CRP and 12 and 24-hour lags of BC, although negative associations were observed with myeloperoxidase, a marker for neutrophil activity.

6.1.15.2 Organic Carbon

In contrast with previous studies, recent studies generally support an association of OC with CVD-related hospital admissions, ED visits, cardiovascular function metrics (e.g., HRV), and biomarkers of inflammation (e.g., WBC, CRP). Due to the relatively few studies, it is difficult to judge the consistency of recent results for any one CVD endpoint. That said, the consistency and magnitude of CVD effect associations generally are similar for OC and $PM_{2.5}$ (Figure 6-14 and Figure 6-15), which are in line with the large contribution of OC to total $PM_{2.5}$ mass (Section 2.4.4).

Like $PM_{2.5}$, OC was associated with CVD-related ED visits and hospital admissions in locations across U.S. regions. One of the most informative studies is an extensive analysis of Medicare beneficiaries in 64 cities, which found CVD hospital admissions were associated with OC, particularly during the cold season at lag 0 (Ito et al., 2013). While these associations were strongest at lag 0 in the cold season, OC showed associations present at longer lag periods; however, no individual component had stronger associations than $PM_{2.5}$ mass. A study in Denver, CO reported that $PM_{2.5}$ concentrations of OC were associated with hospital admissions for IHD and aggregate CVD (Kim et al., 2012). On the other hand, in Denver, CO Kim et al. (2012) did not observe a positive association between OC and CBVD hospital admissions. Sarnat et al. (2015) observed a positive association between ED visits for heart failure and $PM_{2.5}$ OC content in the St. Louis, MO metropolitan area. A study of eight California counties found a small positive association with CVD hospital admissions and vehicle-related $PM_{2.5}$ and OC.

A recent study evaluated HRV metrics and exposure to OC in patients with IHD in Erfurt, Germany; an increase in 24-hour exposure to OC was associated with decreases in HF, rMSSD, and pNN50; similar associations were observed for $PM_{2.5}$ with the exception of the association with HF (Schneider et al., 2010). In addition, a number of studies observed positive associations between OC exposure and biomarkers of coagulation and inflammation. In a quasi-experimental study conducted in Utrecht, the Netherlands, OC was associated with fibrinogen, platelet counts, and vWF (Strak et al., 2013a), while associations were only observed between $PM_{2.5}$ and vWF in this study. Chen et al. (2017) did not observe associations between fibrinogen and OC or $PM_{2.5}$, but positive associations were reported for D-dimer and OC with 1 and 2-day lagged exposures. In a recent panel study, Steenhof et al. (2014) reported mixed results for associations between OC and WBC counts measured 2 and 18 hours post-exposure, though patterns in associations were generally similar to those for $PM_{2.5}$. More specifically, positive associations were observed for WBC counts and monocytes 18 hours post-exposure, though OC was associated with lymphocytes and not neutrophils in contrast to $PM_{2.5}$. In this same panel, positive associations were observed for both $PM_{2.5}$ and OC, but the magnitude of effect was larger for OC (Strak et al., 2013a). Wittkopp et al. (2013) and Chen et al. (2017) examined OC in a panel of older adults and those with risk factors for cardiovascular disease, respectively, and did not find evidence for associations with CRP, although Wittkopp et al. (2013) did find positive associations with soluble receptor for IL6 that were not observed for $PM_{2.5}$.

6.1.15.3 Secondary $PM_{2.5}$—Sulfate, Nitrate, Ammonium

Several recent studies add to the limited supporting evidence in the 2009 PM ISA for associations of sulfate (SO_4^{2-}), nitrate (NO_3^-), and ammonium (NH_4^+) with CVD ED visits and hospital admissions, though the evidence is not entirely consistent. Evidence for effects on other CVD outcomes is limited. In most locations, results are similar between $PM_{2.5}$ and sulfate and nitrate in direction and magnitude of association.

An analysis of Medicare data across 119 U.S. counties found that nitrates from $PM_{2.5}$ were associated with CVD hospital admissions (Levy et al., 2012), and Peng et al. (2009) observed a similar pattern in the same population over a slightly shorter time period. Similarly, Sarnat et al. (2015) observed that ED visits for IHD were positively associated with $PM_{2.5}$ nitrates in St. Louis, MO. In 4 cities in southern Europe, Basagaña et al. (2015) reported positive associations with sulfate from $PM_{2.5}$. In contrast, studies in Denver (Kim et al., 2012), Houston (Liu et al., 2016b) and California (Ostro et al., 2016) reported that $PM_{2.5}$ concentrations of sulfates and nitrates were not associated with aggregate CVD hospital admissions. Using data for transmural myocardial infarctions in the NJ MIDAS registry, Rich et al. (2010) observed the largest effects on the days with the highest tertile of sulfate, nitrate, and ammonium, and the lowest tertile of elemental carbon. The authors interpreted their findings as indicating that $PM_{2.5}$ on days with pollution mixtures that are formed through atmospheric chemistry and depleted in primary $PM_{2.5}$ pollutants were most strongly associated with transmural infarctions.

Evidence for associations between sulfate or nitrate and other CVD endpoints is more limited, but generally positive. Despite reporting a generally null association between $PM_{2.5}$ and ICD activations, Anderson et al. (2010) observed a positive association between SO_4^{2-} and atrial fibrillation in London, England. Strak et al. (2013a) examined associations between sulfate and nitrate with fibrinogen, platelet counts, and vWF. Positive associations were observed for both nitrate and sulfate with fibrinogen, though associations with $PM_{2.5}$ were null. In contrast, $PM_{2.5}$ and sulfate were positively associated with vWF, but associations with nitrate were null. In addition, the extrinsic coagulation pathway was positively associated with nitrate and sulfate, but null for $PM_{2.5}$ (Strak et al., 2013b).

6.1.15.4 Metals

Compared with $PM_{2.5}$ mass, short-term increases in ambient concentrations of metals are inconsistently associated with CVD ED visits and hospital admissions. In the expanded body of recent studies, none observed associations with a metal but not $PM_{2.5}$ mass (Figure 6-15). Most studies observed an association with some metal, and studies that examined numerous metals often observed an association with multiple metals. However, findings are inconsistent for any individual metal or the sum of metals.

Among Medicare beneficiaries in Connecticut and Massachusetts, Bell et al. (2014) found that $PM_{2.5}$ from Ca, Zn, and V were positively associated with CVD hospital admissions. In an additional

study of Medicare beneficiaries in 64 cities, CVD hospital admissions were associated with copper, iron, selenium, silicon, and zinc (Ito et al., 2013). No individual component had stronger associations than $PM_{2.5}$ mass. In separate analyses of hospital admissions (Liu et al., 2016b) and ED visits (Liu et al., 2016a) in Houston, TX authors reported positive associations between stroke and bromine, nickel (ED visits) and As (hospital admissions), but observed negative associations for zinc, calcium, iron, potassium, manganese, vanadium, (ED visits), and potassium, (hospital admissions). Sarnat et al. (2015) reported that ED visits for IHD were negatively associated with 24-hour concentrations of $PM_{2.5}$ Fe and Si concentrations in St. Louis, MO while CVD hospital admissions were negatively associated with Si concentrations. A study of eight California counties (Ostro et al., 2016) found a small positive association with potassium, and zinc, while Basagaña et al. (2015) reported positive associations with Zn, Fe, and Mn from $PM_{2.5}$ in 4 cities in southern Europe.

In Atlanta, GA Suh et al. (2011) observed that $PM_{2.5}$ transition metals were associated with CVD, and specifically IHD, hospital admissions. Similarly, in New York City, NY Ito et al. (2011) found that most of the $PM_{2.5}$ chemical components considered were associated with CVD hospital admissions, making it difficult to draw conclusions about specific components.

Ambient concentrations of metals can be spatiotemporally more heterogeneous than $PM_{2.5}$ total mass, and thus, exposure measurement error could contribute to inconsistent findings for metals. Another uncertainty not addressed in the evidence is whether metals are independently associated with CVD effects as gaseous pollutants were not examined and correlations with gases and other $PM_{2.5}$ components were generally not reported.

6.1.15.5 Other $PM_{2.5}$ components

New information links cardiovascular effects with cyclohexanes and hopanes, though information is available from few studies and locations for each. In a combined analysis from Atlanta, GA Birmingham, AL and Dallas, TX Kioumourtzoglou et al. (2013) observed that cyclohexane concentrations, a marker of gasoline exhaust, were associated with higher rates of IHD and heart failure. Sarnat et al. (2015) observed a positive association between ED visits for heart failure and hopanes in the St. Louis, MO metropolitan area, though Kioumourtzoglou et al. (2013) reported null associations with hopanes.

6.1.15.6 Sources of $PM_{2.5}$

Several recent studies apportioned $PM_{2.5}$ components into source factors and provide some evidence linking $PM_{2.5}$ from traffic to cardiovascular hospital admissions. Studies of CVD hospital admissions are note entirely consistent, but provide some evidence for an association with $PM_{2.5}$

concentration during wildfires. Evidence is generally sparse for $PM_{2.5}$ from dust or soil, oil, salt, and local industry.

Some studies have attempted to identify specific sources or components of $PM_{2.5}$ that may be most strongly associated with hospital admissions or ED visits for CVD. Cardiovascular hospital admissions were associated with $PM_{2.5}$ from motor vehicles or traffic in various U.S. regions. In New York City, NY Lall et al. (2011) found that IHD, heart failure, and cerebrovascular disease hospital admissions were associated with $PM_{2.5}$ from traffic, but not other $PM_{2.5}$ components. In a subsequent analysis in the same data set, Lall et al. (2011) found that $PM_{2.5}$ derived from traffic was associated with same-day rates of hospital admissions for CVD while $PM_{2.5}$ from soil was inversely related. A study of eight California counties found small, positive associations with hospital admissions for IHD, heart failure, and arrhythmia and vehicle- or soil-related $PM_{2.5}$ in addition to $PM_{2.5}$ mass (Ostro et al., 2016). In source-based analyses Ito et al. (2013) reported an association with the traffic category during the cold season and CVD hospital admissions. Another large, multicity Medicare study also found that CVD hospitalizations were strongly related to $PM_{2.5}$ components from traffic sources, as well as sea salt/street salt, industrial combustions, and soil and road sources (Zanobetti et al., 2009). A study of Medicare beneficiaries by Zanobetti et al. (2009) noted stronger associations with MI and $PM_{2.5}$ from traffic, industrial combustion sources, sea salt/street salt, industrial sources, and wood burning and soil. Ostro et al. (2016) also examined $PM_{2.5}$ in relation to MI, and though they reported no association with $PM_{2.5}$ mass, they did report small positive associations with vehicle and soil related $PM_{2.5}$.

Examination of wildfire-related $PM_{2.5}$ was available from different regions across the U.S. In the 2009 PM ISA Delfino et al. (2009a) reported positive associations of total CVD admissions, IHD, CHF, and CBVD with southern California wildfires during 2003. Smaller studies reported inconsistent evidence of associations across outcomes. A study during a month of Colorado wildfires in 2012 reported generally null associations for all CVD outcomes except IHD (Alman et al., 2016). Conversely, a small study in Albuquerque, NM reported positive associations with total CVD admissions, CBVD, and PVD during a 2011 wildfire (Resnick et al., 2015). Additionally, two small studies of rural North Carolina peat wildfire events reported positive associations with hypertension and all-cause cardiac outcomes (Tinling et al., 2016) and CHF (Rappold et al., 2012; Rappold et al., 2011). In a large study of 561 urban and rural counties in the western U.S. using Medicare data Liu et al. (2017) reported null associations between total CVD HA/ED visits on wildfire smoke days compared to nonsmoke days from 2004−2009. This study is notable for the ability to incorporate a large number of rural counties into the analysis by using modeled wildfire-specific $PM_{2.5}$ data; however, the use of dichotomous exposure to define smoke and nonsmoke days may be source of exposure misclassification, even in sensitivity analyses. Furthermore, though wildfires are generally regional events, the use of county level exposure assignment may contribute to exposure misclassification particularly among large, rural western counties. Overall, evidence is limited for any association between exposure to wildfire derived $PM_{2.5}$ and cardiovascular HA/ED visits. Variability in study results may be related to regional heterogeneity in wildfire characteristics that depend on fuel sources, ecology, and meteorological conditions.

6.1.15.7 Associations Between $PM_{2.5}$ Components and Sources and Effects in People with Diabetes

Associations of short-term exposure BC with increases in inflammatory markers and HOMA-IR (Brook et al., 2016; O'Neill et al., 2007), decreased HRV and BAD (Table 6-32). Sulfate was associated with circulating markers of inflammation but not with BAD, FMD or NMD. OC was negatively associated with BAD (Zanobetti et al., 2014b). The single study that considered copollutant confounding reported that the association between BC and HRV did not persist after adjustment for NO_2 or CO.

Table 6-32 Summary of studies evaluating short-term exposure to $PM_{2.5}$ components and sources in people with diabetes.

Study	Study Population	Exposure Assessment	Concentration	Outcome	Copollutants Examined
(O'Neill et al., 2007) Boston, MA 1998−2002	N = 92 RCT participants Type 2 diabetes	24-h avg 1 monitor within 1.5 km of clinic	BC Mean (SD): 1.1 (0.8) IQR 0.6	ICAM-1 VCAM-1 vWF	NR
†(Brook et al., 2016) Beijing, China BC	Adults with metabolic syndrome	24-h avg, lag 1−7 day, 3 monitors	BC Mean (SD) 6.5 (3.7) IQR 4.5	HOMA-IR	NR
†(Sun et al., 2015) Shanghai, China 2010	N = 53 Type 2 diabetes	4-h moving avg prior to clinic visit, monitor near residence (April, June, Sept)	BC Mean (SD): 4.09 (2.37)	SDNN	Correlations (*r*): PNC5−560 = 0.52 2-pollutant models decreased after adjustment for Ozone Increased/null after adjustment for NO_2 and CO
†(Zanobetti et al., 2014b) Boston, MA 2006−2010 Five follow-up exams 2 weeks apart	N = 64 49−54 yr Type 2 diabetes	24 h avg, 1 monitor, reside within 25 km 1 and 5-day avg concentrations	BC Mean 0.61 Median 0.54 IQR 0.35	BAD FMD NMD	Correlations (*r*): $PM_{2.5}$ = 0.65, OC = 0.50, PN = −0.05, SO_4 = 0.52
†(Zanobetti et al., 2014b) Boston, MA 2006−2010 Five follow-up exams 2 weeks apart	N = 64 49−54 yr Type 2 diabetes	24 h avg, 1 monitor, reside within 25 km 1 and 5-day avg concentrations	OC Mean 3.03 Median 2.85 IQR 1.75	BAD FMD NMD	Correlations (*r*): $PM_{2.5}$ = 0.54, BC = 0.50, PN = −0.15, SO_4 = 0.48

Table 6-32 (Continued): Summary of studies evaluating short-term exposure to $PM_{2.5}$ components and sources in people with diabetes.

†(Zanobetti et al., 2014b) Boston, MA 2006−2010 Five follow-up exams 2 weeks apart	N = 64 49−54 yr Type 2 diabetes	24 h avg, 1 monitor, reside within 25 km 1 and 5-day avg concentrations	Sulfate Mean 2.13 Median 1.61 IQR 1.47	BAD FMD NMD	Correlations (*r*): $PM_{2.5}$ = 0.76, BC = 0.52, PN = −0.27, OC = 0.43

BAD = Brachial Artery Diameter; FMD = Flow Mediated Dilation; NR = Not Reported; NDM = Nitroglycerin Mediated Dilation; SDNN = Standard Deviation of NN intervals; rMSSD = Root Mean Square of the Successive Differences between adjacent NNs; ICAM-1 = intercellular adhesion molecule-1; VCAM-1 = vascular cell adhesion molecule-1; vWF = Von Willebrand factor; MPO = myeloperoxidase; hs CRP = high sensitivity c-reactive protein; IL-6 = interleukin 6

6.1.15.8 Toxicology Studies of Individual Components and Sources as Part of the PM Mixture

It is still not known whether particular sources or components of $PM_{2.5}$ are responsible for health effects or if certain sources and components can be ruled out as not contributing to adverse health effects. At the time of the last PM NAAQS review, the ISA concluded that "many constituents of PM can be linked with differing health effects and the evidence is not yet sufficient to allow differentiation of those constituents or sources that are more closely related to health outcomes" (U.S. EPA, 2009). The following section is organized by health endpoint and exposure duration and includes in vivo toxicology studies where animals were exposed via inhalation. Lippmann et al. (2013b) conducted a series of studies where $ApoE^{-/-}$mice were exposed to $PM_{2.5}$ CAPs for six hours/day, five days/week for a total of six months (NPACT Study 1). Separate studies were conducted in Manhattan, NY, Tuxedo, NY, East Lansing, MI, Seattle, WA and Irvine, CA that began in 2007 with the last one concluding in 2011. At all locations, mice were exposed to CAPs at nominal 8−10 times ambient concentrations, resulting in mean exposure concentrations of 138 $\mu g/m^3$ at Irvine, 136 $\mu g/m^3$ at Tuxedo, 122.9 $\mu g/m^3$ at Manhattan, 67.8 $\mu g/m^3$ at East Lansing and 60.5 $\mu g/m^3$ at Seattle. Measured $PM_{2.5}$ components included for source apportionment were Al, Ba, Br, Ca, Cu, Fe, K, Mn, Ni, Pb, S, Se, Si, V, Zn, and EC. In addition, NO_2 data were used for the Manhattan analysis to aid in the identification and separation of a traffic source category. Acute CAPs exposure resulted in some changes in HR and HRV measurements. Generally, the most significant effects were observed for mice exposed to $PM_{2.5}$ from either site in NY, with decreases in HR and LF/HF and increases in SDNN and rMSSD at lag 0 and 1 (and to a lesser extent at lag 2) in animals exposed to Manhattan $PM_{2.5}$. For Tuxedo, the pattern was opposite, with significant increases in HR and LF/HF and significant decreases in SDNN and rMSSD at lag 0 (and to a lesser extent at lag 1 and 2). Very few significant changes in heart rate variability parameters were observed in animals exposed to $PM_{2.5}$ in East Lansing, Seattle or Irvine.

The number of significant changes in HR and HRV by site at Lag day 0 were analyzed for 16 individual components. Across all of the sites, the greatest number of HR/HRV changes were for Na (149), Br (144) and Si (138). As mentioned previously, Manhattan and Tuxedo had double the number of HR/HRV changes compared to East Lansing, Seattle or Irvine. For Manhattan, the greatest number of HR/HRV changes was for Ni and *P* (both with 68) followed by Na (65), V (59), S (54) and EC (50). The pattern was different for Tuxedo, as the greatest number of HR/HRV changes was associated with Br (49), *P* (46), S (43) and K (42). The fewest number of HR/HRV changes across all sites was for Cr (31), Pb (40), Cu (57) and Mn (59).

Embedded within the NPACT study, a subset of data and results were provided in in Chen et al. (2010). This subset focused on the Manhattan and Tuxedo (aka Sterling Forest) exposures and HR and HRV changes. ApoE$^{-/-}$ mice were exposed for 6 months to filtered air or $PM_{2.5}$ CAPs from May to September 2007. Mean CAPs concentrations in Manhattan were identical to those reported in Lippmann et al. (2013b) of 122.9 µg/m^3 and slightly higher than those reported in Lippmann et al. (2013b) of 133.3 µg/m^3 in Sterling Forest. As expected, the changes in HR and HRV parameters with CAPs concentration were similar to the NPACT study. Decreases in HR and LF/HF and increases in SDNN, rMSSD, LF and HF were observed with mice exposed to Manhattan CAPs at all time periods (9 AM−2 PM, 7 PM−10 PM, 1 AM−4 AM) for lags 0 and 1. At Sterling Forest, increases in HR and decreases in SDNN, rMSSD, LF, and HF were observed at lag 0 and select periods at lag 1. When examining 20 individual elements with HR and HRV responses, Br, EC, Na, Ni, *P*, S, and V consistently resulted in significant changes across all time periods (magnitude and directions not provided) on lags 0 and 1 at the Manhattan site. Al and Se were associated with significant changes at lag 1 only and Ni and *P* were associated with significant changes at lag 2. At the Sterling Forest site, only S was associated with significant changes at lag 0, with Br and Zn at lag 1, and only Si for lags 0 and 1.

Two pollutant regression models were also performed using CAPs, S or EC as one factor and individual components as the second factor. For animals exposed to Manhattan CAPs, the CAPs associations were more strongly associated with altered cardiac function compared to the majority of elements for lag 0 and 1. Ni and S demonstrated stronger associations with ECG changes compared to other elements at lag 0. For animals exposed to Sterling Forest CAPs, the CAPs association were also stronger than those for the other elements at lag 0. Individual elements Br, S, Si, and Zn were more strongly associated at lag 1 and lag 2 compared to other elements.

In a study conducted for 13 consecutive days (8 hr/day) in summer 2005 and winter 2006 in southwest Detroit, MI, ECG changes were assessed in male SH rats exposed to $PM_{2.5}$ CAPS (Rohr et al.). Mean concentration of CAPS during the summer exposure was 518 µg/m^3, with mean exposure concentrations in the winter being 357 µg/m^3. PM composition was much more variable in summer compared to winter. Over the entire 8-hour exposure period in summer, significant differences in HR, SDNN or rMSSD were not observed between air controls and CAPs-exposed animals. When 30-minute intervals were examined during summer exposures, reductions in SDNN were associated with EC, Fe, Sr,

Mg, As, Ca, Ti, Mn, Se, Ba, Sb, Pb, Ce and Zn. Over the entire 8-hour period in winter, only HR demonstrated significant responses. Increased HR was associated with Mg and decreased HR was associated with Fe, Ti, Cu, Pb, Sn, Co, EC, OC, Se and In. For 30-minute intervals in winter, both HR and rMSSD were significantly different between the air and CAPs exposed groups. Generally, HR was decreased in the PM-exposed animals and rMSSD was increased. Reductions in HR were associated with Ba, As, Tb, EC, Cd, Zn, S, Sr, Mn, Ca, Ti, Fe, Rb, Cr, Mg, Se, Sb, K and Cu; only La had an association with increased HR. Increases in rMSSD were associated with Ba, EC, Zn, As and Rb.

In a study with similar methods to (Rohr et al., 2011), male SH rats were exposed to $PM_{2.5}$ CAPs from Steubenville, OH for 13 consecutive days (8 hr/day) in August 2006 (Kamal et al., 2011). During exposure, winds originated from the southwest (SW) or northeast (NE). Mean CAPs concentration over the exposure period was 406 $\mu g/m^3$. Approximately 30 $PM_{2.5}$ components were identified and used in univariate regression to connect to ECG changes. Furthermore, PMF was used to determine the major emission sources contributing the $PM_{2.5}$ concentrations during the study period. Sulfate and OC made up over 50% of CAPs mass. Using 30-minute average data over the entire exposure period (regardless of wind direction), significant CAPs effects were observed for HR and SDNN, but not rMSSD. When separating out wind direction, HR and SDNN changes were significant for both the SW and NE wind directions, whereas rMSSD changes were only significant for the SW wind direction. Generally, decreases in HR were observed with wind originating from the NE and associated with S, Se, Pb, Rb, Mn, Zn, Sr, Fe, Cd. In contrast, increases in HR were observed with wind originating from the SW and associated with Mo, La, PM mass, Ce, V, Ti, As and Sb. For SDNN, the majority of changes were decreases with more components associated when winds were from the NE (Sb, Pb, Zn, Rb, As, Sn, K, V, Cd, Mo, Ti, Cr). Fewer components were associated with decreased SDNN with winds from the SE (Mo, As, Sb). Changes in rMSSD were only observed with wind from the SW direction, with both increases (Al, Mg) and decreases noted (Mo, V). To assess the contribution of $PM_{2.5}$ grouped components on resultant health effects in toxicological studies, we used the approach from (Stanek et al., 2011). This approach is consistent with the Review Panel of the NPACT initiative that states both source categories and component concentrations should be used directly in the health analyses (assuming the study design permits) with a focus on examining consistencies and differences between the two approaches (Lippmann et al., 2013b). Four criteria were applied to the studies that were identified during the literature search. Each study needed to meet all of the criteria in order to be included:

- exposures conducted using $PM_{2.5}$ from U.S. airsheds or those representative of the U.S. (e.g., Europe, Canada);
- inclusion of at least five PM components;
- grouping of PM components using statistical methods, for which the groups were not predefined based on common physical or chemical properties (e.g., water soluble vs. nonsoluble); and
- formal statistical analysis investigating the relationship between groups of PM components or PM sources and health effects.

Studies of that examined $PM_{2.5}$ using individual components or individual source emissions are not included, as this is a limited approach that does not consider the combined contribution of the $PM_{2.5}$ mixture to health effects.

In the NPACT Study 1 (Lippmann et al., 2013b), a source characterization statistical model was used to determine associations between identified source categories and the HR and HRV changes.

Table 6-33 shows general HR and HRV results over the exposure period for each location and identified source category. This is a semi-quantitative evaluation of the number of significant associations, given that there were 6 cardiac measures (HR, SDNN, rMSSD, LF, HF, and LF/HF) analyzed over 4 different time periods (9 AM−2 PM, 7 PM−10 PM, 10 PM−1 AM, 1 AM−3 AM) and 3 different lags (0, 1 and 2).

Table 6-33 NPACT study results for identified source categories and occurrence of heart rate (HR) and heart rate variability (HRV) changes.

Location	Identified Source Categories	General HR and HRV Results
Manhattan, NY	Incineration (Pb, Zn); Steel (Fe, Mn); Soil (Al, Si, Ca); Residual oil combustion (Ni, V); Sulfur-coal (S, Se); Fireworks (K, Ba, Cr); Salt (Na, Mg, Cl); Traffic (EC, NO_2); Secondary aerosols (S, OC)	Residual oil combustion had the largest number of HR/HRV changes (54); combining sulfur-coal and secondary aerosol source categories to represent regionally transported $PM_{2.5}$ had even greater number of responses (59); salt and traffic demonstrated changes (48 and 44, respectively); changes associated with soil were less frequent (13); for steel and incineration, the strongest associations were on lag 0 with little response on lag 1 or 2
Tuxedo, NY	Sulfur-coal (Se, S, *P*, Br); Soil (Si, Ti, Al, Ca); Salt (Na, Cl); Ni refinery (Fe, Ni, Zn, Ca, Mn, V)	Sulfur-coal had the most number of HR/HRV changes (27), with soil having the second most (24); soil had most number of responses on lag 1 (18); almost all salt significant associations were on lag 0 (13 of 14)
East Lansing, MI	Soil (Si, Ca, Al, Fe); Sulfur-coal (S); Residual oil combustion (V, Ni); Zn-Cl (Zn, Cl); EC-OC (EC, OC)	Overall much fewer instances of significant HR/HRV associations compared to other sites (20 total across all source categories); soil and Zn-Cl had the most number of HR/HRV changes (6 each), although greatest soil associations were observed with lag 2; the most number of sulfur-coal associations were observed at lag 0 (4); little associations with OC-EC and residual oil combustion (2 and 1, respectively)

Table 6-33 (Continued): NPACT study results for identified source categories and occurrence of heart rate (HR) and heart rate variability (HRV) changes.

Location	Identified Source Categories	General HR and HRV Results
Seattle, WA	Salt (Na, Mg, Cl); Soil (Al, Si, Ca, Fe); Traffic and road dust (Ca, Mn, Cu, Fe, Zn, EC); Biomass combustion (K, Cu, EC); Residual oil combustion (V, Ni); Sulfates (S, Br)	Soil had the most HR/HRV changes (31) across all lags; residual oil combustion and salt had second and third most responses (13 and 8, respectively) with both demonstrating more changes at lag 2; biomass combustion was only associated with HR/HRV changes on lag 0 (6) and sulfates only associated with HR/HRV changes on lag 2 (5)
Irvine, CA	Residual oil combustion (V, Ni); Soil (Si, Al); Traffic (Mn, Cu, Ca, EC); Biomass combustion (K, EC); Salt (Cl, K); Metals (Pb, Zn)	Soil had the most number of significant HR/HRV changes (20), with most observed on lag 2 (14); a similar temporal relationship was demonstrated with biomass combustion (11 total, with 6 on lag 2); residual oil combustion was third (10) distributed evenly across the lags; soil, metals and traffic had much fewer significant associations with HR/HRV changes (5, 4, and 3, respectively)

As expected, those locations with greater $PM_{2.5}$ responses, also demonstrated more counts of significant associations between source categories and HR and HRV measurements, albeit all locations had at least one source category strongly associated with a change in cardiac function.

Looking across locations and source categories, soil was associated with HR/HRV changes in mice exposed to $PM_{2.5}$ at any location, with the greatest frequencies occurring on lag 1 or 2. Residual oil combustion was most frequently associated with HR/HRV changes in Manhattan across all lags and was also frequently observed in Seattle and Irvine, albeit to a greater extent on lags 1 and 2 in Seattle. There was a much greater frequency of HR/HRV changes related to traffic in Manhattan compared to Seattle and Irvine, which is likely explained by the fact that the laboratory in Manhattan is located in close proximity to busy roads. The source categories of secondary aerosols in Manhattan, sulfur-coal in Tuxedo and East Lansing, and sulfates in Seattle were all associated with HR/HRV changes. However, the frequency of these changes were less than other source categories, with the exception of Tuxedo (where concentrations were much higher than Seattle or East Lansing). In Manhattan, Tuxedo, Seattle and Irvine, salt was also associated with HR/HRV changes, with frequency of occurrence being in the middle of the range of all source categories at each location; the timing of the associations (i.e., lag) varied by location. Biomass combustion was associated with HR/HRV changes only in Seattle and Irvine, with the association only being observed at lag 0 in Seattle.

6.1.16 Summary and Causality Determination

A large body of recent evidence confirms and extends the evidence from the 2009 PM ISA (U.S. EPA, 2009) indicating that there is a causal relationship between short-term $PM_{2.5}$ exposure and cardiovascular effects. The strongest evidence in the 2009 PM ISA was from epidemiologic studies of ED visits and hospital admissions for IHD and HF, with supporting evidence from epidemiologic studies of cardiovascular mortality. Changes in various measures of cardiovascular function in CHE studies provided some biological plausibility for these associations. In addition, animal toxicological studies reporting some evidence of reduced myocardial blood flow during ischemia, altered vascular reactivity, and ST segment depression provided additional biological plausibility. In the current review, evidence supporting the causal determination includes generally positive associations reported from epidemiologic studies of hospital admissions and ED visits for cardiovascular-related effects, and in particular, for IHD and HF. Results from these observational studies are supported by experimental evidence from CHE and animal toxicological studies of endothelial dysfunction, as well as endpoints indicating impaired cardiac function, increased risk of arrhythmia, changes in HRV, increases in BP, and increases in indicators of systemic inflammation, oxidative stress, and coagulation. Additional results from observational panel studies, though not entirely consistent, provide at least some evidence of increased risk of arrhythmia, decreases in HRV, increases in BP, and ST segment depression. Thus, epidemiologic panel studies also provide some support to the causal determination and to biological plausibility. Finally, epidemiologic studies of CVD-related mortality provide additional evidence that demonstrates a continuum of effects from biomarkers of inflammation and coagulation, subclinical endpoints (e.g., HRV, BP, endothelial dysfunction), ED visits and hospital admissions, and eventually death. The current body of evidence also reduces uncertainties from the previous review related to potential copollutant confounding and limited biological plausibility for CVD effects following short-term $PM_{2.5}$ exposure. Evidence supporting the causal determination for short-term $PM_{2.5}$ exposure and cardiovascular effects reached in this ISA is discussed below and summarized in Table 6-34, using the framework for causal determination described in the Preamble to the ISAs (U.S. EPA, 2015).

The generally consistent, positive associations observed in numerous epidemiologic studies of ED visits and hospital admissions for IHD, HF and combined cardiovascular-related endpoints contribute to the evidence supporting a causal relationship between short-term $PM_{2.5}$ exposure and CVD. Among this body of evidence, nationwide studies of older adults using Medicare reported positive associations between $PM_{2.5}$ concentrations and HF hospital admissions (Section 6.1.3.1). Consistent with the results of these large Medicare studies, additional multicity studies conducted in the northeast reported positive associations between short-term $PM_{2.5}$ concentrations and ED visits or hospital admissions for IHD (Sections 6.1.2.1), while studies conducted in the U.S. and Canada reported positive associations between short-term $PM_{2.5}$ concentrations and ED visits for HF. Results from epidemiologic studies conducted in single cities contribute additional support to the causal determination, but are less consistent, showing both positive and null associations between $PM_{2.5}$ concentrations and these endpoints (Section 6.1.2 and Section 6.1.3). When considered as a whole, the recent body of IHD and HF epidemiologic evidence is in

agreement with evidence from previous ISAs reporting mainly positive associations between short-term $PM_{2.5}$ concentrations and ED visits and hospital admissions. In addition, a number of more recent CHE, animal toxicological, and epidemiologic panel studies provide evidence that $PM_{2.5}$ exposure could plausibly result in IHD or HF through pathways that include endothelial dysfunction, arterial thrombosis, and arrhythmia (Section 6.1.1). Also supporting the plausibility for IHD and HF endpoints are more recent epidemiologic panel studies reporting some evidence of ST segment depression (Section 6.1.2.2) and a recent CHE study and animal toxicological study showing decreased cardiac function following short-term $PM_{2.5}$ exposure (Section 6.1.3.2 and Section 6.1.3.3).

Results from additional CHE studies published since the last review also support a causal relationship between short-term $PM_{2.5}$ exposure and cardiovascular effects. The most consistent evidence from these studies is for endothelial dysfunction as measured by changes in BAD or FMD. More specifically, in contrast to the last review where a single study did not find changes in endothelial function, all but one of the studies in the current review examining the potential for endothelial dysfunction reported an effect of $PM_{2.5}$ on measures of blood flow (Section 6.1.13.2) relative to FA exposure. That being said, all studies were not in agreement with respect to the timing of the effect or the mechanism by which reduced blood flow was occurring (i.e., endothelial independent vs. endothelial dependent mechanisms). In addition to endothelial dysfunction, CHE studies using CAPs, but not filtered DE generally reported evidence for small increases in blood pressure, although there were inconsistencies across studies with respect to changes in SBP and DBP. It is notable however, that in CAPs studies where increases in one measure of BP (e.g., SBP), but not the other (e.g., DBP) was found to be statistically significant, that other measure of BP usually changed as well, but the change was not found to be statistically significant (Section 6.1.6.3). In addition, although not entirely consistent, there is also some evidence across CHE studies for conduction abnormalities/arrhythmia (Section 6.1.4.3), changes in HRV (Section 6.1.10.2), changes in hemostasis that could promote clot formation (Section 6.1.12.2), and increases in inflammatory cells and markers (Section 6.1.11.2). Thus, when taken as a whole, CHE studies are in coherence with epidemiologic studies by demonstrating that short-term exposure to $PM_{2.5}$ may result in the types of cardiovascular endpoints that could lead to ED visits and hospital admissions.

Animal toxicological studies published since the 2009 PM ISA also support a causal relationship between short-term $PM_{2.5}$ exposure and cardiovascular effects. A recent study demonstrating decreased cardiac contractility and left ventricular pressure in mice is coherent with the results of epidemiologic studies reporting associations between short-term $PM_{2.5}$ exposure and HF (Section 6.1.3.3). In addition, similar to CHE studies, there is generally consistent evidence in animal toxicological studies for indicators of endothelial dysfunction (Section 6.1.13.3). Studies in animals also provide evidence for changes in a number of other cardiovascular endpoints following short-term $PM_{2.5}$ exposure. Although not entirely consistent, these studies provide at least some evidence of conduction abnormalities and arrhythmia (Section 6.1.4.4), changes in HRV (Section 0), changes in BP (Section 6.1.6.4), and evidence for systemic inflammation and oxidative stress (Section 6.1.11.3). Finally, these toxicological studies also

suggest that genetic background, diet, and PM composition may influence the effect of short-term $PM_{2.5}$ exposure on some of these health endpoints.

As outlined above, across the scientific disciplines there is evidence for a continuum of cardiovascular-related health effects following short-term exposure to $PM_{2.5}$. These effects range from relatively modest increases in biomarkers related to inflammation and coagulation, to subclinical CVD endpoints such as endothelial dysfunction, to ED visits and hospital admissions for outcomes such as IHD and HF. In coherence with this continuum of effects is a body of epidemiologic studies reporting a relatively consistent relationship between short-term $PM_{2.5}$ exposure and CVD-related mortality. These epidemiologic studies also reduce a key uncertainty from the last review by providing evidence that gaseous pollutants are not likely to confound the $PM_{2.5}$-cardiovascular mortality relationship.

Taken together, the recent evidence described throughout Section 6.1 extends the consistency and coherence of the evidence base reported in the 2009 PM ISA and 2004 AQCD. Direct evidence for $PM_{2.5}$ exposure-related cardiovascular effects can be found in a number of CHE and animal toxicological studies. In coherence with these results are epidemiologic panel studies also finding that $PM_{2.5}$ exposure is associated with some of the same cardiovascular endpoints reported in CHE and animal toxicological studies. There is a limited number of studies evaluating some of these endpoints, and there are some inconsistencies in results across some of these animal toxicological, CHE and epidemiologic panel studies, though this may be due to substantial differences in study design, study populations, or differences in PM composition across air sheds. That being said, the results from these epidemiologic panel, CHE, and animal toxicological studies, in particular those related to endothelial dysfunction, impaired cardiac function, ST segment depression, thrombosis, conduction abnormalities, and BP provide coherence and biological plausibility for the consistent results from epidemiologic studies observing positive associations between short-term $PM_{2.5}$ concentrations and IHD and HF, and ultimately cardiovascular mortality. Overall, considering the entire evidence base, there continues to be sufficient evidence to conclude that **a causal relationship exists between short-term $PM_{2.5}$ exposure and cardiovascular effects.**

Table 6-34 Summary of evidence for a causal relationship between short-term $PM_{2.5}$ exposure and cardiovascular effects.

Rationale for Causal Determination[a]	Key Evidence[b]	Key References[b]	$PM_{2.5}$ Concentrations Associated with Effects[c]
Consistent epidemiologic evidence from multiple, high quality studies at relevant $PM_{2.5}$ concentrations	Increases in ED visits and hospital admissions for IHD and CHF in multicity studies conducted in the U.S., Canada, Europe, and Asia Increases in cardiovascular mortality in multicity studies conducted in the U.S., Canada, Europe, and Asia.	Section 6.1.2.1 Section 6.1.3.1 Section 6.1.9	5.8−18.6 μg/m^3 5.8−18.0 μg/m^3
Consistent evidence from controlled human exposure studies at relevant $PM_{2.5}$ concentrations	Consistent changes in measures of endothelial dysfunction Generally consistent evidence for small increases in measures of blood pressure following CAPs exposure Additional evidence of conduction abnormalities, heart rate variability, impaired heart function, systemic inflammation/oxidative stress	Section 6.1.13.2 Section 6.1.6.3 Section 6.1.4.3 Section 6.1.3.2 Section 6.1.10.2 Section 6.1.11.2	24−325 μg/m^3 See Tables in identified sections
Consistent evidence from animal toxicological studies at relevant $PM_{2.5}$ concentrations	Consistent changes in indicators of endothelial dysfunction. Additional evidence of changes in impaired heart function, conduction abnormalities/arrhythmia, heart rate variability, blood pressure, systemic inflammation/oxidative stress	Section 6.1.13.3 Section 6.1.6.4 Section 6.1.4.4 Section 6.1.3.3 Section 0 Section 6.1.11.3	168.7−510 μg/m^3 See Tables in identified sections
Epidemiologic evidence from copollutant models provides some support for an independent $PM_{2.5}$ association	The magnitude of $PM_{2.5}$ associations remain positive, but in some cases are reduced with larger confidence intervals in copollutant models with gaseous pollutants. Further support from copollutant analyses indicating positive associations for cardiovascular mortality. Recent studies that examined potential copollutant confounding are limited to studies conducted in Europe and Asia. When reported, correlations with gaseous copollutants were primarily in the low to moderate range ($r < 0.7$).	Section 6.1.14.1	
Consistent positive epidemiologic evidence for associations between $PM_{2.5}$ exposure and CVD ED visits and hospital admissions across exposure measurement metrics	Positive associations consistently observed across studies that used ground-based (i.e., monitors), model (e.g., CMAQ, dispersion models) and remote sensing (e.g., AOD measurements from satellites) methods, including hybrid methods that combine two or more of these methods.	Kloog et al. (2014)	

Table 6-34 (Continued): Summary of evidence indicating that a causal relationship exists between short-term $PM_{2.5}$ exposure and cardiovascular effects.

Rationale for Causal Determination[a]	Key Evidence[b]	Key References[b]	$PM_{2.5}$ Concentrations Associated with Effects[c]
Generally consistent evidence for biological plausibility of cardiovascular effects	Strong evidence for coherence of effects across scientific disciplines and biological plausibility for a range of cardiovascular effects in response to short-term $PM_{2.5}$ exposure. Includes evidence for reduced myocardial blood flow, altered vascular reactivity, and ST segment depression.	Section 6.1.1 Figure 6-1	
Uncertainty regarding geographic heterogeneity in $PM_{2.5}$ associations	Multicity U.S. studies demonstrate city-to-city and regional heterogeneity in $PM_{2.5}$-CVD ED visit and hospital admission associations. Evidence supports that a combination of factors including composition and exposure factors may contribute to the observed heterogeneity.	Section 6.1.2.1 Section 6.1.3.1

[b]Describes the key evidence and references, supporting or contradicting, contributing most heavily to causal determination and, where applicable, to uncertainties or inconsistencies. References to earlier sections indicate where full body of evidence is described.

[c]Describes the $PM_{2.5}$ concentrations with which the evidence is substantiated.

6.2 Long-Term $PM_{2.5}$ Exposure and Cardiovascular Effects

The scientific evidence pertaining to the cardiovascular health effects of $PM_{2.5}$ reviewed in the 2009 PM ISA was "sufficient to infer a causal relationship between long-term $PM_{2.5}$ exposure and cardiovascular effects" (U.S. EPA, 2009). The strongest line of evidence comprised findings from several large U.S. cohort studies that consistently showed positive associations between $PM_{2.5}$ exposure and cardiovascular mortality (Krewski et al., 2009; Miller et al., 2007; Laden et al., 2006; Pope III et al., 2004). While several studies included in the 2009 ISA for PM reported associations of long-term PM_{10} exposure with morbidity outcomes such as post-MI congestive heart failure (CHF) (Zanobetti and Schwartz, 2007) and deep vein thrombosis (DVT) (Baccarelli et al., 2008), epidemiologic evidence relating to $PM_{2.5}$ was limited to a study of postmenopausal women (Miller et al., 2007) and cross-sectional analyses of self-reported cardiovascular effects among participants in the German Heinz Nixdorf Recall (HNR) study (Hoffmann et al., 2009; Hoffmann et al., 2006). These studies reported associations with coronary heart disease (CHD) and stroke. Biological plausibility and coherence with the epidemiologic findings were provided by studies using genetic mouse models of atherosclerosis demonstrating enhanced atherosclerotic plaque development and inflammation following 4 to 6-month exposures to $PM_{2.5}$ CAPs (U.S. EPA, 2009). Evidence from a limited number of toxicological studies in

mice reporting CAPs-induced effects on coagulation factors, hypertension and vascular reactivity was also drawn upon to support the causal conclusion. Recent epidemiologic studies add to the already strong evidence base supporting the association of long-term exposure to $PM_{2.5}$ with cardiovascular mortality (Section 6.2.10). Associations between long-term exposure to $PM_{2.5}$ and cardiovascular morbidity outcomes (i.e., IHD, stroke) were observed in some studies with the most consistent results in people with preexisting diseases (CHAPTER 12). Additional experimental studies of long-term exposure to $PM_{2.5}$ CAPs add to the collective evidence available to support a direct effect of $PM_{2.5}$ on the cardiovascular system, and provide biological plausibility for associations observed in epidemiologic studies.

Some uncertainties remained to be addressed at the completion of the 2009 PM ISA despite the strong evidence supporting a causal relationship between long-term exposure to $PM_{2.5}$ and cardiovascular effects. The following sections provide an evaluation of the most policy relevant scientific evidence, focusing on the extent to which recently available studies further characterize the relationship between long-term exposure to $PM_{2.5}$ and cardiovascular effects. Specifically, the current section focuses on studies where long-term average $PM_{2.5}$ concentrations are less than 20 $\mu g/m^3$ whereas the epidemiologic studies supporting the causal conclusion in the 2009 ISA were generally conducted in urban areas where mean $PM_{2.5}$ concentrations ranged up to 29.0 $\mu g/m^3$. In addition, an expanded set of longitudinal epidemiologic analyses that is currently available to assess the effect of long-term exposure to $PM_{2.5}$ on the incidence of cardiovascular disease and to examine temporal changes in specific endpoints such as coronary artery calcium (CAC), markers of systemic inflammation and coagulation. A more extensive literature on CAPs exposure reduces uncertainties related to inclusion of diesel and other mixture studies in the 2009 PM ISA. These studies, in combination with a limited number of recently available epidemiologic analyses that examine copollutant confounding, strengthen the evidence for a direct effect of long-term $PM_{2.5}$ on the cardiovascular system. Finally, an expanded set of studies describing the shape of the C-*R* function across the range of $PM_{2.5}$ concentrations is available and studies that use spatiotemporal exposure models to characterize exposure to populations that may be at greater distance from air monitors add to the collective evidence in the current review.

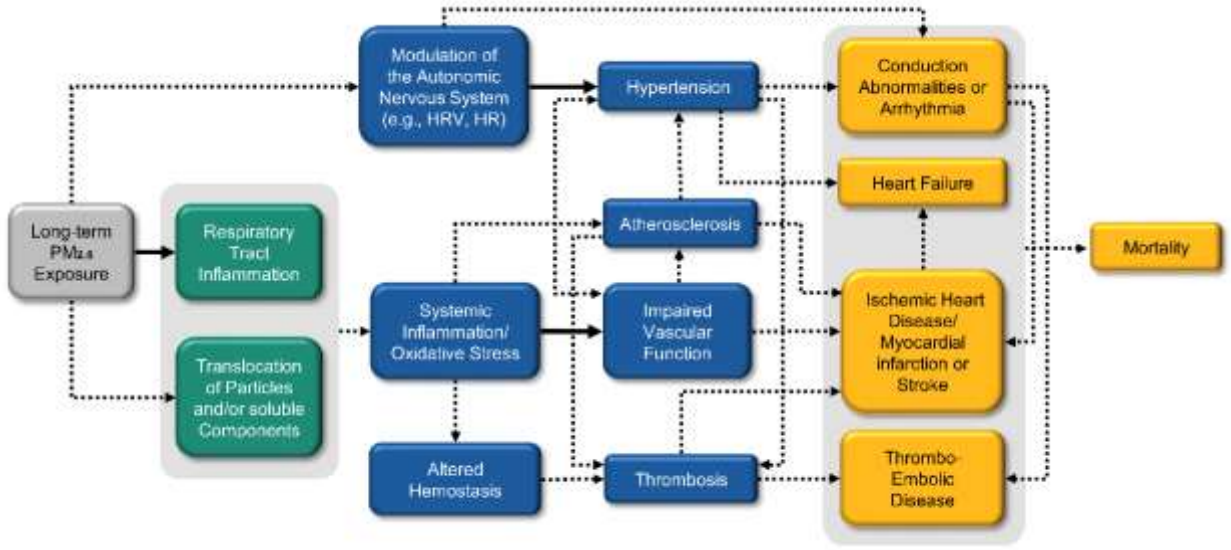
The subsections below provide an evaluation of the most policy relevant scientific evidence relating-long-tern $PM_{2.5}$ exposure to cardiovascular health effects. To clearly characterize and put this evidence into context, there is first a discussion of the biological plausibility of cardiovascular effects following long-tern $PM_{2.5}$ exposure (Section 6.2.1). Following this discussion, the health evidence relating long-tern $PM_{2.5}$ exposure and specific cardiovascular health outcomes is discussed in detail: ischemic heart disease and myocardial infarction (Section 6.2.2), cerebrovascular disease and stroke (Section 6.2.3), atherosclerosis (Section 6.2.4) heart failure and impaired heart function (Section 6.2.5) cardiac electrophysiology and arrhythmia (Section 6.2.6), blood pressure and hypertension (Section 6.2.7), peripheral vascular disease (PVD), venous thromboembolism and pulmonary embolisms (Section 6.2.8), aggregated cardiovascular outcomes (Section 6.2.9), and cardiovascular-related mortality (Section 6.2.10). The evidence for an effect of $PM_{2.5}$ exposures on endpoints such as changes in heart rate variability (HRV) and endothelial function are discussed (Section 6.2.11, Section 6.2.12, Section 6.2.13,

and, Section 6.2.14), as are copollutant confounding (Section 0), shape of the concentration response function (Section 6.2.16), and the relationship between health effects and exposure to specific $PM_{2.5}$ components (Section 6.2.17). Finally, the collective body of evidence is integrated across and within scientific disciplines[62], and the rationale for the causality determination is outlined in Section 6.2.18.

6.2.1 Biological Plausibility

This subsection describes the biological pathways that potentially underlie cardiovascular health effects resulting from long-term inhalation exposure to $PM_{2.5}$. Figure 6-16 graphically depicts these proposed pathways as a continuum of pathophysiological responses—connected by arrows—that may ultimately lead to the apical cardiovascular events observed in long-term epidemiologic studies. This discussion of "how" long-term exposure to $PM_{2.5}$ may lead to these cardiovascular events also provides biological plausibility for the epidemiologic results reported later in Section 6.2. In addition, most studies cited in this subsection are discussed in greater detail throughout Section 6.2.

[62] As detailed in the Preface, risk estimates are for a 5 $\mu g/m^3$ increase in annual $PM_{2.5}$ concentrations unless otherwise noted.



Note: the boxes above represent the effects for which there is experimental or epidemiologic evidence, and the dotted arrows indicate a proposed relationship between those effects. Shading around multiple boxes denotes relationships between groups of upstream and downstream effects. Progression of effects is depicted from left to right and color coded (grey, exposure; green, initial event; blue, intermediate event; orange, apical event). Here, apical events generally reflect results of epidemiologic studies, which often observe effects at the population level. Epidemiologic evidence may also contribute to upstream boxes. When there are gaps in the evidence, there are complementary gaps in the figure and the accompanying text below

Figure 6-16 Potential biological pathways for cardiovascular effects following long-term exposure to $PM_{2.5}$.

When considering the available health evidence, plausible pathways connecting long-term exposure to $PM_{2.5}$ to the apical events reported in epidemiologic studies are proposed in Figure 6-16. The first proposed pathway begins as respiratory tract inflammation leading to systemic inflammation[63]. The second proposed pathway involves modulation of the autonomic nervous system. Once these pathways are initiated, there is evidence from experimental and observational studies that long-term exposure to $PM_{2.5}$ may result in a series of pathophysiological responses that could lead to cardiovascular events such as IHD and HF.

Long-term inhalation exposure to $PM_{2.5}$ may result in respiratory tract inflammation and oxidative stress (Section 5.2). Inflammatory mediators such as cytokines produced in the respiratory tract have the potential to enter into the circulatory system where they may cause distal pathophysiological responses that could lead to overt cardiovascular disease. For example, following long-term exposure to $PM_{2.5}$, Kampfrath et al. (2011) reported that vascular dysfunction occurred via NADPH oxidase and inflammatory pathways that required toll like receptor 4 (TLR4). In addition, release of inflammatory

[63] It is also possible that particles ~200 nm or less, or soluble particle components can translocate directly into the circulatory system (Chapter 4) and lead to systemic inflammation, although the extent to which particle translocation occurs remains unclear.

mediators into the circulation such as monocyte chemoattractant protein 1 (MCP-1) can result in the recruitment of additional inflammatory cells, and thus amplify the initial inflammatory response (Carr et al., 1994). Thus, it is important to note that there is evidence from long-term experimental studies in animals (Tanwar et al., 2017; Aztatzi-Aguilar et al., 2015; Gorr et al., 2014; Lippmann et al., 2013a; Ying et al., 2013; Deiuliis et al., 2012; Wold et al., 2012; Kampfrath et al., 2011) demonstrating an increase in inflammatory cells, cytokines, or oxidative stress markers in the circulatory system following long-term $PM_{2.5}$ exposure. The release of cytokines such as IL-6 into the circulation can stimulate the liver to release inflammatory proteins and coagulation factors that can alter hemostasis and increase the potential for thrombosis (Lucking et al., 2011; van Eeden et al., 2005). Evidence from several $PM_{2.5}$ epidemiologic studies identified an association between long-term exposure to $PM_{2.5}$ and coagulation factor and/or liver derived inflammatory markers (e.g., CRP) in the blood (Hajat et al., 2015; Viehmann et al., 2015; Hennig et al., 2014; Ostro et al., 2014). These observed effects may alter the balance between pro and anticoagulation proteins and therefore, increase the potential for thrombosis, which may then promote IHD, stroke, or thromboembolic disease elsewhere in the body. Systemic inflammation has also been shown to induce impaired vascular function (Kampfrath et al., 2011)—a systemic pathological condition characterized by the altered production of vasoconstrictors and vasodilators—that over time promotes plaque formation leading to atherosclerosis. Specifically, vascular dysfunction is often accompanied by endothelial cell expression of adhesion molecules and release of chemo attractants for inflammatory cells. Macrophages may then internalize circulating lipids leading to the formation of foam cells: a hallmark of atherosclerotic lesions that may increase in size with $PM_{2.5}$ exposure, particularly in the presence of genetic and dietary risk factors (Rao et al.; Lippmann et al., 2013a). Over time, these atherosclerotic lesions may become calcified as evidenced in a longitudinal epidemiologic study of $PM_{2.5}$ (Kaufman et al., 2016), and this often leads to arteriole stiffening and promotion of IHD or stroke. Importantly, evidence for impaired vascular function in response to long-term exposure to $PM_{2.5}$ is found in animal experimental studies (Ying et al., 2015; Kampfrath et al., 2011; Sun et al.).

In addition to long-term $PM_{2.5}$ exposure leading to cardiovascular disease through inflammatory pathways, there is also evidence that exposure to $PM_{2.5}$ could lead to cardiovascular disease through modulation of the autonomic nervous system. That being said, the mechanism by which long-term exposure to $PM_{2.5}$ results in autonomic nervous system modulation remains unclear. Nonetheless, there is evidence from studies in animals demonstrating modulation of autonomic function (as evidenced by changes in HRV and/or HR) following long-term $PM_{2.5}$ exposure (Ying et al.; Lippmann et al., 2013a; Wold et al., 2012). Moreover, there is also evidence for an increase in BP (Aztatzi-Aguilar et al., 2016; Ying et al., 2015; Wold et al., 2012) in animals following long-term $PM_{2.5}$ exposure. These results are consistent with associations reported in epidemiologic studies between long-term exposure to $PM_{2.5}$ and increases in BP and hypertension (Zhang et al., 2016; Chen et al., 2014a). This is important given that hypertension can lead to HF through cardiac remodeling that results in reduced pumping efficiency (Santos et al, 2014). Similarly, hypertension can contribute to impaired vascular function and atherosclerosis (Brook et al., 2010a), which as noted above, may lead to IHD. Hypertension may also result in arrhythmia through cardiac remodeling (Cascio, 2016; Brook et al., 2010a). Thus, it is

noteworthy that there is epidemiologic evidence of associations between long-term exposure to $PM_{2.5}$ and indicators of potential arrhythmia (Van Hee et al., 2011). Arrhythmia can also contribute to IHD and stroke. For example, atrial fibrillation (a type of arrhythmia) is characterized by blood pooling and potentially clotting in the upper chamber (atria) of the heart. These clots can ultimately be pumped out of the heart and lodged in arteries supplying the brain with oxygen, thereby resulting in a stroke. Studies of hypertension and arrhythmia therefore provide additional plausibility for epidemiologic studies finding associations between long-term exposure to $PM_{2.5}$ and IHD, HF, stroke, and ultimately mortality.

When considering the available evidence, there are plausible pathways connecting long-term exposure to $PM_{2.5}$ to cardiovascular health effects. The first proposed pathway begins with respiratory tract injury and inflammation that may enter into the circulatory system potentially inducing a series of pathophysiological responses that could ultimately result in IHD, stroke, HF, or thromboembolic disease elsewhere in the body (Figure 6-16). The second proposed pathway involves changes in the autonomic nervous system that may result in hypertension, arrhythmia, and potentially the same apical events (Figure 6-16). Taken together, these proposed pathways provide biological plausibility for epidemiologic results of cardiovascular health effects and will be used to inform a causal determination, which is discussed later in the chapter (Section 0).

6.2.2 Ischemic Heart Disease and Myocardial Infarction

The terms ischemic heart disease (IHD) coronary artery disease (CAD) or coronary heart disease (CHD) are generally interchangeable as they appear in the epidemiologic literature on the effects of air pollution. The majority of IHD is caused by atherosclerosis (Section 6.2.4), which can result in the blockage of the coronary arteries and restriction of blood flow to the heart muscle. A myocardial infarction (MI) or heart attack is an acute event that results in heart muscle tissue death secondary to coronary artery occlusion. Studies that examine the ability of short-term exposure to $PM_{2.5}$ to trigger an MI are discussed in Section 6.1.2 whereas the studies examining the effect of long-term exposure on the incidence of MI or IHD are discussed here (Section 6.2.2).

The literature examining the association of long-term exposure to $PM_{2.5}$ with IHDs has expanded substantially from the few studies available for inclusion in the 2009 PM ISA. Overall, findings from recent epidemiologic studies do not provide entirely consistent evidence of an association between long-term exposure to $PM_{2.5}$ and IHD in the populations studied. The strongest evidence of an association with IHD, however, is found in populations with pre-existing diseases (CHAPTER 12).

6.2.2.1 Epidemiologic Studies

This section evaluates the epidemiologic studies reporting associations of long-term exposure to $PM_{2.5}$ with the development, prevalence or recurrence of IHDs including MI (Table 6-35).

Table 6-35 Characteristics of the studies examining the association between long-term $PM_{2.5}$ exposures and ischemic heart disease.

Study	Study Population	Exposure Assessment	Concentration µg/m^3	Outcome	Copollutants Examined
Miller et al. 1

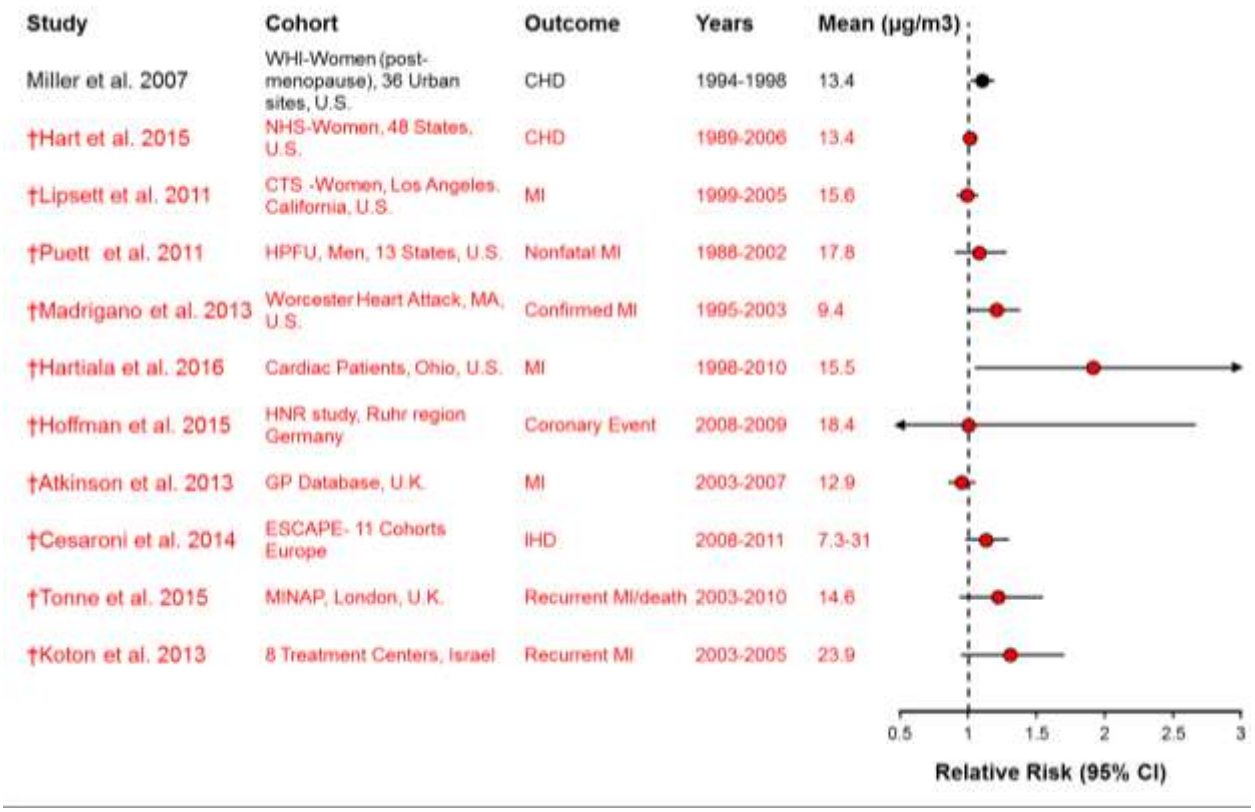
Associations in prospective cohort studies are presented in Figure 6-17. In a large, prospective study reviewed in the 2009 PM ISA, Miller et al. (2007) reported a hazard ratio (HR) for incident CHD morbidity and mortality of 1.10 (95%CI: 1.02, 1.19) among post-menopausal women. Several recent studies have followed up on this finding by examining the effect of long-term exposure to $PM_{2.5}$ in women. Hart et al. (2015b) observed no association between long-term exposure to $PM_{2.5}$ and incident CHD among women enrolled in the Nurses' Health Study (NHS) [HR: 1.01 95%CI: 0.96,1.07] although increased CHD risk was observed among women with diabetes [HR: 1.10 95%CI: 0.99,1.21]. The women in NHS were younger (38% premenopausal) than the women in the WHI, potentially explaining the discrepancy in the findings between these studies. In an analysis of women enrolled in the California Teachers' Study (CTS), Lipsett et al. (2011) reported no association with incident MI (hospitalizations and deaths combined) [HR: 0.99 (95%CI: 0.91, 1.08)], although increased risks of fatal IHD (see Section 6.2.10) and stroke were observed (see Section 6.2.3). Results from a CTS sensitivity analysis that was restricted to post-menopausal women did not indicate a positive association (Lipsett et al., 2011).

The remaining North American studies, which examined populations of men, or both men and women, generally report positive associations between long-term $PM_{2.5}$ exposure and MI, although the width of the confidence intervals varies between studies. Puett et al. (2011) conducted a prospective analysis of the Health Professionals Follow-up Study (HPFS), which consists of male medical professionals reporting an association of 1.08 (95%CI: 0.90, 1.28). This association was largely unchanged after adjustment for $PM_{10-2.5}$ (Puett et al., 2011). In an incident case control analysis of confirmed acute MI Madrigano et al. (2013) reported a stronger association [OR: 1.21 (95%CI: 1.00, 1.38)] between long-term exposure to $PM_{2.5}$ and acute MI. This study derived exposure metrics to distinguish regional $PM_{2.5}$ from local traffic-related $PM_{2.5}$ sources of exposure, and found the association with regional $PM_{2.5}$ was not attenuated in a copollutant model containing local traffic-related $PM_{2.5}$. A limitation of this study was its lack of adjustment for smoking. In another study, Hartiala et al. (2016) reported an association of long-term exposure to $PM_{2.5}$ with confirmed MI among those undergoing cardiac evaluation at a clinic in Ohio. Notably, Madrigano et al. (2013) and Hartiala et al. (2016) confirmed potential cases of MI.



†Studies published since the 2009 Integrated Science Assessment for Particulate Matter.

Figure 6-17 Associations between long-term exposure to $PM_{2.5}$ and Ischemic Heart Disease or Myocardial Infarction. Associations are presented per 5 µg/m^3 increase in pollutant concentration.

Several European studies examined the association of long-term $PM_{2.5}$ and IHD or MI reporting somewhat inconsistent across cohorts. A study from the European ESCAPE project, which includes 11 cohorts in five European countries (Finland, Sweden, Denmark, Germany, and Italy) (Cesaroni et al., 2014) is available for review. Average annual exposure to $PM_{2.5}$ was assigned using the area-specific land use regression models. Cohort specific hazard ratios were variable and the meta-analytically combined effect estimate for $PM_{2.5}$ was [HR: 1.13 (95%CI: 0.98, 1.30)]. In sensitivity analyses the authors considered exposures below various thresholds of average $PM_{2.5}$ concentrations. For the seven cohorts with participants exposed to <15 µg/m^3 average annual $PM_{2.5}$, the meta-analyzed hazard ratio was 1.19 (1.00, 1.42). The outcome determination in the ESCAPE project was cohort-specific, but most cohorts

used ICD codes linked with hospital and death records and defined incidence based on outcome dates. Although most of the cohorts did not include physician review and adjudication for case identification, a separate analysis of data from the HNR study (Hoffmann et al., 2015), with case review by an independent committee, reported no association between coronary events (MI, fatal CHD and sudden death) and long-term $PM_{2.5}$ exposures, after adjustment for noise and other covariates [HR: 1.00 (95%CI: 0.38, 2.67)], although an association with stroke was observed (Section 6.2.3). The confidence intervals from the HNR study were wide due to the small number of cases (n = 135 for coronary events). In another European study, Atkinson et al. (2013) reported a negative association between long-term $PM_{2.5}$ exposure and MI ascertained from a database of information from general practitioners in the U.K. Studies of recurrent MI among MI survivors yielded positive associations (Tonne et al., 2015; Koton et al., 2013). Koton et al. (2013) treated several important confounders (e.g., smoking) as time-varying and both Koton et al. (2013).

Several cross-sectional analyses, including analyses of U.S. national survey data, are available to consider the association of long-term $PM_{2.5}$ exposure with prevalent IHD or hospital admissions (To et al., 2015; Beckerman et al., 2012; Feng and Yang, 2012; Gan et al., 2011). Overall, results from these studies do not provide consistent evidence of an association and only Gan et al. (2011) considered the temporality of the association.

In summary, some well-conducted prospective studies indicate an association between long-term exposure to $PM_{2.5}$ and IHD outcomes in post-menopausal women (Miller et al., 2007) and in a meta-analysis of European cohorts (Cesaroni et al., 2014). Studies also indicate the potential for those with pre-existing disease to be at elevated risk of IHD morbidity [e.g., diabetics in the NHS (Hart et al., 2015b), cardiac patients (Hartiala et al., 2016) or those who experienced a previous MI (Tonne et al., 2015; Koton et al., 2013)]. Most studies considered important covariates such as menopausal status, hormone replacement therapy, smoking and SES. Although the WHI analysis of Miller et al. (2007) did not adjust for SES, Chi et al. (2016a) considered both individual and neighborhood level SES in a subsequent WHI analysis of combined coronary events (see Section 6.2.9), reporting that the association remained unchanged after adjustment for these factors. Lipsett et al. (2011) reported no association between $PM_{2.5}$ exposure and incidence of MI in the CTS, including in a sensitivity restricted to post-menopausal women; however, it is notable that an association with cardiovascular-related mortality was observed in this study. Similarly, no association with coronary events was observed in the HNR study but an association with stroke was reported (Hoffmann et al., 2015). The risk estimate reported by Miller et al. (2007) was for coronary events (i.e., morbidity and mortality combined) providing coherence for the evidence of consistent positive associations between long-term $PM_{2.5}$ exposure and mortality from cardiovascular causes. Several exposure assessment methods including spatiotemporal models and LUR were applied but not studies examined the influence of the choice of exposure model within a study. Consideration of confounding by copollutants was limited while correlations reported between pollutants varied by cohort but were generally moderate to high (Table 6-35).

6.2.3 Cerebrovascular Disease and Stroke

Cerebrovascular disease typically includes conditions hemorrhagic stroke, cerebral infarction (i.e., ischemic stroke) and occlusion of the precerebral and cerebral arteries (see Section 6.1.5). The 2009 PM ISA identified one study that indicated a positive association between $PM_{2.5}$ and cerebrovascular morbidity and mortality in post-menopausal women (Miller et al., 2007). Although the results are not entirely consistent across studies or stroke subtype, some recent well-conducted studies also support a positive association between long term exposure to $PM_{2.5}$ and stroke.

6.2.3.1 Epidemiologic Studies

Studies of the association between long-term exposure to $PM_{2.5}$ and cerebrovascular diseases are summarized in Table 6-36.

Table 6-36 Characteristics of the studies examining the association between long-term $PM_{2.5}$ exposures and cerebrovascular disease.

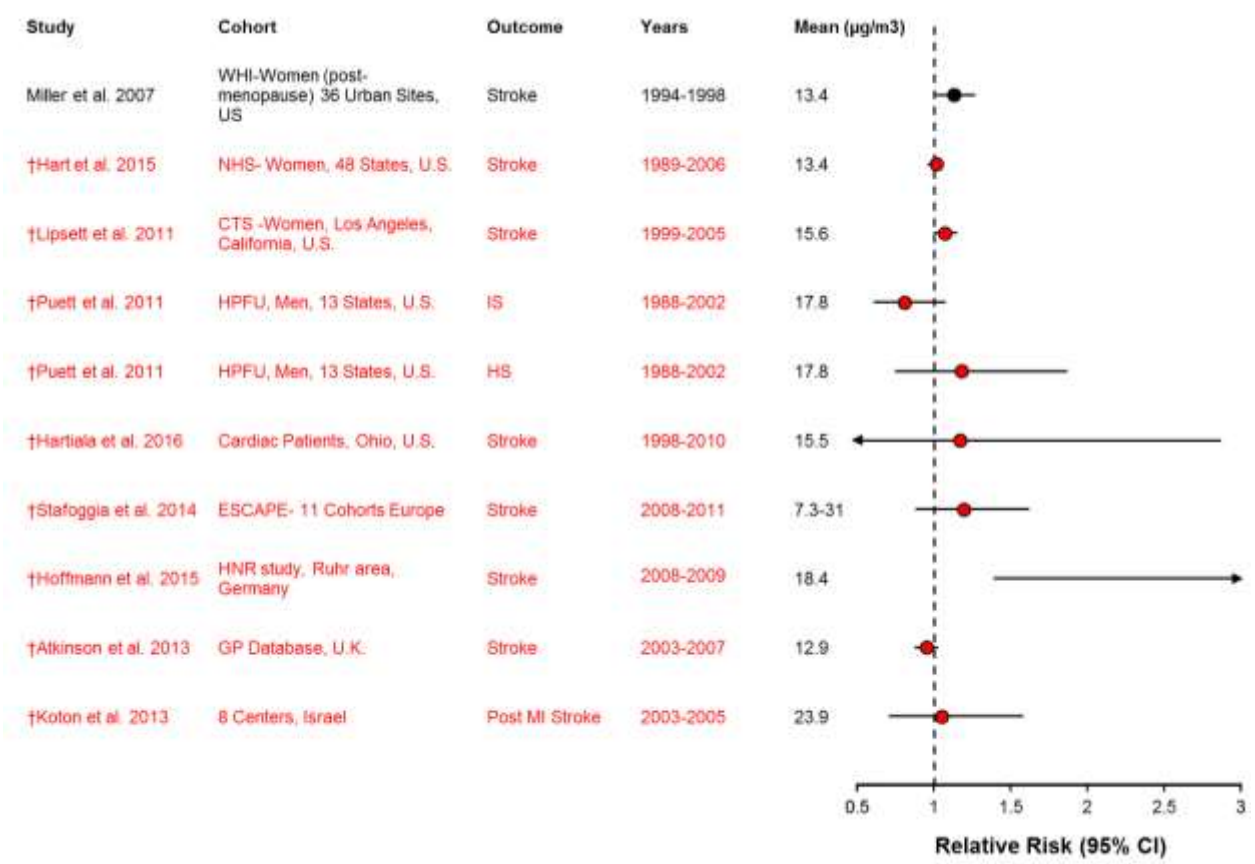
1

Prospective studies of the association between long-term $PM_{2.5}$ exposure and the incidence of stroke are presented in Figure 6-18. In a study reviewed in the 2009 PM ISA Miller et al. (2007) reported associations of both CBVD and stroke with long-term exposure to $PM_{2.5}$ among post-menopausal women enrolled in WHI who were free of the conditions at baseline [HR: CBVD: 1.16 (95%CI: 1.04, 1.30) and HR stroke: 1.13 (95%CI: 1.04, 1.30)]. Several recent studies conducted in cohorts of women are available for comparison to the WHI findings. The CTS reported associations of $PM_{2.5}$ on incident stroke [HR: 1.07 (95%CI: 0.99, 1.15)] (Lipsett et al., 2011). The association with incident stroke did not include the null value when the sample was restricted to postmenopausal women [HR: 1.09 (95%CI: 1.01, 1.17)]. A prospective analysis of the relatively younger women enrolled in the NHS, reported an increased risk among women with diabetes [HR: 1.29 (95%CI: 1.14, 1.45)] but not in the population, overall [HR: 1.01 (95%CI: 0.96, 1.05)] (Hart et al., 2015b).

Several U.S. studies of men or men and women combined were also available for review. In a cohort of men enrolled in the HPFU study, Puett et al. (2011) examined the effect of long-term exposure to $PM_{2.5}$ on hemorrhagic stroke (HS) and ischemic stroke (IS), classified using National Survey of Stroke criteria and reviewed by physicians. The number of case was small (n = 230 for IS and n = 70 for HS), resulting in estimates with wide CIs [HR: 0.80 (95%CI: 0.61, 1.08)] for IS and HR: 1.18 (95%CI: 0.74, 1.85) HS]. In a study of cardiac patients in Ohio, Hartiala et al. (2016) reported an imprecise association (i.e., wide confidence intervals) between long-term exposure to $PM_{2.5}$ and stroke [HR: 1.17 (95%CI: 0.49, 2.87)] that was attenuated in fully adjusted models that considered a large array of cardiovascular risk factors (i.e., obesity smoking, physical activity and land use development).



†Studies published since the 2009 Integrated Science Assessment for Particulate Matter. Circles represent point estimates; horizontal lines represent 95% confidence intervals for $PM_{2.5}$. Black text and circles represent evidence included in the 2009 PM ISA; red text and circles represent recent evidence not considered in previous ISAs or AQCDs. Mean concentrations in $\mu g/m^3$. Hazard Ratios are standardized to a 5- $\mu g/m^3$ increase in $PM_{2.5}$ concentrations. Corresponding quantitative results are reported in Supplemental Table 6S-17 (U.S. EPA, 2018). MI = Myocardial Infarction; IS = ischemic stroke; HS = hemorrhagic stroke; WHI = Women's Health Initiative; NHS = Nurses' Health Study; HPFU = Health Professional's Follow-up; ESCAPE = European Study of Cohorts for Air Pollution; HNR = Heinz Nixdorf Recall; GP = General Practitioner.

Figure 6-18 Associations between long-term exposure to $PM_{2.5}$ and the incidence of stroke. Associations are presented per 5 $\mu g/m^3$ increase in pollutant concentration.

Within the European ESCAPE study, long-term exposure to $PM_{2.5}$ was positively associated with incident stroke [HR: 1.19 (95%CI: 0.88, 1.62)] in the fully adjusted model, which included variables to control for SES (Stafoggia et al., 2014). Researchers observed a more precise result when restricting to the six cohorts for which the LUR model performed the best (R^2>0.6) [HR 1.75 (1.30, 2.35)]. Additionally, stratified analyses indicated that effects may be larger in magnitude in older age groups and among never-smokers. The authors restricted the analysis to individuals exposed to <15 $\mu g/m^3$ concentrations of $PM_{2.5}$ and observed a HR of 1.33 (95%CI: 1.01, 1.77). As mentioned previously, most ESCAPE cohorts did not have physician review and adjudication of cases. A separate analysis of data

from the HNR study, one of the ESCAPE cohorts, with case review by an independent committee, reported a relatively large association between long-term $PM_{2.5}$ exposure and stroke that persisted after adjustment for noise [HR: 5.24 (95%CI: 1.39, 19.65).] In contrast to these studies indicating an association between $PM_{2.5}$ and stroke, the previously described English general practice database found no association; however, cases were not validated by physician review and the $PM_{2.5}$ prediction model performance was relatively low (R^2 = 0.5) (Atkinson et al., 2013). A final study examined the effect of $PM_{2.5}$ on first stroke and recurrent stroke in a cohort of Israeli first MI patients (Koton et al., 2013). Numbers of events were small and exposures higher than some areas in the US (median $PM_{2.5}$: 23.9 $\mu g/m^3$); however, cases were validated by physician review and analyses included time-varying confounders. The study reported an imprecise relationship between $PM_{2.5}$ and the first stroke after MI [HR: 1.05 (95%CI: 0.71, 1.58)] but a larger magnitude association for recurrent strokes [HR: 1.22 (95%CI: 0.95, 1.55)].

Several cross sectional or ecological analyses of prevalent stroke or first hospital admission for stroke that provide some support for the associations observed in prospective studies were also conducted (To et al., 2015; Feng and Yang, 2012; Johnson et al., 2010).

In summary, studies of women enrolled in the WHI study and in the CTS support a positive association between long term exposure to $PM_{2.5}$ and stroke (Lipsett et al., 2011; Miller et al., 2007). Hart et al. (2015b) reported an association in women with diabetes but not in the NHS population, overall. Evidence was inconsistent across other populations studied and confidence intervals around effect estimates were generally wide (Figure 6-18). Several studies are limited by lack of physician adjudication of stroke and outcomes and small sample sizes for stroke subtype analyses. The exposure assessment methods that were applied varied by study but included spatiotemporal models and LUR. There was no evaluation of the influence of the exposure model choice within a study and analysis of copollutant confounding was limited.

6.2.3.1.1 Subclinical Cerebrovascular Disease

Various diagnostic tools can be used to examine risk of cerebrovascular disease. Cerebrovascular hemodynamics, measured through transcranial Doppler ultrasound, is an important component of assessing cerebrovascular blood flow. White matter hyperintensity, detected through magnetic resonance imaging (MRI), is thought to be caused in part by ischemia in the brain and has been shown to predict stroke, dementia, and death (Debette and Markus, 2010). Covert or silent brain infarcts can also be detected with MRI. Both white matter hyperintensity and covert brain infarcts can appear in persons with no history of clinical cerebrovascular event history, and can therefore be used as markers of subclinical disease in asymptomatic individuals. Recent epidemiologic studies have examined subclinical measures of cerebrovascular disease. No studies of this type were available for the 2009 PM ISA (U.S. EPA, 2009). There is a paucity of laboratory animal studies on stroke and cerebrovascular disease with long-term particle exposure. There were no studies on this endpoint in the 2009 PM ISA, and no new studies have

been published since. The nervous system chapter in this ISA reviews studies of brain morphology that are relevant to cerebrovascular disease.

Wellenius et al. (2013) assessed cerebrovascular hemodynamics within the NAS, a cohort of older adults in Boston, by calculating cerebrovascular resistance (i.e., mean arterial blood pressure/middle cerebral artery blood flow velocity) at rest as well as in response to a CO_2 challenge (i.e., induces cerebral vasodilation and increased blood flow) and a sit-to-stand maneuver (i.e., cerebral autoregulation). While no effects of $PM_{2.5}$ were observed on cerebral vasoreactivity or autoregulation, there was an effect of 28-day average $PM_{2.5}$ on increasing resting cerebrovascular resistance [14.33% (95%CI: 6.17, 23.00) due to a decreasing resting middle cerebral artery blood flow [-12.50% (95%CI: -17, 7.0,) (Wellenius et al., 2013). Wilker et al. (2015) examined the effect of $PM_{2.5}$ on white matter hyperintensity and presence of covert brain infarcts (binary) among participants with no history of dementia, stroke, or transient ischemic attack. While there was little evidence of a $PM_{2.5}$ association with white matter hyperintensity, a predictor of stroke, there was a relationship with the presence of cerebral brain infarcts [OR: 2.20 (95%CI: 1.05, 4.66)]. Although studies are limited in number, they provide some evidence to support an effect of $PM_{2.5}$ on cerebrovascular conditions in participants exposed to average $PM_{2.5}$ exposures 12.6-12.1 $\mu g/m^3$ [(Wellenius et al., 2013) and (Wilker et al., 2015), respectively].

6.2.4 Atherosclerosis

Atherosclerosis is the process of plaque buildup into lesions on the walls of the coronary arteries that can lead to narrowing of the vessel, reduced blood flow to the heart and IHD. The development of atherosclerosis is dependent on the interplay between plasma lipoproteins, inflammation, endothelial activation, and neutrophil attraction to the endothelium, extravasation, and lipid uptake. Risk factors for atherosclerosis include high LDL/low HDL cholesterol, high blood pressure, diabetes, obesity, smoking and increasing age. The 2009 PM ISA reviewed a series of cross-sectional studies examining measures that assessed atherosclerosis within large arterial vascular beds in distinct regions of the body [i.e., carotid intima-media thickness (CIMT), coronary artery calcium (CAC), and ankle-brachial index (ABI).] Overall, findings from these studies were inconsistent, with studies reporting null or positive imprecise associations with CIMT, CAC, and ABI (U.S. EPA, 2009). Exposure measurement error, variation in baseline measures of atherosclerosis as well as statistical power were noted as possible explanations for the lack of association observed in these studies. Although findings from more recent studies are not entirely consistent across populations and measures of atherosclerosis, an extended MESA analysis reported a longitudinal increase in coronary artery calcification (CAC) (Kaufman et al., 2016) At the time the 2009 ISA was completed, the biological plausibility for $PM_{2.5}$ induced atherosclerotic plaque development was provided by a small number of experimental animal studies, with several of the experiments conducted in the same laboratory (U.S. EPA, 2009). An additional experimental study is currently available for review.

6.2.4.1 Epidemiologic Studies

Studies that examine the relationship between long-term exposure to $PM_{2.5}$ and measures of atherosclerosis are characterized in Table 6-37.

Table 6-37 Characteristics of the studies examining the association between long-term $PM_{2.5}$ exposures and atherosclerosis.

1

Several analyses from the MESA Air cohort, which comprises a large ethnically diverse study population recruited between 2000 and 2002 from six U.S. communities thus allowing within-city contrasts. Recent analyses of this cohort contribute to the evidence describing the relationship between long-term exposure to $PM_{2.5}$ and atherosclerosis. In general, cross-sectional analyses that included control for study site reported no association regardless of $PM_{2.5}$ exposure assessment method (Adar et al., 2013; Sun et al., 2013). Results from an interim longitudinal analysis (Adar et al., 2013) showing a $PM_{2.5}$ associated increase in cIMT were not retained when additional years of follow-up were available (Kaufman et al., 2016). Kaufman et al. (2016) observed no association with cIMT [-0.9 mm (95%CI: -3.0, 5.0)] while reporting a 4.1 agatston unit increase per year (95%CI: 1.4, 6.8) for CAC. CAC is a stronger predictor of subsequent CHD than cIMT, which typically indicates earlier vascular injury than CAC, in MESA study participants (Gepner et al., 2015). The effect of $PM_{2.5}$ on CAC progression was stronger in people with hypertension, those who are not obese and older adults. Modification of this association by race was not observed. Also in the MESA cohort, Chi et al. (2016b) observed associations of long-term $PM_{2.5}$ exposure with DNA methylation in circulating monocytes. By contrast, Dorans et al. (2016) reported an imprecise (i.e., wide CIs) association between exposure to long-term $PM_{2.5}$ and CAC progression using defined thresholds based on the variability of within-person repeated CAC measurements in the Framingham Heart Study [OR: 1.23 (95%CI: 0.77, 1.92)]. The change in CAC in association with long-term exposure to $PM_{2.5}$ was also reported [-2.86 (95%CI: -8.57, 2.86)]. The shape of the concentration-response functions for these studies are discussed in Section 6.2.16.

Several other studies examined the longitudinal changes in atherosclerosis indicated by the presence of lesions or cIMT, but studies of CAC were not available for comparison to results reported in the MESA and Framingham Health Studies. Long-term exposure to $PM_{2.5}$ was associated with both mild and severe atherosclerosis, defined as ≥50 stenosis in 1-2 and >3 vessels, respectively among coronary artery disease patients in Ohio (Hartiala et al., 2016). Künzli et al. (2010) examined the relationship between long-term exposure to $PM_{2.5}$ and the rate of atherosclerosis progression reporting a small positive association of $PM_{2.5}$ with cIMT progression rate [1.27 µm/yr (95%CI: -0.16, 2.69)]. The association of $PM_{2.5}$ with cIMT in was more than twofold larger among those living within 100 meters of a highway, however. By contrast, Gan et al. (2014) observed no association with change in cIMT in a smaller sample (N = 509) in Vancouver Canada where the mean $PM_{2.5}$ concentration is relatively low (4 $\mu g/m^3$).

Several cross-sectional analyses examined atherosclerotic lesions and cIMT reported results that were not entirely consistent (Aguilera et al., 2016; Newman et al., 2015; Perez et al., 2015; Bauer et al., 2010). Studies of the effect of exposure during prenatal and childhood lifestages and atherosclerosis as young adults were also conducted. Among young adults in their twenties, neither Lenters et al. (2010) nor (Breton et al., 2012) observed large (relative the width of the confidence interval) increases in cIMT in association with $PM_{2.5}$ exposure, regardless of childhood exposure window [0.69 µm (95% CI: -4.41, 5.79) and -1.51 (95%CI: -5.19, 2.17)]. In an analysis focusing on prenatal exposure Breton et al. (2016) reported an imprecise (i.e., wide CIs) small magnitude association with $PM_{2.5}$ [1.48% increase in cIMT (95% CI: -1.77, 4.74)].

In summary, several epidemiologic studies have continued to examine the relationship between long-term $PM_{2.5}$ exposure and atherosclerosis among adults since the completion of the 2009 PM ISA. These studies were conducted within North America and Europe with some extending analyses of the same populations discussed in the 2009 PM ISA (i.e., MESA, HNR). A strength of the expanded body of literature is that it includes analyses of the longitudinal change in measures of atherosclerosis in relation to long-term exposure to $PM_{2.5}$ (Hartiala et al., 2016; Kaufman et al., 2016; Gan et al., 2014; Künzli et al., 2010). MESA analyses supported a $PM_{2.5}$ effect on CAC among middle to older aged adults, while the Dorans et al. (2016) analysis of Framingham Heart Study offspring did not provide support for an association with CAC progression or longitudinal change in CAC. Associations of long-term exposure to $PM_{2.5}$ with cIMT were not consistently observed across cohorts or when variable methods (e.g., exposure assessment methods) were applied within the same cohort. Relationships between $PM_{2.5}$ and CIMT at younger ages were generally not supported in the limited number of studies. Consideration of copollutant confounding was limited across the evidence base.

6.2.4.2 Toxicological Studies of Atherosclerosis

Atherosclerosis and related pathways have been studied primarily in the Apolipoprotein E (ApoE) knockout mouse (Piedrahita et al., 1992; Zhang et al., 1992), The ApoE molecule is involved in the clearance of fats and cholesterol. When ApoE (or the low- density lipoprotein (LDL) receptor) is deleted from the genome, mice develop severely elevated lipid and cholesterol profiles. As a result, the lipid uptake into the vasculature is increased and the atherosclerotic process is dramatically hastened. Furthermore, the LDLs in $ApoE^{-/-}$ mice are highly susceptible to oxidation (Hayek et al., 1994), These mice exhibit cholesterol levels exceeding 1,000 mgdL (normal is ~150 mgdL) (Moore et al., 2005; Huber et al., 1999). which may be a crucial event in the air pollution-mediated vascular changes. However, it should be noted that this model is primarily one of peripheral vascular disease rather than coronary artery disease.

In the 2009 PM ISA, studies found increased atherosclerotic plaque area in aortas of $ApoE^{-/-}$ mice exposed to $PM_{2.5}$ CAPs for 4-6 months from an exurban site located in Tuxedo NY or an urban site located in Manhattan, NY. Since the publication of the 2009 PM ISA, Lippmann et al. (2013a) have conducted additional plaque progression analyses in Irvine, CA; Lansing, MI; and Seattle, WA, as well as in Tuxedo and Manhattan, NY. The authors reported that plaque progression in $ApoE^{-/-}$ mice varied by site. Specifically, increased ($p < 0.05$) plaque areas relative to control animals were identified in the brachiocephalic artery of mice exposed to $PM_{2.5}$ from Manhattan, NY (6 mo after exposure), Tuxedo, NY (3 and 6 mo after exposure), and ($p < 0.05$) in East Lansing, MI. Increased (6 mo after exposure, $p < 0.05$) plaque progression relative to control animals was also identified in the left common carotid artery of mice exposed to $PM_{2.5}$ from Tuxedo (6 mo after exposure) and Irvine (2 mo after exposure). Animals exposed to $PM_{2.5}$ from Seattle did not have increased plaque progression relative to controls in either the brachiocephalic or the carotid arteries. However, it is important to note that the mice were older

in the studies performed in Seattle and Irvine. Therefore, the Seattle and Irvine mice were older at the onset of PM exposures than animals used in studies at the other sites and this could have affected the results of these studies. Nonetheless, the results in other locations provide evidence for $PM_{2.5}$-mediated effects on atherosclerotic plaque progression in a genetically susceptible mouse model. More information on this study can be found in Table 6-38 below.

6.2.5 Heart Failure and Impaired Heart Function

Heart failure (HF) refers to a set of conditions including congestive heart failure (CHF) in which the heart's pumping action is weakened. With CHF the blood flow from the heart slows, failing to meet the oxygen demands of the body, and returning blood can back up, causing swelling or edema in the lungs or other tissues (typically in the legs and ankles). Risk factors for HF include IHD, high blood pressure, atrial fibrillation, and diabetes. Right sided HF, is typically a consequence of left-sided HF but can also result from damage to the pulmonary vasculature, which can result in increased right ventricular (RV) mass, reduced flow to the left ventricle and reduced left ventricular (LV) mass. In chronic HF, the heart typically enlarges and develops more muscle mass. LV mass is known to predict the development of HF and can be assessed with magnetic resonance imaging (MRI) (Drazner et al., 2004). Ejection fraction (EF), which is the percent of blood that is pumped from the ventricle during each contraction, is another measure of how well the heart pumps that can be assessed through echocardiography. Although depressed EF provides evidence of HF, EF may be normal in a large proportion of HF patients. There were no studies examining the association between long-term exposure to $PM_{2.5}$ and CHF reviewed in the 2009 PM ISA. The evidence has expanded substantially with the recent epidemiologic and toxicological studies providing support for an effect of long-term exposure to $PM_{2.5}$ on CHF and impaired cardiac function.

6.2.5.1 Epidemiologic Studies

There were no epidemiologic studies examining the association between long-term exposure to $PM_{2.5}$ and CHF reviewed in the 2009 PM ISA (U.S. EPA, 2009). A small number of recent studies have examined the effects of $PM_{2.5}$ on heart failure or related indices (Table 6-39) generally reporting positive associations. The U.K. general practice cohort described in Section 6.2.2, which included nearly 13,000 cases of incident heart failure identified by ICD codes with physician review, reported a positive association with long-term exposure to $PM_{2.5}$ [HR 1.17 (95%CI: 1.03, 1.17)] (Atkinson et al., 2013). A relatively small Israeli cohort was exposed to higher $PM_{2.5}$ concentrations than most areas of the U.S. (median [range]: 23.9 [17.0-26.6]), and benefitted from physician review of medical records for case ascertainment and reported a HR for heart failure and recurrent heart failure after first MI with increasing $PM_{2.5}$ of 1.22 (95%CI: 0.89, 1.67) (Koton et al., 2013). A cross-sectional analysis of women reported a positive association between $PM_{2.5}$ and the prevalence of heart failure [OR: 1.14 (95%CI: 1.06, 1.23)] (To et al., 2015).

1

No association of long-term exposure to $PM_{2.5}$ with left ventricular mass index LVMI or depressed EF was observed in a cross-sectional analysis of the MESA cohort after adjustment for study center (Van Hee et al., 2009). An increase in RV mass [0.11 g (95%CI: -0.05, 0.27)] was observed in the MESA cohort, in association with long term exposure to $PM_{2.}$ after controlling for site and other covariates, however. Associations with RV end diastolic volume and RV mass/end-diastolic volume ratio were also observed but were attenuated after adjustment for site. A sensitivity analysis showed that the increase in RV mass persisted after adjustment for LV mass, indicating that the findings may be explained by pulmonary vascular damage. D'Souza et al. (2017) found that this increase in RV mass was slightly reduced but remained after adjustment for $PM_{10-2.5}$ and NO_2.

Ohlwein et al. (2016) conducted a cross-sectional analysis of the SALIA cohort to determine the association, using an adjusted means ratio (MR) of long-term $PM_{2.5}$ exposure with diastolic function. Two metrics, E/E' ratio and left atrial volume index (LAVI) were determined. The E/E ratio is the ratio of peak early diastolic filling velocity to peak early diastolic mitral annulus velocity and a value less than eight indicates normal diastolic function. LAVI is an indicator of diastolic function severity and a known predictor for cardiovascular disease. The authors observed that LAVI was increased in association with long-term exposure to $PM_{2.5}$.

In summary, the small number of studies provide evidence supporting a possible relationship between heart failure and $PM_{2.5}$ with the epidemiologic studies of long-term exposure to $PM_{2.5}$ reporting positive associations with HF. An association with RV mass was observed, but no association was with LVM or EF, among MESA participants. A cross-sectional association between $PM_{2.5}$ and increased LAVI was observed in the SALIA cohort.

6.2.5.2 Toxicology Studies of Impaired Heart Function

There were no animal studies in the 2009 PM ISA examining heart failure in response to long-term $PM_{2.5}$ exposure. Since the publication of the 2009 PM ISA, (Aztatzi-Aguilar et al., 2015) reported increased ($p < 0.05$) coronary artery wall thickness and a statistically significant ($p < 0.05$) increase in two genes typically associated with responding to cardiac damage: Acta 1 and Col3a1-. Similarly, Ying et al. (2015) reported that long-term exposure to $PM_{2.5}$ increased ($p < 0.05$) heart weight, and ($p < 0.05$) contractility of aortic rings in response to phenylephrine, while decreasing ($p < 0.05$) stroke volume, and ($p < 0.05$) cardiac output in SH rats. Importantly, these effects were reversible after stopping $PM_{2.5}$ exposure and allowing 5 weeks of recovery time. These authors also found an increase in the cardiac hypertrophic markers Acta1 and Myh7 ($p < 0.05$), but not in Serca2. In an additional study, Wold et al. (2012) reported that relative to controls, mice exposed long-term to $PM_{2.5}$ had a statistically significant increase in heart weight ($p < 0.05$), displayed cardiac remodeling as evidenced by increased diastolic dimensions, and had a statistically significant decrease ($p < 0.05$) in contractility in response to dobutamine, but preserved coronary flow. Cardiac remodeling results were consistent with additional

experiments indicating a statistically significant decrease in ($p < 0.05$) Serca-2 protein levels, increased ($p < 0.05$) myosin heavy chain β protein levels, and increased ($p < 0.05$) collagen expression in whole heart homogenates (Wold et al., 2012). However, in contrast to these studies, Lippmann et al. (2013a) did not find changes in cardiac function measurement following long-term exposure of $APOE^{-/-}$ mice to $PM_{2.5}$ from Manhattan or Tuxedo, NY. Nonetheless, there is evidence across multiple animal toxicological studies demonstrating that long-term exposure to $PM_{2.5}$ may lead to impaired heart function.

Recent studies also highlight that exposure to $PM_{2.5}$ during gestation may result in cardiac dysfunction later in life. Gorr et al. (2014) exposed female mice to $PM_{2.5}$ during pregnancy and while nursing and then assessed cardiac function in offspring. The authors reported that at adulthood, offspring had reduced left ventricular fractioning with greater ventricular systolic diameter ($p < 0.05$), reduced ejection fraction ($p = 0.0005$), and other indicators of cardiac dysfunction when compared to FA control mice. In a follow-up study using a similar exposure scenario, Tanwar et al. (2017) confirmed earlier findings of ventricular dysfunction and also reported collagen deposition, as well as prolonged increased ($p > 0.05$) action potentials in isolated cardiomyocytes. They also measured decreased levels of calcium homeostasis proteins (Serca-2A, NCX, *p*-PLN). Furthermore, work from the same lab, Tanwar et al. (2017) demonstrated that prenatal exposure alone was sufficient to produce heart failure in adulthood, looking at similar outcomes as Gorr et al. (2014). More information on studies published since the 2009 ISA can be found in Table 6-40 below.

Table 6-40 Study-specific details from toxicological studies of long-term $PM_{2.5}$ exposure and impaired heart function.

Study	Study Population	Exposure Details	Endpoints Examined
(Aztatzi-Aguilar et al., 2015)	Adult Sprague-Dawley rats, M, n = 4 per treatment group	Inhalation of 178 µg/m^3 $PM_{2.5}$ from a high traffic and industrial area north of Mexico City in early summer for 5 h/day for 8 weeks (4 days/week).	Coronary artery wall thickness measured in myocardial slices collected 24 h post-exposure Gene expression consistent with cardiac damage in heart tissue collected 24 h post-exposure
(Gorr et al., 2014)	Pregnant (In utero) and neonatal FVB mice offspring	Inhalation of 51.69 µg/m^3 $PM_{2.5}$ CAPS from Columbus, OH, exposures of dams for 6 h/day, 7 days/week, from the day after vaginal plug discovery until weaning of pups. After weaning, mice were exposed to room air until 3 mo old	Birth weight, body and heart weights, end-systolic and end-diastolic ventricular dimensions, fractional shortening and posterior wall thickness. Contraction length and calcium reuptake during relaxation, cardiac collagen content.

Table 6-40 (Continued): Study-specific details from toxicological studies of long-term $PM_{2.5}$ exposure and impaired heart function.

Study	Study Population	Exposure Details	Endpoints Examined
(Tanwar et al., 2017)	FVB mice, pregnant (in utero) and offspring	In utero inhalation of 73.61 ug/m^3 $PM_{2.5}$ CAPs for 6h/day, 7 days/week throughout pregnancy.	Pressure-volume loop, fractional shortening, left ventricular end-systolic and -diastolic diameter, left ventricular posterior wall thickness, end-systolic elastance, contractile reserve, contractility, collagen deposition, inflammatory response, epigenetic markers 12 week after birth
(Wold et al., 2012)	8 week old C57BL/6 mice, M	Inhalation of 85 µg/m^3 (16.9-266.4 µg/m^3) $PM_{2.5}$, for 6 h/day, 5 days/week, for 9 mo from Columbus, OH	Heart weight, contractility, cardiac remodeling, hypertrophic markers, cardiac fibrosis post exposure
(Ying et al., 2015)	4 week old SH rats, M, n = 6/treatment group	Inhalation of 128.3 ± 60.4 µg/m^3 $PM_{2.5}$ CAPs Exposed 6 h/day, 5 days/week for 15 week from Columbus, OH	Heart weight, contractility of aortic rings, stroke volume and cardiac output post 15 week exposure other exposed rats were not sacrificed in order for stroke volume and cardiac output analysis to be repeated after removal of $PM_{2.5}$ exposure. Hypertrophic markers 15 week post
(Lippmann et al., 2013a) NPACT Study 1	$ApoE^{-/-}$ mice, M, n = 4-8 per treatment group,	CAPs from Tuxedo, NY, Manhattan, NY (136, 123, ug/m^3, respectively) for 6 h/day, 5 days/week for 6 mo	Ejection fraction, fractional shortening, cardiac wall thickness
(Tanwar et al., 2017)		Pregnant FVB mice and their offspring	Exposure to filtered air or Ohio State $PM_{2.5}$ CAPs at an average concentration of 73.61 µg/m^3 for 6 h/day, 7 days/week throughout pregnancy (prenatal only).
			At 12 weeks of age in offspring, echocardiographic assessment of pressure and volume changes in the heart including left ventricular (LV) systolic and diastolic internal dimensions (LVESd and LVEDd) and systolic and diastolic posterior wall thickness (PWTs and PWTd). Percent fractional shortening (%FS). Ca++ flux. Collagen deposition in the heart. Epigenetic modification (Sirt 1 and 2, Dnmt1, 3a and 3b).

$APOE^{-/-}$ = apolipoprotein E null mice, CAPs = concentrated ambient particles, d = day, h = hour, m = male, n = number, SH = spontaneously hypertensive, week = week.

6.2.6 Cardiac Electrophysiology and Arrhythmia

Electrical activity in the heart is typically measured using surface electrocardiography (ECG). ECGs measure electrical activity in the heart due to depolarization and repolarization of the atria and

ventricles (see Section 6.1.4). Atrial fibrillation (AF) is the most common type of arrhythmia. Despite being common, clinical and subclinical forms of AF are associated with reduced functional status, quality of life and is associated with downstream consequences such as ischemic stroke (Prystowsky et al., 1996; Laupacis et al., 1994) and CHF (Roy et al., 2009), contributing to both cardiovascular disease (CVD) and all-cause mortality (Kannel et al., 1983). Ventricular fibrillation is a well-known cause of sudden cardiac death and commonly associated with myocardial infarction, heart failure, cardiomyopathy, and other forms of structural (e.g., valvular) heart disease. Pathophysiologic mechanisms underlying arrhythmia include electrolyte abnormalities, modulation of the ANS, membrane channels, gap junctions, oxidant stress, myocardial stretch and ischemia. Ventricular conduction and repolarization abnormalities such as QRS and QT interval prolongation, their subclinical correlates including left ventricular hypertrophy, and clinical antecedents including hypertension are also associated with cardiac arrest (Rautaharju et al., 1994).

In a study reviewed in the 2009 PM ISA Liao et al. (2009) reported that neither 30- nor 365-day $PM_{2.5}$ concentrations were associated with supraventricular or ventricular ectopy, which are the most frequent forms of arrhythmia in the general population, among women enrolled in the WHI clinical trials. The association between long-term exposure to $PM_{2.5}$ and ventricular repolarization abnormalities was not studied at the time the 2009 PM ISA was published. There are no experimental animal studies and such studies continue to be lacking.

6.2.6.1 Epidemiologic Studies

Several recent studies have examined the association between long-term exposure to $PM_{2.5}$ and arrhythmogenic effects in additional populations (Table 6-41). Atkinson et al. (2013) found that ICD-coded arrhythmias and cardiac arrest were not associated with annual mean $PM_{2.5}$ concentrations. In the REGARDS cohort, O'Neal et al. (2016) examined the cross-sectional association with premature atrial contractions (PACs) and long-term $PM_{2.5}$ exposure reporting [OR: 1.19 (95%CI: 1.05, 1.34)]. Van Hee et al. (2011) examined associations between ventricular conduction, repolarization, and spatiotemporally modeled annual mean $PM_{2.5}$ concentrations of 4,783 MESA participants in six U.S. centers. Consistent with O'Neal et al. (2016), Van Hee et al. (2011) found strong, positive, and ORs for associations between prolonged QRS, prolonged QT, and long-term $PM_{2.5}$ concentrations. The study also found increasing ORs when controlling for study center that were robust to additional control for subclinical atherosclerosis, findings that were presented to support the importance of the study's within-city $PM_{2.5}$ gradients and their atherosclerosis-independent mechanism of ECG effects (Van Hee et al., 2011).

6.2.7 Blood Pressure and Hypertension

High blood pressure is typically defined as a systolic blood pressure above 140 mm hg or a diastolic blood pressure above 90 mm Hg. Hypertension, the clinically relevant consequence of chronically high blood pressure, typically develops over years. Small population-level changes in blood pressure, even in the absence of clinical hypertension, can have large effects on clinical outcome prevalence (Rose, 1985). Pulse pressure (PP) or the difference between SBP and DBP, as well as mean arterial pressure (MAP), which is a function of cardiac output, systemic vascular resistance and central venous pressure, are additional outcome metrics used in studies of air pollution on blood pressure. Because high blood pressure increases the force on the artery walls the condition can damage the blood vessels and increase risk for cardiovascular disease and stroke. Ventricular remodeling that occurs with hypertension leads to the repolarization abnormalities (see Section 6.2.6) often accompany hypertension and chronic conditions such diabetes and renal disease. Further, hypertension is one of the array of conditions including high blood sugar, excess body fat around waste and abnormal triglycerides that comprise metabolic syndrome (see CHAPTER 7), which is a risk factor for heart disease, stroke and diabetes.

The 2009 PM ISA reviewed a limited number of long-term PM exposure and blood pressure reporting small magnitude effects. The body of literature has grown substantially, and currently includes longitudinal analyses generally showing small magnitude increases in SBP, PP, and MAP in association with long term exposure to $PM_{2.5}$. Recent studies of children did not support an association between long-term $PM_{2.5}$ exposure and blood pressure.

6.2.7.1 Epidemiologic Studies

6.2.7.1.1 Blood Pressure

Several analyses of data from established cohorts, that generally report associations between increasing long-term $PM_{2.5}$ concentration and increasing blood pressure, are available for review (Table 6-42). Hicken et al. (2013) completed blood pressure measurements among 5,570 MESA participants with $PM_{2.5}$ exposure assigned using 30- day averages from all monitors within their MESA site. Chan et al. (2015) examined 43,629 participants from across the United States enrolled in the Sister Study. Both studies showed elevated SBP, PP, and MAP with $PM_{2.5}$ exposures but no effect on DBP. A sensitivity analysis in MESA study using 60-day average $PM_{2.5}$ exposure yielded similar results. Effect sizes reported in these studies were typically small (e.g., SBP: 1.4 (0.4, 1.7) mm hg (Chan et al., 2015); SBP: 0.95 (0.5, 1.4) mm hg (Hicken et al., 2013)). No evidence of modification by race was observed, while associations with blood pressure were higher in the higher income group in MESA (Hicken et al., 2013).

Wellenius et al. (2012b), examined blood pressure changes during an orthostatic challenge of older adult participants in the MOBILIZE study (changes between supine blood pressure and 1- and 3-minute standing blood pressure). Although effects of $PM_{2.5}$ were observed on static supine and standing diastolic blood pressures, no evidence was found to indicate that $PM_{2.5}$ exposure over the previous 28 days influences the change in blood pressure that occurs between supine and standing states. By contrast, the pooled analysis of 12 European cohorts from ESCAPE, reported null effects of $PM_{2.5}$ for both systolic and diastolic blood pressure (Fuks et al., 2014). Study-specific estimates were variable in magnitude and direction (Fuks et al., 2014). Meta-analyzed associations reported in the ESCAPE study were strengthened after adjustment for NO_2.

Children

Studies (Table 6-43) examining long term $PM_{2.5}$ exposure and blood pressure among children (Bilenko et al., 2015a; Bilenko et al., 2015b; Liu et al., 2014a) were completed in the United States and Europe. A study of newborns in Massachusetts found elevated SBP with higher $PM_{2.5}$ averages over the 30-, but not 60- or 90-day periods before birth (van Rossem et al., 2015) while trimester specific associations between $PM_{2.5}$ and increased SBP increased but confidence intervals were wide [β = 0.66 (95%CI: -1.31, 2.62)]. The three studies of annual $PM_{2.5}$ exposure conducted in European countries among 10- and 12-year olds (Bilenko et al., 2015a; Bilenko et al., 2015b; Liu et al., 2014a) did not provide evidence supporting an association between long-term $PM_{2.5}$ exposure and increased blood pressure in children. Both small increases and small decreases were observed in these studies.

6.2.7.1.2 Hypertension

Prospective studies of the association between long-term exposure to PM2.5 and hypertension are described in Table 6-44. Zhang et al. (2016) conducted a prospective analysis of long-term exposure to $PM_{2.5}$ and self-reported hypertension among women enrolled in the NHS. A positive association of incident hypertension with annual average $PM_{2.5}$ exposure was reported [HR: 1.02 (95%CI: 1.00, 1.03)]. By contrast Coogan et al. (2016) reported no association between long-term $PM_{2.5}$ exposure and hypertension in the Black Women's Health Study (BWHS) [HR: 0.98 (95%CI: 0.88, 1.11)]. This finding, which was based on a refined spatiotemporal exposure model and included additional years of follow-up, supersedes the earlier report indicating a large but imprecise association with hypertension in this cohort [HR: 1.22 (95%CI: 0.97, 1.52)] (Coogan et al., 2012). The largest study of incident hypertension, conducted within a population-based sample of Ontario, Canada residents, reported a fully adjusted HR of 1.07 (95% CI: 1.03, 1.11) (Chen et al., 2014a). This study used the Ontario hypertension database to classify hypertension, including those with at least one hospital admission with a diagnosis of hypertension or two physician claims for hypertension within a two-year period. Larger magnitude associations were reported among participants with diabetes [HR: 1.23 (95%CI: 1.04, 1.46) vs. 1.05 (95%CI: 1.01, 1.10) among those without diabetes]. There was no statistical evidence of modification by other factors (i.e., age, sex, BMI, education, smoking and COPD). Results of Chen et al. (2014a) that pertain to the shape of the C-*R* function are discussed in Section 6.2.16.

Several additional studies examine the cross-sectional association between long-term $PM_{2.5}$ exposure and hypertension (To et al., 2015; Babisch et al., 2014; Fuks et al., 2014; Johnson and Parker, 2009). These cross-sectional studies generally provide support for an association between long-term exposure to $PM_{2.5}$ and the prevalence of hypertension.

Table 6-44 Characteristics of the studies examining the association between long-term $PM_{2.5}$ exposures and hypertension.

1

In summary, this expanded body of literature provides evidence of association between long-term $PM_{2.5}$ exposure, blood pressure, and hypertension, although consistency of associations varied with the specific outcome and averaging times examined. Limited evidence from studies of adult blood pressure indicated increases in systolic and diastolic blood pressure (SBP, DBP) as well as pulse pressure (PP) and mean arterial pressure (MAP) 28 to 60-day average exposures. Studies of children did not consistently report associations of between long-term exposures of months to years and increased blood pressure.

6.2.7.1.3 Gestational Hypertension and Preeclampsia

Epidemiologic studies examining increases in $PM_{2.5}$ concentrations and hypertensive disorders of pregnancy, including preeclampsia, are discussed in detail in Section 9.2.1. Overall, these do not observe consistent results. The methods by which exposure was assigned in these studies may contribute to the heterogeneity in associations observed across these studies. For example, the association between a composite outcome of gestational hypertensive disorders and $PM_{2.5}$ changed based on how concentrations were determined in a study conducted in California (Wu et al., 2011; Wu et al., 2009). However, two meta-analyses have estimated positive odds ratios (ORs 1.15-1.47) for $PM_{2.5}$ and preeclampsia, however both had large heterogeneity scores, and therefore a combined effect may be inappropriate (Hu et al., 2014; Pedersen et al., 2014).

6.2.7.1.4 Renal Function

Observed effects of long-term $PM_{2.5}$ exposure on renal function may be secondary to hypertension because chronic increases in vascular pressure can contribute to glomerular and renal vasculature injury, which can lead to progressive renal dysfunction. The relationship between BP and renal function is complicated, however, because hypertension contributes to renal dysfunction but damage to the kidneys can also cause increased BP. The 2009 PM ISA did not review studies of the association between long-term exposure to $PM_{2.5}$ and renal function. The literature remains limited but an epidemiologic study of older adult males in the NAS, Mehta et al. (2016) reported an association between annual average $PM_{2.5}$ exposure and lower estimated glomerular filtration rate (eGFR) (-4.45 mL/min/1.73 m^2 [95%CI: -7.12, -1.81]). A longitudinal decrease was also observed as a per year reduction in eGFR in this study.

6.2.7.2 Toxicology Studies of Changes in Blood Pressure (BP)

In the current ISA, studies using rats have demonstrated increased ($p < 0.05$) blood pressure in response to long-term $PM_{2.5}$ exposure. Aztatzi-Aguilar et al. (2016) exposed adult male Sprague–Dawley rats to Mexico City fine CAPS and measured BP on the 4th day of each weekly exposure for 8 weeks.

The mean arterial pressure (MAP) was calculated and found to be increased ($p < 0.05$) at weeks 1, 5, and 8. In an additional study, Ying et al. (2015) identified that long-term CAPs exposure increased ($p < 0.05$) BP in SH rats compared to filtered air controls. This increase in BP persisted throughout the 15-week exposure, but returned to baseline two weeks after $PM_{2.5}$ was withdrawn. Furthermore, Wold et al. (2012) found that relative to controls, mice exposed long-term to $PM_{2.5}$ had a statistically significant increase in SBP, DBP, and MAP, while pulse pressure decreased relative to controls ($p > 0.05$). In summary, these studies individually and collectively support that long term $PM_{2.5}$ exposure can increase BP. More information on studies published since the 2009 ISA can be found in Table 6-45 below.

6.2.7.2.1 Renin-Angiotensin System

As noted above (see Section 6.1.6.4.1), the renin-angiotensin system can have direct effects on changes in blood pressure. Since the publication of the 2009 PM ISA, additional studies have evaluated the effects of PM on this system. Long-term $PM_{2.5}$ exposure resulted in a statistically significant increase ($p < 0.05$) in At1r and B1r mRNA levels in rat heart tissue, whereas At2r, and ACE were not appreciably changed (Aztatzi-Aguilar et al., 2015). In a follow-up study, Aztatzi-Aguilar et al. (2016) found that in rat kidney tissue, although mRNA levels of Ace and At1r statistically significantly decreased at 8 weeks post exposure ($p > 0.05$), protein levels statistically significantly increased ($p < 0.05$) relative to controls. In addition, the authors also reported that B1r mRNA and protein was statistically significantly ($p < 0.05$) higher following long-term $PM_{2.5}$ exposure. Thus, there is evidence that long-term $PM_{2.5}$ exposure can result in the types of changes in the renin-angiotensin system that could lead to changes in blood pressure.

Table 6-45 Study-specific details from toxicological studies of long-term $PM_{2.5}$ exposure and blood pressure (BP).

Study	Study Population	Exposure Details	Endpoints Examined
(Aztatzi-Aguilar et al., 2015)	Adult Sprague-Dawley rats, M, n = 4 per treatment group	Inhalation of 178 µg/m^3 $PM_{2.5}$ from a high traffic and industrial area north of Mexico City in early summer for 5 h/day for 8 weeks (4 days/week).	Angiotensin and bradykinin system gene and protein expression in heart tissue post exposure
(Aztatzi-Aguilar et al., 2016)	Sprague Dawley rats, M, n = 12/group	Inhalation of 375 µg/m^3 $PM_{2.5}$ CAPs, 5 h/day, 4 day/week, for 8 week from Mexico City	Mean blood pressure on the 4th day of each weekly exposure for 8 weeks Angiotensin and bradykinin system gene and protein expression in kidney tissue post exposure
(Ying et al., 2015)	4 week old male SH rats, n = 6/group	Inhalation of 128.3 ± 60.4 µg/m^3 $PM_{2.5}$ CAPs for 6 h/day, 5 days/week for 15 weeks from Columbus, OH	SBP measured weekly during exposure
(Wold et al., 2012)	8 week old C57BL/6 mice, M	Inhalation of 85 µg/m^3 (16.9-266.4 µg/m^3) $PM_{2.5}$, for 6 h/day, 5 days/week, for 9 mo from Columbus, OH	SBP, DBP, and MAP recorded daily for 3 days post exposure

1

6.2.8 Peripheral Vascular Disease (PVD), Venous Thromboembolism, Pulmonary Embolism

2 Thrombosis refers to intravascular formation of a blood clot inside the blood vessel. The clot can
3 form an embolism that moves from its point of origin to a distant vessel where it can become lodged and
4 occlude blood flow. Thrombi typically form in the deep (i.e., popliteal, femoral, iliac) veins of the lower
5 extremities and can give rise to emboli that lodge in the pulmonary arteries. Deep vein thromboses
6 (DVTs) and pulmonary emboli (PE) are the most common subtypes of venous thromboembolism (VTE).
7 Although no studies of $PM_{2.5}$ were in the 2009 PM ISA, a case-control study reported an association
8 between PM_{10} exposure and risk of deep vein thrombosis (DVT) (Baccarelli et al., 2008). Recent
9 longitudinal analyses of report inconsistent results regarding the association of long-term exposure to
10 $PM_{2.5}$ and VTE.

6.2.8.1 Epidemiologic Studies

Following the DVT study of Baccarelli et al. (2008), longitudinal analyses of the WHI (Shih et al., 2011) and the NHS (Pun et al., 2015) examined other $PM_{2.5}$ in relation to VTE. Shih et al. (2011) found no evidence of association with VTE [HR: 0.96 (95%CI: 0.73, 1.26)], nor did they find evidence of an interaction with hormone therapy as did Baccarelli et al. (2008). By contrast, Pun et al. (2015) reported a positive association [HR: 1.11 (95%CI: 1.00, 1.24)] among women in the NHS. VTE events are uncommon, especially in women with and without established risk factors for VTE and its subtypes. Overall, the evidence remains limited (Table 6-46).

6.2.9 Aggregated Clinical Cardiovascular Outcomes

Several studies define outcome categories that aggregate across specific types of cardiovascular and cerebrovascular disease (CVD and CBVD) (Table 6-47). The outcomes, variously defined and combined, include MI, angina, atherosclerosis, aneurysm, chronic and acute ischemic heart disease, stroke or other cerebrovascular disease, coronary heart disease, heart failure, cardiac arrest, arterial embolism and thrombosis, and peripheral vascular disease, as well as relevant procedures such as revascularization, angioplasty, bypass, or cardiac device implants. Associations of long-term exposure to $PM_{2.5}$ with such aggregated clinical outcomes are presented here with an emphasis on studies that leverage large sample sizes and numbers of events within aggregated outcome groupings to conduct stratified analyses.

The analysis of post-menopausal women enrolled in WHI Miller et al. (2007) was described in the 2009 PM ISA and reported an association of long-term exposure to $PM_{2.5}$ and coronary events, including MI, revascularization and death from CHD, of 1.11 (95%CI: 1.04, 1.19). Recent studies continue to strengthen the evidence supporting an effect of long-term exposure $PM_{2.5}$ on aggregated cardiovascular outcomes. In a follow-up WHI analysis Chi et al. (2016a) examined modification by individual and neighborhood-level socioeconomic status (SES) to determine if these factors could explain the findings of Miller et al. (2007). Authors found that the association was not attenuated after adjustment for SES indicators [HR: 1.14 (95% CI: 1.02, 1.27)]. Although individual SES did not modify the association between long-term exposure to $PM_{2.5}$ and CVD, there was statistical evidence of modification by neighborhood SES. The strongest association was found in most disadvantaged neighborhood SES group [HR: 1.39 (95% CI: 1.21, 1.61)] with a null association in the least disadvantaged neighborhood SES group [HR: 0.90 (95%CI: 0.72, 1.07)].

In an analysis of data from Medicare recipients across the U.S. Makar et al. (2017) examined the association of 2-year $PM_{2.5}$ concentrations with hospital admissions for diseases of the circulatory system among those with annual average concentrations less than 12 $\mu g/m^3$. Authors found an increase in circulatory system hospital admissions [HR: 1.06 (95%CI: 1.02, 1.09), cutpoint of 12 $\mu g/m^3$ and [HR: 1.18 (95% CI 1.10, 1.27) cutpoint of 8 $\mu g/m^3$]. Positive associations between long-term exposure to $PM_{2.5}$ and cardiovascular disease were reported in cross-sectional studies (Feng and Yang, 2012; Johnson and Parker, 2009).

In summary, these studies generally support an effect of long-term exposure $PM_{2.5}$ on a variety of pooled cardiovascular outcomes. These studies are generally large, allowing stratified analyses. Findings of Feng and Yang (2012) and Hart et al. (2015b) related to regional differences in the association between long-term exposure to $PM_{2.5}$ and CVDs are discussed in Section 6.2.17.

Table 6-47 Characteristics of the studies examining the association between long-term $PM_{2.5}$ exposures and cardiovascular diseases.

6.2.10 Long-Term $PM_{2.5}$ Exposure and Cardiovascular Mortality

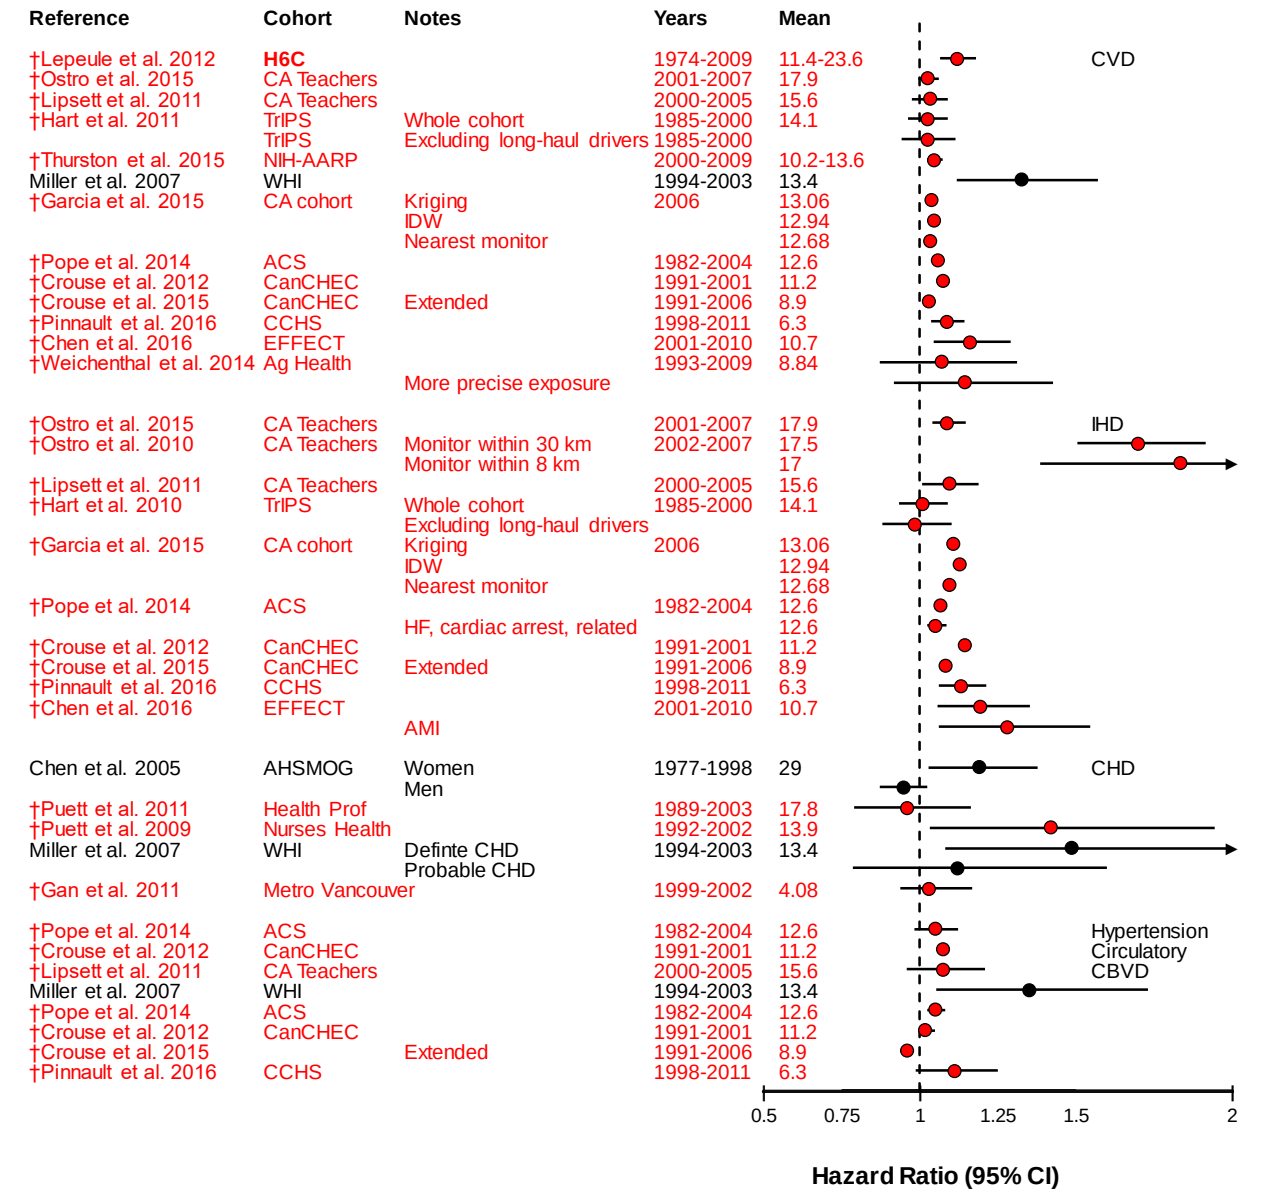
Studies that examine the association between long-term $PM_{2.5}$ exposure and cause-specific mortality outcomes, such as cardiovascular mortality, provide additional evidence for $PM_{2.5}$-related cardiovascular effects, specifically whether there is evidence of an overall continuum of effects. Evidence from studies of long-term $PM_{2.5}$ exposure and mortality are presented in detail in Section 6.2.10 evidence from studies investigating cardiovascular mortality provided some of the strongest evidence for a cardiovascular effect related to long-term $PM_{2.5}$ exposure in the 2009 PM ISA (U.S. EPA, 2009) and are summarized here to inform the effect of long-term $PM_{2.5}$ exposure on the continuum of cardiovascular health effects. The 2009 PM ISA (U.S. EPA, 2009) included evidence from a number multicity U.S. studies, including the American Cancer Society (ACS) cohort (Pope III et al., 2004), the Harvard six cities cohort (Laden et al., 2006), the Women's Health Initiative (WHI) (Miller et al., 2007), and the Seventh-Day Adventist (AHSMOG) cohort (Chen et al., 2005). These studies continue to provide strong support for the relationship between long-term exposure to $PM_{2.5}$ and cardiovascular mortality. In addition, extended analyses of the ACS and Harvard Six Cities studies, as well as results from recent cohort studies contribute to the body of evidence for this relationship (Figure 6-19).

Pope et al. (2014) and Turner et al. (2016) used the extended follow-up period of the ACS to examine the associations between long-term $PM_{2.5}$ exposure and cardiovascular, ischemic heart disease, heart failure and cardiac arrest, cerebrovascular disease, and hypertensive disease. The results of these extended analyses were consistent with previous results from the ACS cohort for cardiovascular and ischemic heart disease. In addition, these extended analyses provide associations for causes of death that had previously not been evaluated among the ACS cohort. Positive associations were observed with heart failure and cardiac arrest, cerebrovascular disease, and hypertensive disorder. Lepeule et al. (2012) reported the results of an extended analysis of the Harvard Six Cities cohort, extending the follow-up period to include deaths between 1974 and 2009, and the strong association with cardiovascular mortality persisted.

A recent series of studies conducted in Canada linked census data with data from the Canadian Mortality Database to create the Canadian Census Health Environment Cohort (CanCHEC) and evaluated the relationship between long-term $PM_{2.5}$ exposure and CVD (including IHD, CBVD, and circulatory) mortality. The authors observed positive associations between CVD mortality and long-term $PM_{2.5}$ exposure, with similar estimates for satellite-derived estimates and ground monitor estimates. The strongest association was for IHD mortality and the weakest was for cerebrovascular mortality (Figure 6-19). (Chen et al., 2016) limited their analyses to CanCHEC cohort participants residing in Ontario who had experienced an acute myocardial infarction, and observed positive associations with CVD, and IHD deaths, as well as deaths due to subsequent acute myocardial infarctions. Crouse et al. (2015) extended the follow-up period of the CanCHEC cohort to include five additional years (1991-2006) and observed positive associations for cardiovascular mortality, with the strongest association observed between long-

term exposure to $PM_{2.5}$ and mortality due to diabetes, followed by IHD. The association for cerebrovascular mortality was just below the null value. The general pattern and magnitude of these associations were generally unchanged in cumulative risk models that include O_3 and/or NO_2. Weichenthal et al. (2016a) evaluated the subset of the CanCHEC cohort living within 5 km of a ground monitor (n = 193,300) and observed associations with IHD mortality that were close to the null value.

Several recent U.S. cohort studies examined the association between long-term $PM_{2.5}$ exposure and cardiovascular mortality. The California Teachers Study (Lipsett et al., 2011; Ostro et al., 2010) observed positive associations between long-term $PM_{2.5}$ exposure and IHD and cerebrovascular mortality, with the strongest association observed with IHD (HR: 1.70; 95% CI: 1.51, 1.91 per 5.0 $\mu g/m^3$ increase in long-term $PM_{2.5}$ concentration). Analyses restricted to post-menopausal women yielded results similar to those for all subjects. Puett et al. (2009) examined the association between long-term $PM_{2.5}$ exposure and all-cause mortality among a cohort of female nurses in the Nurses' Health Study. The authors observed positive associations with CHD mortality (HR: 1.42, 95% CI: 1.03-1.94). Using a design like that of the Nurses' Health Study, Puett et al. (2011) investigated the effect of long-term $PM_{2.5}$ exposure and mortality among men enrolled in the Health Professionals Follow-up Study cohort. Near null associations were observed for CHD mortality in this cohort. Hart et al. (2011) examined the association between residential exposure to $PM_{2.5}$ and mortality among men in the U.S. trucking industry in the Trucking Industry Particle Study (TrIPS) and observed a modest positive association with cardiovascular mortality.



Associations are presented per 5 µg/m^3 increase in pollutant concentration. Circles represent point estimates; horizontal lines represent 95% confidence intervals for $PM_{2.5}$. Black text and circles represent evidence included in the 2009 PM ISA; red text and circles represent recent evidence not considered in previous ISAs or AQCDs. Study results from Lepeule et al. (2012) are representative of results from the Harvard Six Cities Cohort; Study results from Pope et al. (2014) are representative of the results from the American Cancer Society Cohort. For complete results from these two cohorts, see Figures 1 and 2. IQR: interquartile range; CVD: cardiovascular disease; IHD: ischemic heart disease; CHD: coronary heart disease; CBVD: cerebrovascular disease; H6C: Harvard Six Cities cohort; TrIPS: Trucking Industry Particle Study; NIH-AARP: National Institutes of Health American Association of Retired Persons Diet & Health Cohort; WHI: Women's Health Initiative; ACS: American Cancer Society Cohort; IDW: inverse distance weighting; HF: heart failure; CCHS: Canadian Community Health Survey; EFFECT: Enhanced Feedback For Effective Cardiac Treatment; AMI: acute myocardial infarction. †Studies published since the 2009 Integrated Science Assessment for Particulate Matter.

Figure 6-19 Associations between long-term exposure to $PM_{2.5}$ and cardiovascular mortality in recent North American cohorts.

The magnitude of the associations for long-term $PM_{2.5}$ exposure and cardiovascular mortality among women (Hart et al., 2015a; Lipsett et al., 2011; Ostro et al., 2010; Puett et al., 2009) was higher than those observed in many of the other North American cohorts of men or men and women combined, but similar to that observed by Miller et al. (2007), who also evaluated fatal CHD events among a cohort of post-menopausal women. Several studies that included cohorts of both men and women conducted stratified analyses to see if there was a difference in the association based on sex. Thurston et al. (2015) observed no difference between men and women when examining cardiovascular mortality. Weichenthal et al. (2014b) and (Pinault et al., 2016) reported slightly higher associations with men compared to women, while Beelen et al. (2014) observed higher associations compared among women compared to men. It is unclear why cohort studies that include only women tend to observe higher associations between long-term exposure to $PM_{2.5}$ and cardiovascular mortality compared to other cohorts, and that when cohorts that include both men and women are stratified by sex, the higher association among women is much less consistent.

Overall, the results of these recent U.S. and Canadian cohort studies demonstrate a consistent, positive association between long-term $PM_{2.5}$ exposure and cardiovascular mortality across various spatial extents, exposure assessment techniques, and statistical techniques, and locations, where mean annual average concentrations are ≤12 μg/m^3 (see CHAPTER 11 for study details related to exposure assessment and statistical methods). Additional cohort studies conducted in Europe observed similarly consistent, positive associations between long-term $PM_{2.5}$ exposure and cardiovascular mortality (see Table 11-6 in Section 11.2.2.2), and support the evidence from the U.S. and Canada. Particularly noteworthy is a study conducted in Europe that combined data from 22 existing cohort studies and evaluated the association between long-term $PM_{2.5}$ exposure and cardiovascular (Beelen et al., 2014) mortality. Generally, the associations for cardiovascular mortality were near the null value, except for the subset of cardiovascular deaths attributable to cerebrovascular disease (HR: 1.21, 95% CI: 0.87, 1.69 per 5 μg/m^3 increase in $PM_{2.5}$) (Beelen et al., 2014).

6.2.11 Heart Rate (HR) and Heart Rate Variability (HRV)

Heart rate variability (HRV) represents the degree of difference in the inter-beat intervals of successive heartbeats, and is an indicator of the balance between the sympathetic and parasympathetic arms of the autonomic nervous system. Heart rate (HR) is modulated at the sinoatrial node by both parasympathetic and sympathetic branches of the autonomic nervous system (see Section 6.1.10).

6.2.11.1 Epidemiologic Studies of Heart Rate Variability (HRV)

Most studies have focused on the association between short-term PM exposure and HRV (see Section 6.1.10). There were no studies of the association between long-term PM exposure and HRV

in the 2009 PM ISA (U.S. EPA, 2009). In a recent study, Park et al. (2010) examined the long-term $PM_{2.5}$-HRV association. Thirty- to 60-day mean $PM_{2.5}$ concentrations from the closest monitor with available data were assigned to geocoded addresses of MESA cohort participants at the baseline cohort exam (2000-2002). Although some inverse HRV-$PM_{2.5}$ associations were observed in the population, overall, the evidence of decreased HRV (i.e., rMSSD, SDNN) was stronger among MESA participants with metabolic syndrome than without metabolic syndrome. Such $PM_{2.5}$-associated decreases in HRV are thought to be harmful given that reduced HRV is a risk factor for cardiovascular disease. This finding in MESA is consistent with that of Whitsel et al. (2009) who reported an inverse association between long-term PM_{10} exposure and HRV that was stronger among those with impaired glucose metabolism (IGM) enrolled in the WHI clinical trial studies.

6.2.11.2 Toxicological Studies of Heart Rate (HR) and Heart Rate Variability (HRV)

In the 2009 PM ISA, long term effects of $PM_{2.5}$ exposure on HRV and HR were not reported. Since the publication of the last review, the HEI NPACT study (Lippmann et al., 2013a) examined the effects of long-term $PM_{2.5}$ exposure from five airsheds (Tuxedo, NY; Manhattan, NY; E Lansing, MI; Seattle, WA and Irvine, CA) on measures of HRV in $APOE^{-/-}$ mice. These authors estimated by fitted curve a statistically significant increases in HR in Manhattan, NY for the first 50 days of the experiment that gradually decreased over the rest of the study. In contrast, using the same methodology, the authors estimated a statistically significant decrease in HR in Tuxedo, NY after 75 days. There were no statistically significant chronic changes in HR at other locations. In an additional study, Wold et al. (2012) reported that long term $PM_{2.5}$ exposure increased HR in SH rats. With respect to HRV, no changes were associated with chronic $PM_{2.5}$ exposure at any location in the NPACT study (Lippmann et al., 2013a). Thus, there is some evidence from animal toxicological studies for changes in HR, but not HRV following long-term exposure to $PM_{2.5}$. More information on studies published since the 2009 ISA can be found in Table 6-48 below.

Table 6-48 Study-specific details from toxicological studies of long-term $PM_{2.5}$ exposure and heart rate (HR) and heart rate variability (HRV).

Study	Study Population	Exposure Details	Endpoints Examined
(Lippmann et al., 2013a) NPACT Study 1	$ApoE^{-/-}$ mice, M, n = 4-8 per treatment group,	CAPs from Irvine, CA; Tuxedo, NY; Manhattan, NY, Lansing, MI; or Seattle, WA (138, 136, 123, 68, or 60 µg/m^3, respectively) for 6 h/day, 5 days/week for 6 mo	HR HRV time and frequency domains
(Wold et al., 2012)	8 week old C57BL/6 mice, M	Inhalation of 85 µg/m^3 (16.9-266.4 µg/m^3) $PM_{2.5}$, for 6 h/day, 5 days/week, for 9 mo from Columbus, OH	HR post exposure

$APOE^{-/-}$ = apolipoprotein E null mice n = number, h = hour, CAP = concentrated ambient particle, HR = heart rate, HRV = heart rate variability.

6.2.12 Systemic Inflammation and Oxidative Stress

Chronic systemic inflammation is known to affect the vascular system, potentially leading to thrombosis, plaque rupture, MI and stroke, metabolic effects, as well as effects in other organ systems (e.g., central nervous and reproductive systems). Systemic inflammation is associated with changes in the acute phase response, circulating white blood cells, pro-coagulation effects, and endothelial dysfunction. The epidemiologic studies that were reviewed in the 2009 ISA were limited to a cross-sectional study of the association of long-term exposure to PM_{10} with inflammation and coagulation and ecological studies of hematologic measures that could potentially provide insight into oxygen carrying capacity, viscosity and pro-coagulant potential of the blood (U.S. EPA, 2009). Recent longitudinal analyses that consider the time-dependent nature of pulmonary and systemic inflammatory responses have been conducted, and generally show effects on markers of inflammation. Recent experimental studies also add to the evidence reviewed in the 2009 PM ISA that demonstrated inflammatory effects in animals.

6.2.12.1 Epidemiologic Studies

Several studies of long-term $PM_{2.5}$ exposure and C-reactive protein (CRP) were published since the 2009 PM ISA. CRP is an acute phase reactant, a well-known biomarker of inflammation and clinical tool that can be used to inform decisions regarding treatment of patients with an intermediate risk of atherosclerotic cardiovascular disease (Goff et al., 2014; Pearson et al., 2003). Findings from several recent studies that considered the temporality of the $PM_{2.5}$-CRP association generally found positive associations between one- to twelve-month mean $PM_{2.5}$ exposures and log-transformed CRP as

determined by a variety of methods. These longitudinal studies leveraged the availability of repeated, time-varying measures of both the exposure and outcome, applying multi-variable adjusted mixed models and were conducted in well characterized U.S. and European cohorts including the Study of Women's Health Across the Nation (SWAN) [12.75% change (95%CI: 5.1, 21.45)] (Ostro et al., 2014) and the HNR study [22.65% change (95%CI: 13.8, 31.65)] (Hennig et al., 2014) and [11.25% change (95% CI (1.25,21.88)] (Viehmann et al., 2015). Viehmann et al. (2015) also reported results indicating that white cell count (WCC) may increase with long-term exposure to $PM_{2.5}$ [3.13% change WCC 95%CI: 0.83, 5.42)] among the HNR study population. The longitudinal analysis of the MESA cohort provided little support for an association with CRP [1% change (95%CI: -4, 6)], although a 6% (95%CI: 2, 9) higher IL-6, another indicator of systemic inflammation, was reported (Hajat et al., 2015). A meta-analysis of cross-sectional results from the ESCAPE cohorts (Lanki et al., 2015) provides little support for an association between long-term exposure to $PM_{2.5}$ and CRP [2.4% difference (95%CI: -7.5, 13.4)]. A cross-sectional analysis of the NHANES participants reported small magnitude associations of annual average $PM_{2.5}$ exposure, with CRP which was stronger in people with diabetes (Dabass et al., 2016b).

6.2.12.2 Toxicology Studies

The 2009 PM ISA included findings from several studies that pointed to inflammation in response to long-term $PM_{2.5}$ exposure, particularly in association with atherosclerotic progression (2009 PM ISA). More recent animal toxicological studies continue to provide evidence that long-term exposure to $PM_{2.5}$ may result in inflammatory effects. More specifically, a recent study demonstrated statistically significant ($p < 0.05$) changes in circulating T-cell populations in mice following long-term $PM_{2.5}$ exposure (Deiuliis et al., 2012). Similarly, in mice Kampfrath et al. (2011) demonstrated that long-term exposure to $PM_{2.5}$ results in increased ($p < 0.05$) inflammatory monocytes in the blood from the bone marrow, and that this increase in monocytes is at least partially dependent on TLR4 expression.

When examining cytokines and other inflammatory mediators, Tanwar et al. (2017) reported increased mRNA expression of the cytokines IL-1β and IL-6, as well as the matrix metalloproteinases MMP-9 and MMP-13 at birth in heart tissue of mice exposed to $PM_{2.5}$ in utero. In addition, Aztatzi-Aguilar et al. (2015) found increased ($p < 0.05$) IL-6 protein levels in mouse hearts, and Ying et al. (2013) reported increased ($p < 0.05$) Il-6, TNFα, and MCP-1 mRNA, but not e selectin, ICAM-1 or VCAM-1 in mesenteric arteries when compared to control mice exposed to FA. Similarly, an additional study in mice reported that long-term exposure to $PM_{2.5}$ was found to statistically significantly increase ($p < 0.05$) plasma levels of TNF-α and MCP-1, but not IL-6, IL 12 or Il-10, or IFN-γ when compared to control animals (Kampfrath et al., 2011). Moreover, Kampfrath et al. (2011) also demonstrated upregulation of these cytokines was at least partially dependent on TLR4 expression. In $ApoE^{-/-}$ mice, Lippmann et al. (2013a) reported increased IL-10 ($p < 0.05$) following 3 months of exposure in Manhattan, NY and decreased ($p < 0.05$) IL-6 and IL-10 at 6 months in Irvine, CA relative to control mice. Other locations did not have statistically significant changes in IL-6 or IL-10 and no location

reported appreciable changes in CRP, TNF-α, IL-13, MCP-1 or Il-12. In addition, in Irvine, CA was there a statistically significant change (increase; p >0.05) in GM-CSF. Taken together, these studies may appear somewhat inconsistent, however it should be noted that markers of systemic inflammation are often transiently expressed, thus making it difficult to consistently report changes across studies that use different study designs and a variety of methodological approaches. Thus, it can be concluded that the animal toxicological evidence presented above supports long-term exposure to $PM_{2.5}$ resulting in increased markers of systemic inflammation. Moreover, there is also evidence to support that the location from which the $PM_{2.5}$ is collected influences the inflammatory response.

With respect to oxidative stress, Rao et al. (2014) reported that relative to FA, long-term exposure of $ApoE^{-/-}$ mice to $PM_{2.5}$ in resulted in increased oxidation of cholesterol. Moreover, Kampfrath et al. (2011) demonstrated that long-term exposure to $PM_{2.5}$ in mice results in an increase in NADPH oxidase derived O_2- production in the aorta. In contrast, Ying et al. (2013) did not find that long-term $PM_{2.5}$ exposure resulted in a statistically significant effect on the oxidative stress marker 8-isoprostane. Thus, there is limited evidence of oxidative stress following long-term $PM_{2.5}$ exposure. More information on studies published since the 2009 ISA can be found in Table 6-49 below.

Table 6-49 Study-specific details from toxicological studies of long-term $PM_{2.5}$ exposure and inflammation and oxidative stress.

Study	Study Population	Exposure Details	Endpoints Examined
(Tanwar et al., 2017)	FVB mice, pregnant F, and offspring	In utero inhalation of 73.61 µg/m^3 $PM_{2.5}$ CAPs for 6h/day, 7 days/week throughout pregnancy.	Markers of inflammation in hearts of mice at birth after exposure in utero
(Lippmann et al., 2013a) NPACT Study 1	$ApoE^{-/-}$ mice, M, n = 4-8 per treatment group,	CAPs from Irvine, CA; Tuxedo, NY; Manhattan, NY, Lansing, MI; or Seattle, WA (138, 136, 123, 68, or 60 µg/m^3, respectively) for 6 h/day, 5 days/week for 6 mo	Markers of inflammation in blood at 3 and 6 mo post-exposure
(Aztatzi-Aguilar et al., 2015)	Adult Sprague-Dawley rats, M, n = 4 per treatment group	Inhalation of 178 µg/m^3 $PM_{2.5}$ from a high traffic and industrial area north of Mexico City in early summer for 5 h/day for 8 weeks (4 days/week).	Markers of inflammation in heart tissue collected 24 h post-exposure
(Ying et al., 2013)	Adult $ApoE^{-/-}$ mice, M	Inhalation of 69.6 µg/m^3 $PM_{2.5}$ CAPs for 6 h/day, 5 days/week for 12 week.	Markers of systemic inflammation in mesenteric artery tissue Marker of oxidative stress

Table 6-49 (Continued): Study-specific details from toxicological studies of long-term $PM_{2.5}$ exposure and inflammation and oxidative stress.

Study	Study Population	Exposure Details	Endpoints Examined
(Kampfrath et al., 2011)	Balb/c mice, M TLR4 null mice, M TRR4 wt mice, M	Inhalation of 92.4 μg/m^3 $PM_{2.5}$ for 6 h/day 5days/week for 20 weeks from Columbus, OH	Monocyte population counts and egress from bone marrow to blood post exposure Markers of systemic inflammation post exposure Markers of oxidative stress
(Rao et al., 2014)	ApoE$^{-/-}$ mice, M	9.1 ± 7.3 μg/m^3 from Columbus, OH fro 6 mo	Cholesterol oxidation
(Deiuliis et al., 2012)	C57BL/6 mice, M,	Inhalation of 115.5 μg/m^3 $PM_{2.5}$ for 6 h/day 5days/week for 24- 28 weeks	Changes in circulating T-cell populations post exposure

n = number, h = hour, d = day, week = week, M = male, f = female, SH = spontaneously hypertensive, CAP = concentrated ambient particle, TLR = toll like receptor

6.2.13 Coagulation

Systemic inflammation is associated with pro-coagulation effects. Fibrinogen, a soluble glycoprotein and acute phase reactant that can be proteolytically converted to fibrin, cross-linked into clots, and degraded into dimerized fragments called D-dimers, are potential predictors of cardiovascular thrombosis. There were no studies of long-term exposure to $PM_{2.5}$ and markers of coagulation in the 2009 PM ISA (U.S. EPA, 2009). Several recent epidemiologic studies provide evidence that long-term exposure to $PM_{2.5}$ can affect fibrinogen, D-dimer and platelet count.

6.2.13.1 Epidemiologic Studies

Longitudinal analyses of the U.S. or European cohorts are available. Viehmann et al. (2015) reported a positive association between $PM_{2.5}$ and fibrinogen among the HNR study population [0.21% change (95% CI: -2.08, 2.29)] and a positive, $PM_{2.5}$- platelet count association [4.79% change (95%CI: 2.92, 6.88)]. Hajat et al. (2015) observed a positive $PM_{2.5}$-D-dimer association [7% change (95% CI: 2, 13)] and inverse $PM_{2.5}$-fibrinogen association [-3.45 % change (-7.43, 0.52)] among MESA participants. In addition, 28-day $PM_{2.5}$ was not associated with increased fibrinogen in a longitudinal analysis of the NAS cohort (Bind et al., 2012). Cross-sectional studies do not generally support an association. A meta-analyses of cross-sectional, study-specific results, from the ESCAPE cohorts does not indicate an association between $PM_{2.5}$ and fibrinogen [0.5% change (95%CI: -1.1, 2)] (Lanki et al., 2015). A cross-sectional analysis of the NHANES participants reported no association of annual average exposure to $PM_{2.5}$ with fibrinogen (Dabass et al., 2016b).

6.2.14 Impaired Vascular Function and Arterial Stiffness

Endothelial dysfunction is the physiological impairment of the inner lining of the blood vessels. Endothelial dysfunction is typically measured by flow mediated dilation percent (FMD%). This method is a noninvasive technique involving measurement of the percent change in brachial artery diameter (BAD) after reactive hyperemia (increased blood flow following removal of an artery-occluding blood pressure cuff) (Thijssen et al., 2011). Biomarkers of endothelial activation, including intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule 1 (VCAM-1), and E-selectin, soluble forms of which are released in response to inflammation-induced endothelium damage, are also examined in epidemiologic studies.

Arterial stiffness is associated with a variety of cardiovascular risk factors and outcomes (Laurent et al., 2006). Carotid-femoral pulse wave velocity (PWV) is the gold standard for directly and noninvasively measuring arterial stiffness. PWV measures the velocity at which the pulse generated by the heart travels through the arteries, typically measured by the foot-to-foot method (end diastole of the wave in the carotid artery to end diastole of the wave in the femoral artery). Increases in PWV are indicative of increased arterial stiffness. Several tools can be used to detect the pulse wave as it travels, including pressure, distension, and Doppler, allowing PWV to be calculated as the distance divided by change in time between the two points. Augmentation index is an indirect measure of arterial stiffness and cannot be used in place of PWV in assessing regional stiffness; however, its measurement in concert with PWV can provide additional evidence for arterial stiffness. Large and small artery compliance and Young's modulus (a measure of elasticity adjusted for wall thickness) are measures of local arterial stiffness, which require more advanced measurement techniques. Aside from PWV, evidence supporting the validity of arterial stiffness measures as predictors of cardiovascular outcomes is not extensive.

6.2.14.1 Epidemiologic Studies

There were no epidemiologic studies of long-term exposure to $PM_{2.5}$ and FMD, BAD or markers of endothelial activation reviewed in the 2009 PM ISA. A limited number of studies have been published subsequently. In an analysis of MESA data, Krishnan et al. (2012) reported that $PM_{2.5}$ was inversely associated with FMD% [-0.50% change FMD (95% CI: -1.00, -0.05)] with potential effect modification by sex, smoking status, age, and hypertensive status but not associated with BAD [0.00% difference BAD (95% CI: -0.10, 1.00)]. Wilker et al. (2014) reported a comparable inverse association [-0.40 % change (95% CI: -0.68, -0.13)] between $PM_{2.5}$ and FMD% among a subset of participants in the Framingham Offspring Study and Third Generation Studies. Wilker et al. (2014) also examined associations with measures of arterial and microvascular function, BAD, baseline mean flow velocity, and mean hyperemic flow velocity. Only hyperemic flow velocity was additionally associated with $PM_{2.5}$ [-1.80 % change (95%CI: -3.45, -0.15)] These effects are relatively large given that normal ranges are between 5-10% (Järhult et al., 2009). Hajat et al. (2015) observed no association of annual $PM_{2.5}$ exposure with soluble

ICAM-1 [-2.07% (95% CI: -7.69, 3.56)] or E-selectin [1.08 % (95%CI: -0.66, 2.82)]. In addition, Tallon et al. (2017) reported an association [OR: 1.27 (95%CI:0.87, 1.84)] with erectile dysfunction, which may be a consequence of $PM_{2.5}$-mediated effects on vascular function.

There were no studies of long-term $PM_{2.5}$ exposure and PWV reviewed in the 2009 PM ISA. Currently available studies do not provide evidence of an effect of $PM_{2.5}$ on arterial stiffness. A cross-sectional analysis of the Atherosclerosis Risk in Young Adults study in which PWV could only be measured in a subset of participants (Lenters et al., 2010) reported no association [−0.99 % change PWV (95% CI: -6.7, 4.71)]. Similarly, O'Neill et al. (2011) measured large and small artery compliance as well as Young's modulus among participants in the MESA population and found no associations between $PM_{2.5}$ and arterial stiffness overall or stratified by sites [0.4% difference PWV (95% CI: 0.7, -0.15)]. There was evidence of possible effect modification by race and diabetes (O'Neill et al., 2011).

6.2.14.2 Toxicology Studies

Since the publication of the 2009 PM ISA, Ying et al. (2015) reported that in SH rats, long-term exposure to $PM_{2.5}$ resulted in statistically significant ($p < 0.05$) reduced vasodilation in response to the vasodilator acetylcholine. Similarly, these authors also demonstrated that long-term exposure to $PM_{2.5}$ resulted in a statistically significant ($p < 0.05$) increase in the contractile response following treatment of aortic rings with vasoconstrictors. Thus, long-term $PM_{2.5}$ exposure can result in greater contractility and reduced dilation in SH rats. These results are in agreement with an additional study in mouse aortic rings that reported both reduced vasodilation in response to acetylcholine as well as increased contractile response following vasoconstrictor treatment (Kampfrath et al., 2011). Thus there is some evidence that long-term exposure to $PM_{2.5}$ can result in impaired vascular function. More information on these studies can be found in Table 6-50 below.

Table 6-50 Study specific details from toxicological studies of long-term $PM_{2.5}$ exposure and impaired vascular function.

Study	Study Population	Exposure Details	Endpoints Examined
(Ying et al., 2015)	4 week old SH rats, M, n = 6/treatment group	Inhalation of 128.3 ± 60.4 $\mu g/m^3$ $PM_{2.5}$ CAPs Exposed 6 h/day, 5 days/week for 15 week from Columbus, OH	contractility of rat aortic rings, Hypertrophic markers 15 week post
(Kampfrath et al., 2011)	Balb/c mice, M TLR4 null mice, male TRR4 wt mice, male	Inhalation of 92.4 $\mu g/m^3$ $PM_{2.5}$ for 6 h/day 5 days/week for 20 weeks from Columbus, OH	contractility of mouse aortic rings

n = number, m = male, h = hour, week = week, CAP = concentrated ambient particle.

6.2.15 Copollutant Confounding

The independence of the association between long-term exposure to $PM_{2.5}$ and cardiovascular health effects can be examined through the use of copollutant models. A change in the $PM_{2.5}$ risk estimates, after adjustment for copollutants, may indicate the potential for confounding. Recent studies presenting copollutant model results address a previously identified data gap by informing the extent to which effects associated with exposure to $PM_{2.5}$ are independent of co-exposure to correlated copollutants in long-term analyses. A limited number of studies are available to assess copollutant confounding of the association between long-term exposure to $PM_{2.5}$ and cardiovascular morbidity (Figure 6-20). Overall, risk estimates from these few studies remain largely unchanged after adjustment for $PM_{10-2.5}$, NO_2, and $PM_{2.5}$ from traffic sources.

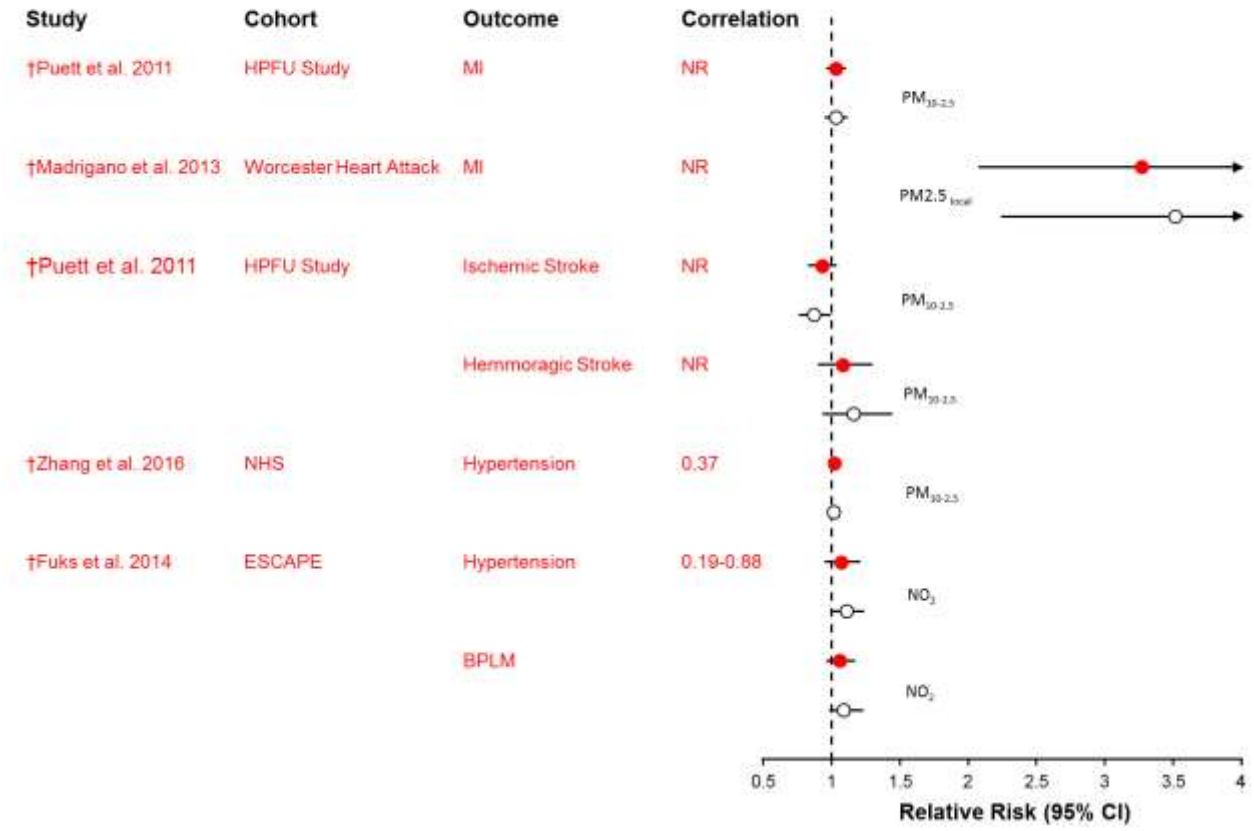


Figure 6-20 Associations between long-term exposure to $PM_{2.5}$ and cardiovascular morbidity in single pollutant models and models adjusted for copollutants.

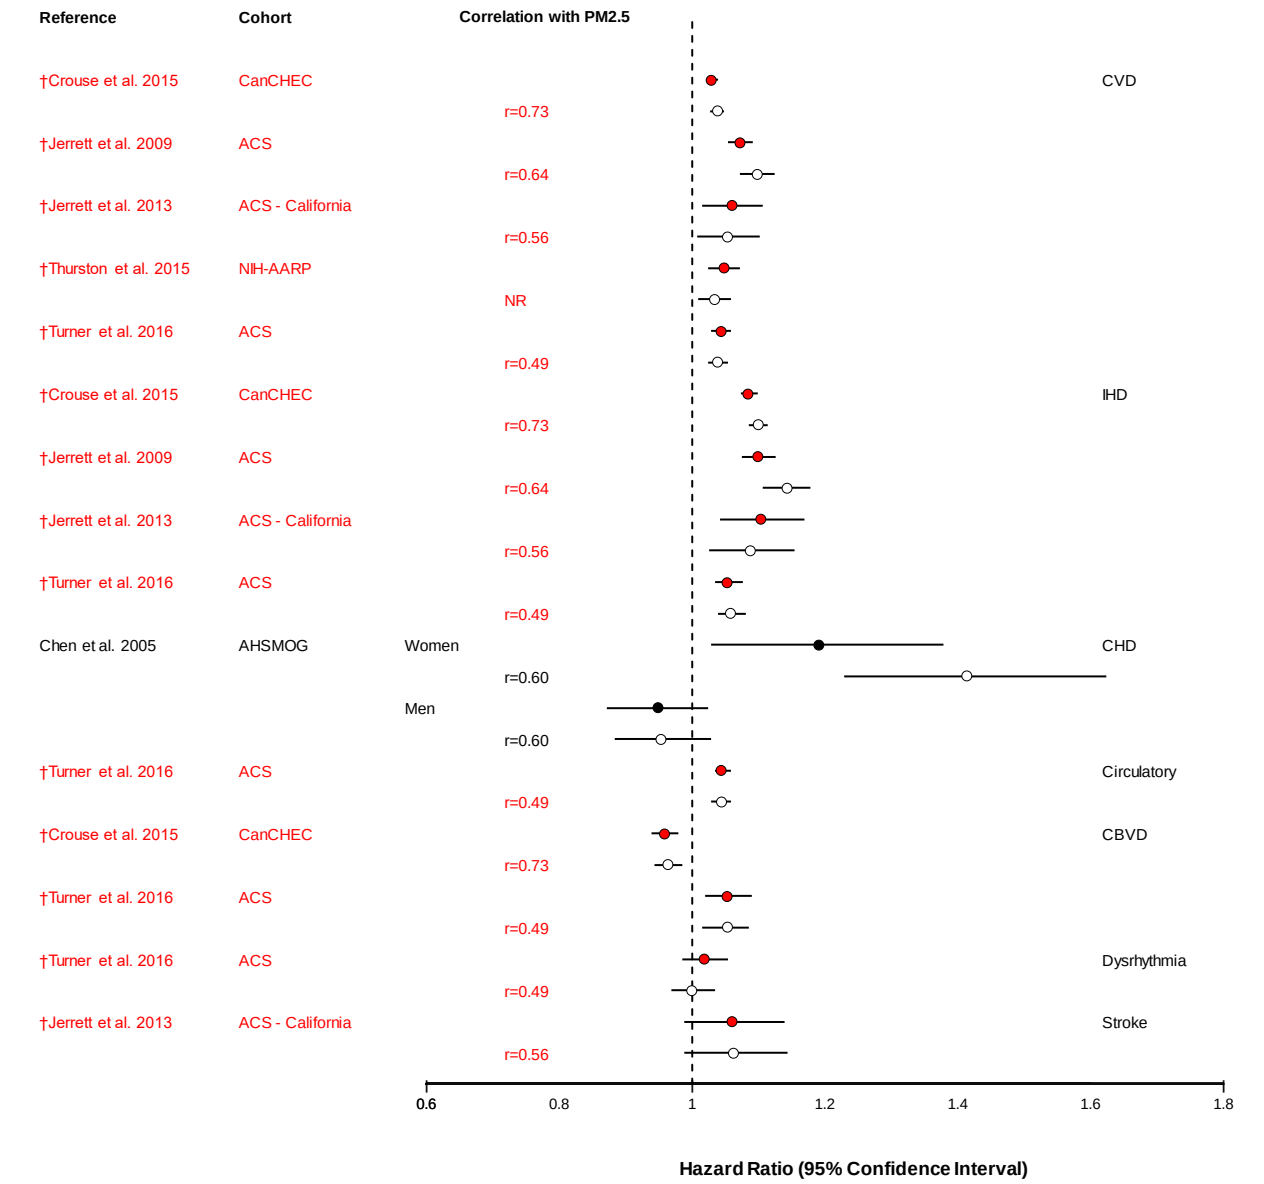
There is a larger body of studies that examined the potential for copollutant confounding of the association between long-term exposure to $PM_{2.5}$ and mortality from cardiovascular causes. The results for associations between long-term $PM_{2.5}$ exposure and cardiovascular mortality in single pollutant models and copollutant models adjusted for ozone are shown in Figure 6-21. The correlations between $PM_{2.5}$ and ozone exposures in the studies that conducted copollutant analyses were generally positive and moderate to strong, ranging from $r = 0.49$ to 0.73. Generally, the $PM_{2.5}$ effect estimates remained relatively unchanged in copollutant models adjusted for ozone. The trend persisted across different specific causes of cardiovascular mortality. There was one exception to the trend. The effect of long-term $PM_{2.5}$ exposure on CHD mortality among women in the AHSMOG cohort (Chen et al., 2005) increased after adjusting for ozone in the model. The results for associations between long-term $PM_{2.5}$ exposure and cardiovascular mortality in single pollutant models and copollutant models adjusted for NO_2, $PM_{10-2.5}$, or

SO_2 are shown in Figure 6-22. The correlations between $PM_{2.5}$ and NO_2 exposures in studies that conducted copollutant analyses were positive and weak (r = 0.25) or moderate (r = 0.40; r = 0.55). The correlations between $PM_{2.5}$ and $PM_{10-2.5}$ were not reported in the single study evaluating coarse particles (Puett et al., 2009). One study evaluated SO_2 (Chen et al., 2005) in copollutant models and reported a correlation of r = 0.30. Generally, the $PM_{2.5}$ effect estimates remained relatively unchanged in copollutant models adjusted for NO_2, $PM_{10-2.5}$, or SO_2.



Associations are presented per 5 µg/m^3 increase in pollutant concentration. Circles represent point estimates, horizontal lines represent 95% confidence intervals for $PM_{2.5}$. Black circles represent effect of $PM_{2.5}$ in single pollutant models, white circles represent effect of $PM_{2.5}$ adjusted for ozone. ACS: American Cancer Society Cohort; CanCHEC = Canadian Census Health and Environment Cohort; NIH-AARP: National Institutes of Health American Association of Retired Persons Diet & Health Cohort; AHSMOG: Adventist Health Air Pollution Study; CVD: cardiovascular; IHD: ischemic heart disease; CHD: coronary heart disease; CBVD: cerebrovascular disease; CPD: cardiopulmonary disease; COPD: chronic obstructive pulmonary disease; NR: not reported.
†Studies published since the 2009 Integrated Science Assessment for Particulate Matter.

6.2.16 Shape of the Concentration-Response Function

An important consideration in characterizing the association between long-term $PM_{2.5}$ exposure and mortality is whether the concentration-response relationship is linear across the full concentration range that is encountered, or if there are concentration ranges where there are departures from linearity. The 2009 PM ISA characterized the results of an analysis by Miller et al. (2007) that demonstrated that the shape of the concentration-response curve for cardiovascular mortality was generally linear. Recent studies add to the evidence base on the C-*R* relationships for cardiovascular morbidity (Table 6-51) and mortality (Table 6-52) outcomes. However, complicating the interpretation of these results is both the lack of thorough empirical evaluations of alternatives to linearity as well as the results from cut-point analyses that provide some potential indication for nonlinearity in the relationship between long-term $PM_{2.5}$ exposure and cardiovascular disease.

Two analyses of the C-*R* function for the relationship between $PM_{2.5}$ and CAC are available. Kaufman et al. (2016) generated a C-*R* curve using a thin plate regression spline with 5 degrees of freedom. The curve shows an increase in CAC with increasing long-term exposure to $PM_{2.5}$ and attenuation of the curve at higher concentrations (Figure 6-23). Dorans et al. (2016) reported a deviation from linearity such that log transformed CAC increased with increasing $PM_{2.5}$ concentrations at lower concentrations (<~10µg/m^3) while log transformed CAC decreased with increasing $PM_{2.5}$ at higher concentrations (Figure 6-24). A restricted cubic spline with 5 knots was used to examine the shape curve. The concentration and variability in the $PM_{2.5}$ concentrations were notably lower in the Framingham Heart Study cohort compared to the MESA population.

Chen et al. (2014a) examined the shape of the C-*R* function or the relationship between long-term $PM_{2.5}$ exposure and hypertension using a natural cubic spline with 2 degrees of freedom, is shown in Figure 6-25. The reference concentration for the HRs, which generally increase in a linear fashion, was 2.9 µg/m^3. In an analysis of IHD incidence, Cesaroni et al. (2014) restricted the data used in their meta-analysis of ESCAPE cohorts to include only those exposed below various thresholds. For the cohorts with participants exposed to <15 µg/m^3 average annual $PM_{2.5}$, the meta-analyzed HR for the association of long-term $PM_{2.5}$ exposure and IHD incidence was like the HR for the entire range of concentrations [1.19 (95%CI: 1.00, 1.42)].

Table 6-51 Summary of studies examining the concentration-response relationship or conduction threshold analyses for long-term exposure to $PM_{2.5}$ and cardiovascular morbidity.

Study Location – Cohort (Table/Figure from Reference)	Outcome	Exposure $PM_{2.5}$ Mean: (Range) in $\mu g/m^3$	Statistical Analysis Summary
Cesaroni et al. (2014) 11 Cohorts Europe ESCAPE	IHD Incidence	NR	Restricted the meta-analysis to persons exposed below various thresholds. HR <15 $\mu g/m^3$ similar to HR across the full range of concentrations
Kaufman et al. (2016) 6 Urban sites U.S. MESA	CAC	Mean: 14.2 (range: 9.2-22.6)	Thin plate regression spline with 5 degrees of freedom. Attenuation at higher concentrations suggested
Dorans et al. (2016) Framingham Heart Study Offspring	CAC	Median (IQR) = 10.7 (1.4) for 2003	Restricted cubic spline with 5 knots. Non-linear relationship of log CAC with long-term $PM_{2.5}$ concentration observed
Chen et al. (2014a) Ontario, Canada	Hypertension	Mean 10.7 (range 2.9-19.2)	Natural cubic spline with 2 degrees of freedom (reference concentration 2.9 $\mu g/m^3$). No evidence of departure from linearity across the range of concentrations

CAC = coronary artery calcium, ESCAPE = European Study of Cohorts for Air Pollution Effects, HR = hazard ration, IHD = ischemic heart disease, IQR = interquartile range.

Figure 6-25 Concentration-response relationship between the concentration of $PM_{2.5}$ and incident hypertension. The relative risks are adjusted covariates including sex, marital status, education, income body mass index (BMI), physical activity, smoking alcohol, diet race, urban residency neighborhood level socioeconomic status (SES) and unemployment rate, diabetes and COPD.

A number of recent studies have conducted analyses to inform the shape of the concentration-response relationship for the association between long-term exposure to $PM_{2.5}$ and mortality, and are summarized in Table 6-52. Generally, the majority of the results from these analyses continue to support a

linear, no-threshold relationship for cardiovascular mortality, especially at lower ambient concentrations of $PM_{2.5}$. A number of the concentration-response analyses include concentration ranges ≤12 μg/m^3. For example, Lepeule et al. (2012) observed a linear, no-threshold concentration-response relationship for cardiovascular mortality in the most recent analysis of the Harvard Six Cities study, with confidence in the relationship down to a concentration of 8 μg/m^3 (Figure 6-26). Similar linear, no-threshold concentration-response curves were observed for cardiovascular mortality in other studies (Thurston et al., 2015; Villeneuve et al., 2015; Cesaroni et al., 2013; Gan et al., 2011). However, some studies reported that the slope of the concentration-response function tended to be steeper at lower concentrations, especially for IHD mortality. For example, in Crouse et al. (2012) statistical tests did not provide evidence for departure from linearity in the concentration-response function for IHD, but the risk was greater (HR = 1.20) at lower concentrations (<10 μg/m^3) compared to higher concentrations (10-15 μg/m^3) of $PM_{2.5}$ (Figure 6-27). Similar results were observed in other studies (Jerrett et al., 2016; Weichenthal et al., 2014b). Additional evidence to support a supralinear concentration-response relationship comes from a series of studies that looked at exposure to $PM_{2.5}$ from both ambient air pollution and cigarette smoke (Pope et al., 2011; Pope et al., 2009). These studies concluded that including the full concentration range of $PM_{2.5}$ from both ambient air pollution and cigarette smoking, it is clear that the relationship between long-term exposure and cardiovascular mortality cannot be adequately characterized as linear with no threshold. The concentration-response relationship is much steeper at lower $PM_{2.5}$ concentrations (such as those due to ambient air pollution) compared to the higher concentrations associated with cigarette smoking. This indicates the importance of considering the cause of death when characterizing the concentration-response relationship between long-term $PM_{2.5}$ exposure and cardiovascular mortality.

Table 6-52 Summary of studies examining the concentration-response relationship or conduction threshold analyses for long-term exposure to $PM_{2.5}$ and cardiovascular mortality.

Study Location – Cohort (Table or Figure from Reference)	Exposure $PM_{2.5}$ Mean; (Range) in μg/m^3	Statistical Analysis Summary
Cesaroni et al. (2013) Italy–RoLS (Figure 2B)	Eulerian Dispersion Model (1 km x 1 km) 23.0; (7.2-32.1)	Natural splines with 2, 3, or 4 df, compared goodness of fit using BIC and likelihood ratio test No evidence of deviation from linearity; Results similar for 2, 3 or 4 df

Table 6-52 (Continued): Summary of studies examining the concentration-response relationship or conduction threshold analyses for long-term exposure to $PM_{2.5}$ and cardiovascular mortality.

Study Location – Cohort (Table or Figure from Reference)	Exposure $PM_{2.5}$ Mean; (Range) in $\mu g/m^3$	Statistical Analysis Summary
Crouse et al. (2012) Canada – CanCHEC (Figure 2A-D)	Ground monitors in 11 cities; Satellite RS (10 km x 10 km) 11.2; (1.9-19.2)	Natural splines with 2, 3, or 4 df, compared goodness of fit using BIC. Log function of $PM_{2.5}$ ($\ln[PM_{2.5} + 1]$) yielded lower BIC than each of the spline models No evidence for departure from linearity for, CVD or CBVD. Risk was higher (HR = 1.20) from 5 $\mu g/m^3$ to 10 $\mu g/m^3$, and lower (HR = 1.12) from 10 $\mu g/m^3$ to 15 $\mu g/m^3$ for IHD mortality
Gan et al. (2011) Canada – Metro Vancouver (Figure 1b)	LUR 4.08; (0-10.24)	Study subjects divided into quintiles based on $PM_{2.5}$ concentration Consistent magnitude of RRs across quintiles suggests linearity. (Magnitude of effect is near null)
Jerrett et al. (2016) U.S. – ACS (Figures S2 and S3)	BME LUR: 12.0; (1.5-26.6) Satellite RS: 11.9; (1.9–24.6)	Natural splines with 2 df BME LUR curve is generally linear and has a steeper slope compared to the satellite RS curve, though slope decreases at concentrations above 20 $\mu g/m^3$; satellite RS curve is generally linear though slope begins to flatten for concentrations above has 13 - 15 $\mu g/m^3$
Lepeule et al. (2012) U.S.–HSC (Supplemental Figure 1)	Ground Monitor 15.9; (11.4-23.6)	Penalized spline models Linear relationship with exposures down to 8 $\mu g/m^3$. No evidence of a threshold. Highest confidence from 10 – 20 $\mu g/m^3$ based on greatest data density
Thurston et al. (2015) U.S.–NIH–AARP (Figure 2)	Hybrid LUR geo-statistical model 12.2; (2.9 – 28.0)	Natural spline plots with 4 df (Referent HR = 1.0 at mean exposure level) Observed linear relationship
Villeneuve et al. (2015) Canada–CNBSS (Figure 3)	Satellite RS (10 km x 10 km) 9.1; (0.1 – 20.0)	C-*R*: Natural cubic spline functions with 3 df; Threshold analysis: newly defined exposure variables based on concentration corresponding to the largest log-likelihood value from the Cox model Linear relationships for CVD and IHD mortality; Threshold analysis demonstrates no improvement in fit over a no-threshold linear model for CVD and IHD mortality
Weichenthal et al. (2014b) U.S.–Ag Health (Figure 2)	Satellite RS (10 km x 10 km) 8.84; (5.7-19.2)	Natural splines with 2 df. Natural splines with 3 and 4 df were examined but didn't not improve model fit Linear increase observed from 6 to 10 $\mu g/m^3$, with slope flattening out for concentrations between 10 and 14 $\mu g/m^3$

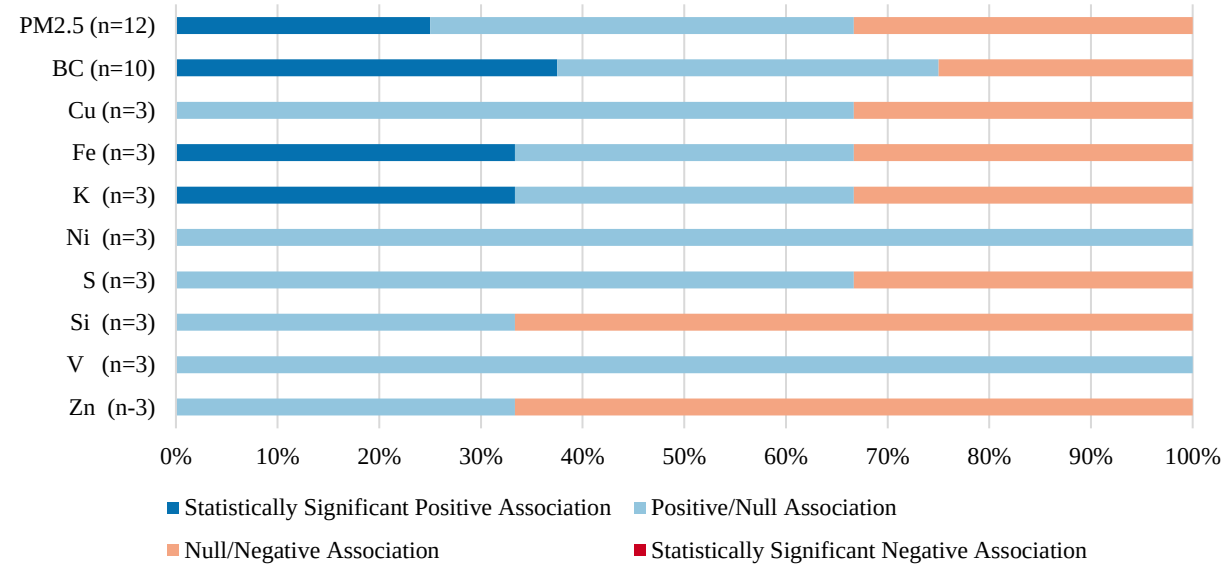
6.2.17 Associations between $PM_{2.5}$ Components and Sources and Cardiovascular Effects

There were no studies that examined the association between $PM_{2.5}$ components and cardiovascular outcomes available for review in the 2009 PM ISA. A limited number of studies have been published since the previous review. Overall, this set of studies reports a range of findings from positive and statistically significant to null or negative (Figure 6-28). Figure 6-29 presents associations for specific

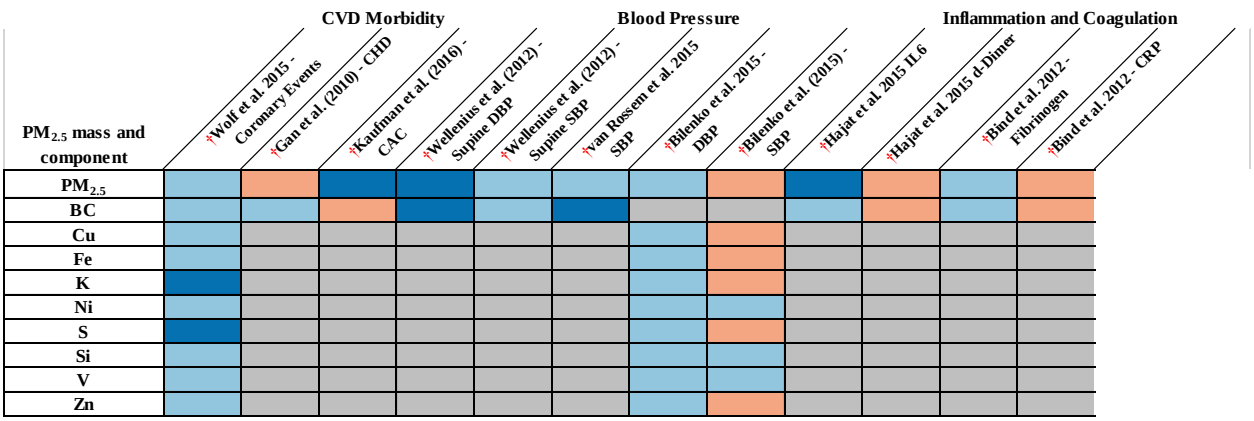
studies showing the lack of comparability across studies regarding the cardiovascular outcome and the component examined.

Wolf et al. (2015b) positive associations of $PM_{2.5}$ and $PM_{2.5}$ components with coronary events in the ESCAPE cohort. Gan et al. (2011) reported an association between long-term black carbon (BC) exposure and CHD hospitalizations but not between long-term $PM_{2.5}$ exposure and CHD hospitalizations in Vancouver, Canada. As discussed in Section 6.2.4 on atherosclerosis, Kaufman et al. (2016) reported a longitudinal association between exposure to $PM_{2.5}$ and CAC, but not between $PM_{2.5}$ and cIMT as indicated in the interim analysis of Adar et al. (2013). Consequently, associations of $PM_{2.5}$ components with cIMT (Kim et al., 2014; Sun et al., 2013) are not pictured in Figure 6-28. Kaufman et al. (2016) did not observe an association between black carbon (BC) and increased CAC. Wellenius et al. (2012b) reported significant associations of both 28-day average $PM_{2.5}$ and 28-day average BC exposure with resting supine DBP. Non-significant increases between both pollutants and resting supine SBP were also observed. Association between $PM_{2.5}$ and most measured components and DBP were observed among children (12 years old) participating in the PIAMA cohort in the Netherlands (Bilenko et al., 2015a). Positive associations between IL-6 and fibrinogen but not CRP or d-Dimer were observed for both $PM_{2.5}$ and BC (Hajat et al., 2015; Bind et al., 2012).



Note: Bars represent the percent of associations across studies for $PM_{2.5}$ mass or $PM_{2.5}$ components for long-term exposure studies of cardiovascular outcomes where dark blue = statistically significantly positive, light blue = positive/null, light orange = null/negative, red = statistically significantly negative N = number of studies that provided an estimate. $PM_{2.5}$ = particulate matter with mean aerodynamic diameter 2.5 µm, BC = black carbon, Cu = copper, Fe = iron, K = potassium, Ni = nickel, S = sulfur, Si = silica, V = vanadium, Zn = zinc

Figure 6-28 Distribution of associations of long-term exposure to $PM_{2.5}$ and $PM_{2.5}$ component concentrations with cardiovascular outcomes.



Note: Cells represent associations examined for studies of long-term exposure to $PM_{2.5}$ mass and $PM_{2.5}$ components and cardiovascular outcomes. Dark blue = statistically significant positive association; light blue = positive or null association; light orange = null or negative association; red = statistically significant negative association; grey = component not examined. Only $PM_{2.5}$ components for which there were at least three studies available were included in the table. $PM_{2.5}$ = particulate matter with mean aerodynamic diameter 2.5 µm, BC = black carbon, Cu = copper, Fe = iron, K = potassium, Ni = nickel, S = sulfur, Si = silica, V = vanadium, Zn = zinc.

Figure 6-29 Results of studies of long-term exposure to $PM_{2.5}$ and $PM_{2.5}$ component concentrations and cardiovascular outcomes.

Regional Heterogeneity

The 2009 PM ISA concluded that there is variation in both $PM_{2.5}$ mass and composition between cities and that the variation may be due, in part to differences in $PM_{2.5}$ sources as well as meteorology and topography. Although east-west gradients were observed for PM components including SO_4^{2-}, OC, and NO_3^-, the amount of city-specific speciated $PM_{2.5}$ data was limited and did not explain the heterogeneous effect estimates for PM across locations. There were no national-scale studies that examined regional differences in the associations between long-term exposure to $PM_{2.5}$ and cardiovascular effects included in the 2009 PM ISA, however, a large U.S.-based multicity study of short-term exposure and CVD hospital admissions provided evidence indicating larger risks in the Northeast compared to the West and multicity epidemiologic studies of cardiovascular mortality generally observed a similar pattern.

A limited number of studies published since the 2009 PM ISA examine regional differences in the associations between long-term exposure and cardiovascular outcomes including CHD and stroke. An analysis of region specific HRs in the NHS indicated slight increases in the Northeast and the South compared to the Midwest and West, although confidence intervals were wide. In a sensitivity analyses restricted to more recent years (2000-2006) the regional differences were more pronounced. Note that Hart et al. (2015b) observed no of association between long-term exposure to $PM_{2.5}$ and incident CHD [HR: 1.01 95%CI: 0.96,1.07], overall. Feng and Yang (2012) compared prevalence odds ratios across nine U.S. regions reporting that the largest ORs for the associations with MI and CHD were in "east central" region of the US.

Sources

The literature examining the relationship between sources of $PM_{2.5}$ and health effects that was included in the 2009 PM ISA was limited to a small number of studies examining the associations of traffic-related sources with mortality. The evidence provided by these studies was not sufficient to distinguish specific sources that could be linked to health effects. The currently available studies on this topic are tabulated below. Aguilera et al. (2016) reported an association between cIMT and $PM_{2.5}$ from traffic but not between cIMT and $PM_{2.5}$ from crustal sources. Positive cross-sectional associations of cIMT with traffic load and traffic intensity were reported in a meta-analysis of four ESCAPE cohorts. $PM_{2.5}$ from traffic exhaust was associated with readmission for MI in MINAP study in London (Tonne et al., 2015). Overall, these studies were not designed to evaluate whether long-term exposure to $PM_{2.5}$ traffic sources was more strongly or independently associated with cardiovascular health effects, however.

6.2.17.1 Toxicology Studies of Individual Components and Sources as Part of a PM Mixture

Campen et al. (2014) exposed young, male $ApoE^{-/-}$ mice on a high fat, high cholesterol diet to motor vehicle exhaust (MVE), MVE with particles removed, sulfate particles, ammonium nitrate particles or paved road dust at target concentrations of 300 $\mu g/m^3$ for 50 days (6 hr/day, 7 day/week). Given that the MVE exposures included gases, the focus of the discussion on this study is on those exposures that contained particles only. Measurements informative for biologic pathways of vascular toxicity, atherosclerosis, and coronary artery disease were obtained the day following the last exposure. Multiple Additive Regression Tree (MART) analysis was performed to assess the relationship between concentrations of individual components with the measurements of biological endpoints. Ultimately a "predictor values" of ranked components is produced based on the strength of their association with each biological marker. In addition, an estimated concentration-response curve is generated using the biological outcome and the predictor after accounting for the average effects of all other chemical predictors across their experimental exposure ranges. MART analysis chemical predictor variables include particle mass, ammonium, elements, nitrate, sulfate, EC, OC, particle phase organics (i.e., organic acids, organic phenols, organic sterols, organic sugars, organic hopanes, organic steranes, organic PAHs, organic nitro-PAHs, and organic alkanes). There were very few changes in biologic endpoints compared to control animals exposed to air for the sulfate, ammonium nitrate or road dust exposures. The sulfate exposure did result in significant enhancement of PE-induced contraction in mouse aortas compared to air controls, with ammonium nitrate exposure resulting in significantly diminished PE-induced contraction compared to air controls. Plaque area was also increased and linked to ammonium nitrate, albeit the group size was quite small (as low as 3). Two measurements appeared dependent on PM (more so than the gases) – oxidized low-density lipoprotein and vasoconstriction. However, in general, MVE gases were

required to elicit significant responses in toxicological measurements and the PM alone did not appear to drive any of the statistically significant effects observed.

Chen et al. (2010) examined mice exposed to Manhattan and Sterling Forest (aka Tuxedo) CAPs as a part of the NPACT study. They evaluated changes in HR and HRV parameters with source categories identified using factor analysis of 17 components (including NO_2 to identify a traffic factor). Seven factors were identified for Manhattan and four factors for Sterling Forest.

Table 6-53 shows general ECG results over the exposure period for each location and identified source category. This is a semi-quantitative evaluation of the number of significant associations, given that there were 6 HR/HRV parameters (HR, SDNN, rMSSD, LF, HF, and LF/HF) analyzed over 4 different time periods (9:00 a.m.−2:00 p.m., 7:00 p.m.−10:00 p.m., 10:00 p.m.−1:00 a.m., 1:00 a.m.−3:00 a.m.) and three different lags (0, 1 and 2).

Table 6-53 Study results for identified source categories and occurrence of heart rate (HR) and heart rate variability (HRV) changes (Chen et al., 2010).

Location	Identified Source Categories	General HR and HRV Results
Manhattan	Incineration (Cu, Zn, Pb); Soil (Al, Si, Ca); Long-range transport (S, Se, Br, EC); Iron-manganese (Fe, Mn); Residual oil (V, Ni, EC); Traffic (EC, NO_2); Fireworks (K, Cu, Ba)	Residual oil had the most number of changes in HR/HRV (59) that were fairly evenly split across lags and time periods; long-range transport had the second most changes (45), with the majority at lag 0 and 1; traffic (30), FeMn (22) and incineration (21) were 3rd, 4th and 5th for number of changes; FeMn had the greatest number of responses on lag 0 and incineration had the greatest number of responses at lag 1; HR/HRV changes attributed to soil (14) were nearly all observed on lag 0; fireworks was associated with 1 HR/HRV change at lag 0 during the 7 PM-10 PM time period
Sterling Forest	Long-range transport (S, Se, Br, EC); Residual oil/traffic (V, BC); Ni-refinery (Ni, Cr, Fe); Soil (Al, Si, Ca)	Long range transport had double the number of occurrences of HR/HRV changes (34) compared to the next source factor, Ni refinery (17); the most numerous changes were at lag 0 and 1 for long-range transport; the most number of changes in HR/HRV for soil were observed at lag 1 (7 of 11); residual oil/traffic had the fewest counts of HR/HRV changes (3), all of which were observed at lag 0 in the 1 AM-4 AM time period

In looking at the two sites, long-range transport was associated with changes in cardiac function with both Manhattan and Sterling Forest CAPS. In contrast, the residual oil source factor was associated with the most number of changes in HR and HRV in Manhattan and the least in Sterling Forest (albeit it

was a combined residual oil and traffic source factor). The number of occurrences of HR and HRV changes associated with soil was similar in across the two sites, with the majority at lag 0 in Manhattan and lag 1 in Sterling Forest.

In another study of rats exposed to $PM_{2.5}$ CAPs in Detroit, for the summer months, 29 components were analyzed and PMF was used to investigate source factors (Rohr et al., 2011). Decreases in SDNN using 30-minute data in the summer were associated with 4 of 6 identified source factors - iron/steel manufacturing, sludge incinerator, cement/lime production and gasoline and diesel-powered vehicles. The strongest association was with the vehicle source factor and no association was observed with the refinery or secondary sulfate source factors. Similar to summer, 6 source factors were identified in winter. However, there were differences in that sludge incinerator source was only identified in summer and the iron/steel manufacturing was a part of the gasoline and diesel powered-vehicles and metal processing in winter. Increased HR in winter was associated with a refinery source factor and decreased HR was associated with the sludge incineration, cement/lime production and coal/secondary sulfate factors. For rMSSD, increases were associated with two factors - coal/secondary sulfate and gasoline and diesel-powered vehicles and iron/steel manufacturing.

In a study akin to (Rohr et al., 2011) that took place in Steubenville, OH, approximately 30 $PM_{2.5}$ components were measured and used to identify source factors using PMF (Kamal et al., 2011). Six factors were identified – coal/secondary, incineration, lead, metal coating/processing, mobile sources, and iron/steel manufacturing. There was a distinct difference in source contribution and ECG effects based on wind direction. Increased HR was associated with SW winds and the metal processing factor, whereas decreased HR was associated with NE winds and incineration, lead and iron/steel manufacturing factors. Decreased SDNN was associated with NE winds and the incineration factor and with SW winds and the metal factor. Increased rMSSD was only associated with combined winds and the iron/steel manufacturing factor.

6.2.18 Summary and Causality Determination

The evidence reviewed in the 2009 PM ISA provided the rationale to conclude that there is "a causal relationship between long-term $PM_{2.5}$ exposure and cardiovascular effects" (U.S. EPA, 2009). Studies of mortality from cardiovascular causes provided the strongest evidence in support of this conclusion. While several studies included in the 2009 PM ISA reported associations between long-term PM_{10} exposure and morbidity outcomes such as post-MI CHF and DVT, studies of $PM_{2.5}$ were limited. One large prospective study of post-menopausal women reported an increased risk of cardiovascular events, including CHD and stroke, in association with long-term exposure to $PM_{2.5}$ (Miller et al., 2007). Cross-sectional analyses provided supporting evidence and experimental studies demonstrating enhanced atherosclerotic plaque development and inflammation following long-term exposures to $PM_{2.5}$ CAPs provided biological plausibility for the epidemiologic findings. In addition, a limited number of

toxicological studies reporting CAPs-induced effects on hypertension and vascular reactivity were drawn upon to support the causal conclusion. With respect to the current review, the evidence for the relationship between long-term exposure to $PM_{2.5}$ and cardiovascular effects is described below and summarized in Table 6-54, using the framework for causality determination described in the Preamble to the ISAs (U.S. EPA, 2015).

The studies of long-term exposure to $PM_{2.5}$ and cardiovascular mortality continue to provide strong evidence that there is a causal relationship between long-term exposure to $PM_{2.5}$ and cardiovascular effects. Results from recent U.S. and Canadian cohort studies demonstrate consistent, positive associations between long-term $PM_{2.5}$ exposure and cardiovascular mortality (see Figure 6-19). Overall, studies reporting positive associations examine the relationship at varying spatial scales and employ different exposure assessment and statistical methods (Section 6.2.10). The studies were conducted in locations where mean annual average concentrations ranged from 4.08-17.9 $\mu g/m^3$. Generally, most of the $PM_{2.5}$ effect estimates relating long-term $PM_{2.5}$ exposure and cardiovascular mortality remained relatively unchanged or increased in copollutant models adjusted for ozone, NO_2, $PM_{10-2.5}$, or SO_2. In addition, most the results from analyses examining the C-R function for cardiovascular mortality supported a linear, no-threshold relationship for cardiovascular mortality, especially at lower ambient concentrations of $PM_{2.5}$ (Table 6-52).

The body of literature examining the relationship between long-term $PM_{2.5}$ exposure and cardiovascular morbidity has greatly expanded since the 2009 PM ISA, with positive associations reported in several cohorts. The findings from the WHI cohort of post-menopausal women (Miller et al., 2007), reporting associations of long-term $PM_{2.5}$ and coronary events, were strengthened through a subsequent analysis that considered potential confounding and modification by SES and applied enhanced exposure assessment methods (Chi et al., 2016a). Analyses of the NHS and CTS, which are both cohorts of women and include extensive data on covariates (i.e., hormone use, menopausal status and SES), were not entirely consistent with the WHI findings, however. Although the NHS cohort is comparable to WHI in that it is made of predominantly post-menopausal women, no associations with CHD or stroke were observed in this population (Hart et al., 2015b). An association with stroke, but not CHD, that was stronger among post-menopausal women was observed in the CTS (Lipsett et al., 2011). Several studies conducted among cardiovascular disease patient populations generally reported positive associations with MI (Hartiala et al., 2016; Tonne et al., 2015; Koton et al., 2013) and a sensitivity analysis of the NHS restricted to women with diabetes detected a positive association with CHD. Although the evidence is not consistent across the populations studied, heterogeneity is expected when the methods, or the underlying distribution of covariates vary across studies (Higgins, 2008).

Longitudinal change in measures of atherosclerosis in relation to long-term exposure to $PM_{2.5}$ add to the collective evidence base (Hartiala et al., 2016; Kaufman et al., 2016; Gan et al., 2014; Künzli et al., 2010). Findings were somewhat variable across cohorts and depended, in part, on the vascular bed in which atherosclerosis was evaluated. Kaufman et al. (2016) reported an association of $PM_{2.5}$ with CAC

among middle to older aged adults in the MESA study, while Dorans et al. (2016) reported no association in the Framingham Heart Study. Associations of long-term exposure to $PM_{2.5}$ with cIMT were not consistently observed across cohorts or between analyses of the same cohort with variable methods. Relationships between $PM_{2.5}$ and CIMT at younger ages were not observed. However, a recent toxicological study adds to similar evidence from the 2009 PM ISA by demonstrating increased plaque progression in $ApoE^{-/-}$ mice following long-term exposure to $PM_{2.5}$ collected from multiple locations across the U.S. (Section 6.2.4.2). Thus, this study provides direct evidence that long-term exposure to $PM_{2.5}$ may result in atherosclerotic plaque progression. This study is also coherent with those epidemiologic studies discussed above reporting positive associations between long-term exposure to $PM_{2.5}$ and indicators of atherosclerosis.

A small number of epidemiologic studies also report positive associations between long-term $PM_{2.5}$ exposure and HF (Section 6.2.5), blood pressure and hypertension (Section 6.2.7). These HF studies are in agreement with animal toxicological studies demonstrating decreased cardiac contractility and function, and increased coronary artery wall thickness following long-term $PM_{2.5}$ exposure (Section 6.2.5.2). Similarly, a limited number of animal toxicological studies demonstrating a relationship between long-term exposure to $PM_{2.5}$ and consistent increases in BP in rats and mice are coherent with epidemiologic studies reporting positive associations between long-term exposure to $PM_{2.5}$ and hypertension.

Longitudinal epidemiologic analyses also support the observation of positive associations with markers of systemic inflammation (Section 6.2.12), coagulation (Section 6.2.13), and endothelial dysfunction (Section 6.2.14). These results are in coherence with animal toxicological studies generally reporting increased markers of systemic inflammation and oxidative stress (Section 6.2.12.2), as well as with toxicological studies generally demonstrating endothelial dysfunction as evidenced by reduced vasodilation in response to acetylcholine (Section 6.2.14).

There is also consistent evidence from multiple, high-quality epidemiologic studies that long-term exposure to $PM_{2.5}$ is associated with mortality from cardiovascular causes. Associations with CHD, stroke and atherosclerosis progression were observed in several additional high-quality epidemiologic studies providing coherence with the mortality findings. Results from copollutant models generally support the independence of the $PM_{2.5}$ associations. Additional evidence of the direct effect of $PM_{2.5}$ on the cardiovascular system is provided by experimental studies in animals, which in part, demonstrate biologically plausible pathways by which long-term inhalation exposure to $PM_{2.5}$ could potentially result in outcomes such as CHD, stroke, CHF and cardiovascular mortality (Section 6.2.1). Taken together, these epidemiologic and experimental studies constitute strong evidence that **a causal relationship exists between long-term exposure to $PM_{2.5}$ and cardiovascular effects.**

Table 6-54 Summary of evidence for a causal relationship between long-term $PM_{2.5}$ exposure and cardiovascular effects.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{2.5}$ Concentrations Associated with Effects[c]
Consistent epidemiologic evidence from multiple, high-quality studies at relevant $PM_{2.5}$ concentrations	Positive associations between long-term $PM_{2.5}$ exposure and cardiovascular mortality in U.S. and Canadian cohorts; positive associations persisted after adjustment for common confounders.	Section 6.2.10 Figure 6-19	Mean concentrations ranged from 4.08 $\mu g/m^3$ (CCHS) – 17.9 $\mu g/m^3$ CA Teachers
	Positive associations observed in studies examining varying spatial scales and across different exposure assessment and statistical methods.	Section 6.3.10.1	
Evidence from copollutant models generally supports an independent $PM_{2.5}$ association	Positive associations observed between long-term $PM_{2.5}$ exposure and cardiovascular mortality remain relatively unchanged after adjustment for copollutants. Correlations with ozone were generally moderate to high (0.49-0.73). When reported, correlations with SO_2, NO_2 and $PM_{10-2.5}$ ranged from weak to moderate (r = 0.25-0.55).	Section 6.3.10.25 Figure 6-21 Figure 6-22	
Epidemiologic evidence supports a linear no-threshold concentration response (C-R) relationship.	Majority of analyses support a linear, no-threshold relationship for cardiovascular mortality, especially at lower ambient concentrations of $PM_{2.5}$. Confidence in C-*R* relationship extends to 8 $\mu g/m^3$ in Harvard Six Cities study	Section 6.2.10 Lepeule et al. (2012)	
Inconsistent evidence from epidemiologic studies of CHD or stroke	High quality epidemiologic study reports association with coronary events, CHD and stroke (mortality and morbidity combined) among post-menopausal women that persist after adjustment for SES. Association with stroke but not CHD in the CA Teachers cohort No association with CHD or stroke in the NHS or HPFU	(Chi et al., 2016a; Miller et al., 2007) Lipsett et al. (2011) Puett et al. (2011) Hart et al. (2015b)	Mean: 13.4 $\mu g/m^3$ Mean: 15.6 $\mu g/m^3$ Mean: 17.8 $\mu g/m^3$ Mean: 13.4 $\mu g/m^3$

Table 6-54 (Continued): Summary of evidence indicating that a causal relationship exists between long-term $PM_{2.5}$ exposure and cardiovascular effects.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{2.5}$ Concentrations Associated with Effects[c]
Generally consistent evidence of an association with CHD or stroke among those with preexisting disease	Consistent associations with MI in patient populations Association among women with diabetes in NHS	Hartiala et al. (2016) Tonne et al. (2015) Koton et al. (2013) Hart et al. (2015b)	Mean: 15.5 µg/m^3 Mean: 14.6 µg/m^3 Mean: 23.9 µg/m^3 Mean: 13.4 µg/m^3
Some but not all high quality epidemiologic studies provide evidence for effect of long-term $PM_{2.5}$ on CAC	Longitudinal change in CAC observed in MESA but not in Framingham Heart Offspring study	Kaufman et al. (2016) Dorans et al. (2016)	Mean: 14.2 µg/m^3 Median: 9.8 µg/m^3
Consistent evidence from animal toxicological studies at relevant $PM_{2.5}$ concentrations	Consistent changes in measures of impaired heart function and blood pressure Additional evidence of atherosclerosis, systemic inflammation, changes in endothelial function	Section 0 Section 6.2.4.2 Section 6.2.7.2 Section 6.2.12.2 Section 6.2.14.2	~85- 130 µg/m^3 See Tables in identified sections
Generally consistent evidence for biological plausibility of cardiovascular effects	Strong evidence for coherence of effects across scientific disciplines and biological plausibility for a range of cardiovascular effects in response to long-term $PM_{2.5}$ exposure. Includes evidence for impaired heart function, atherosclerosis, and increased blood pressure.	Section 6.2.1	

$PM_{2.5}$ = particulate matter with a nominal aerodynamic diameter less than or equal to 2.5 µm; PM_{10} = particulate matter with a nominal aerodynamic diameter less than or equal to 10 µm; $PM_{10-2.5}$ = particulate matter with a nominal aerodynamic diameter less than or equal to 10 µm and greater than a nominal diameter of 2.5 µm; SO_2 = sulfur dioxide.

[a]Based on aspects considered in judgments of causality and weight of evidence in causal framework in Tables I and II of the Preamble.

[b]Describes the key evidence and references contributing most heavily to causal determination and, where applicable, to uncertainties or inconsistencies. References to earlier sections indicate where the full body of evidence is described.

[c]Describes the $PM_{2.5}$ concentrations with which the evidence is substantiated.

6.3 Short-Term $PM_{10-2.5}$ Exposure and Cardiovascular Effects

The 2009 PM ISA concluded that the available evidence for short-term $PM_{10-2.5}$ exposure and cardiovascular effects was "suggestive of a causal relationship." This conclusion was based on several epidemiologic studies reporting associations between short-term $PM_{10-2.5}$ exposure and cardiovascular

effects including ischemic heart disease (IHD) hospitalizations, supraventricular ectopy, and changes in heart rate variability (HRV). In addition, dust storm events resulting in high concentrations of crustal material were linked to increases in cardiovascular disease emergency department (ED) visits and hospital admissions. However, it was noted in the last review that there were concerns with respect to the potential for exposure measurement error in these epidemiologic studies because of the methods employed to estimate $PM_{10-2.5}$ concentrations. In addition, there was limited evidence of cardiovascular effects from the few experimental studies that examined short-term $PM_{10-2.5}$ exposures. Thus, in the last review, key uncertainties included the potential for exposure measurement error and biological plausibility of associations reported in epidemiologic studies.

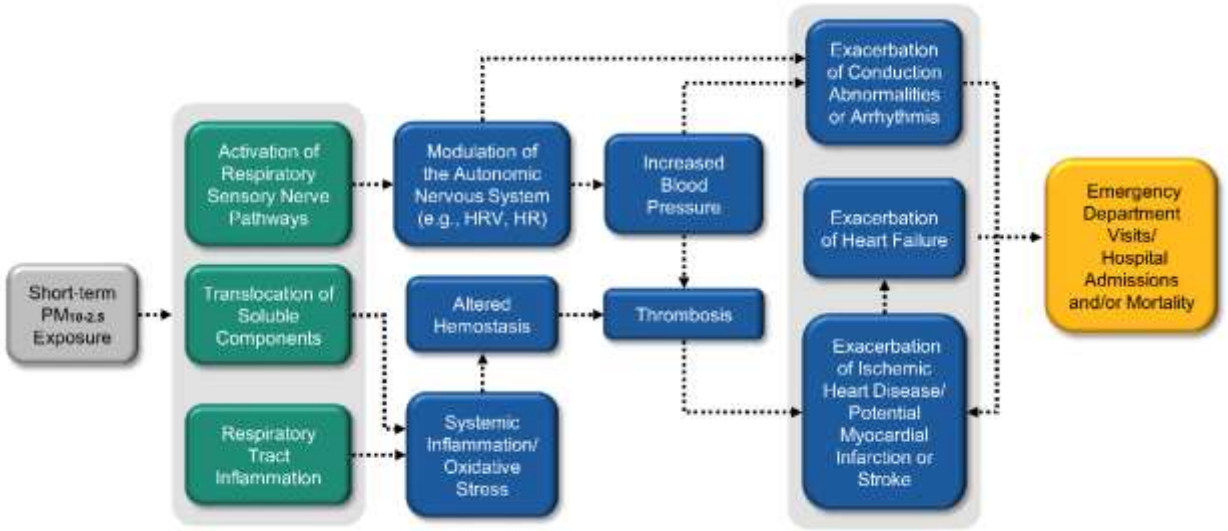
Evidence published since the completion of the 2009 PM ISA continues to be suggestive of a causal relationship between short-term exposures to $PM_{10-2.5}$ and cardiovascular effects. Since the publication of the 2009 PM ISA, there were a small number of epidemiologic studies reporting positive associations between exposure to $PM_{10-2.5}$ and IHD ED visits and hospital admissions. However, there is only limited evidence to suggest that these associations are independent of copollutant confounding. Similarly, there is only limited biological plausibility for IHD ED visits or hospital admissions from CHE, epidemiologic panel, and animal toxicological studies. Finally, similar to those studies evaluated in the 2009 PM ISA, the approaches used to estimate $PM_{10-2.5}$ concentrations continue to vary across studies leading to uncertainty regarding the extent to which exposure measurement error might be impacting the epidemiologic results.

The subsections below provide an evaluation of the most policy relevant scientific evidence relating-short-term $PM_{10-2.5}$ exposure to cardiovascular health effects. To clearly characterize and put this evidence into context, there is first a discussion of the biological plausibility of cardiovascular effects following short-term $PM_{10-2.5}$ exposure (Section 6.3.1). Following this discussion, the health evidence relating short-term $PM_{10-2.5}$ exposure and specific cardiovascular health outcomes is discussed in detail: ischemic heart disease and myocardial infarction (Section 6.3.2), heart failure and impaired heart function (Section 6.3.3) cardiac electrophysiology and arrhythmia (Section 6.3.4), cerebrovascular disease and stroke (Section 6.3.5), increased blood pressure and hypertension (Section 6.3.6), aggregated cardiovascular outcomes (Section 6.3.7), and cardiovascular-related mortality (Section 6.3.8). The evidence for an effect of $PM_{10-2.5}$ exposures on endpoints such as changes in heart rate variability (HRV) and endothelial function are then discussed (Section 6.3.9, Section 6.3.10, Section 6.3.11, and Section 6.3.12). Finally, considering the all of the information presented above, summary and causal determinations are presented (Section 6.3.13).

6.3.1 Biological Plausibility

This subsection describes the biological pathways that potentially underlie cardiovascular health effects resulting from short-term inhalation exposure to $PM_{10-2.5}$. Figure 6-30 graphically depicts these

proposed pathways as a continuum of pathophysiological responses—connected by arrows—that may ultimately lead to the apical cardiovascular events observed in epidemiologic studies. This discussion of "how" short-term exposure to $PM_{10-2.5}$ may lead these cardiovascular events also provides at least some biological plausibility for the epidemiologic results reported later in Section 6.3. In addition, most studies cited in this subsection are discussed in greater detail throughout Section 6.3.



Note: the boxes above represent the effects for which there is experimental or epidemiologic evidence, and the dotted arrows indicate a proposed relationship between those effects. Shading around multiple boxes denotes relationships between groups of upstream and downstream effects. Progression of effects is depicted from left to right and color coded (grey, exposure; green, initial event; blue, intermediate event; orange, apical event). Here, apical events generally reflect results of epidemiologic studies, which often observe effects at the population level. Epidemiologic evidence may also contribute to upstream boxes.

Figure 6-30 Potential biological pathways for cardiovascular effects following short-term exposure to $PM_{10-2.5}$.

When considering the available health evidence, plausible pathways connecting short-term exposure to $PM_{10-2.5}$ to the apical events reported in epidemiologic studies are proposed in Figure 6-30. The first pathway begins as respiratory tract inflammation leading to systemic inflammation.[64] The second pathway involves activation of sensory nerves in the respiratory tract that leads to modulation of the autonomic nervous system. Once these pathways are initiated, there is evidence from experimental and observational studies that short-term exposure to $PM_{10-2.5}$ may result in a series of pathophysiological

[64] It is also possible that soluble particle components can translocate directly into the circulatory system (Chapter 4) and lead to systemic inflammation, although the extent to which particle translocation occurs remains unclear.

responses that could lead to cardiovascular events such as ED visits and hospital admissions for IHD and HF, and ultimately mortality.

Short-term exposure to $PM_{10-2.5}$ may result in respiratory tract inflammation (Section 5.2). Inflammatory mediators such as cytokines produced in the respiratory tract may then enter into the circulatory system where they can cause distal pathophysiological responses and can contribute to overt cardiovascular disease (see Section 6.1.1). There is some evidence from a controlled human exposure study (Behbod et al., 2013) that following short-term exposure to $PM_{10-2.5}$, systemic inflammation may occur. Once in the circulation, inflammatory cytokines such as IL-6 can stimulate the liver to release coagulation factors that can alter hemostasis and increase the potential for thrombosis (see Section 6.1.1). It is therefore important to note that there is some evidence from a CHE (Graff et al., 2009) and an epidemiologic panel study (Huttunen et al., 2012) that following short-term exposure to $PM_{10-2.5}$, altered hemostasis may occur. Thus, the IHD and HF-related ED visit and hospital admission associations reported in epidemiologic studies are at least plausible through a pathway that includes thrombosis (Figure 6-30). This potential pathway could also plausibly contribute to the development of MI or stroke (Figure 6-30).

In addition to short-term $PM_{10-2.5}$ exposure potentially leading to worsening of cardiovascular disease through respiratory tract inflammation, there is also evidence that short-term exposure to $PM_{10-2.5}$ could potentially lead to worsening of cardiovascular disease through the activation of sensory nerves in the respiratory tract (CHAPTER 5). Sensory nerve activation can potentially result in modulation of the autonomic nervous system which may lead to changes in BP, conduction abnormalities, or arrhythmia (see Section 6.1.1). Thus, it is notable that there is a CHE study (Brook et al., 2014) that demonstrates autonomic nervous system modulation (as evidenced by changes in HRV and HR) following short-term $PM_{10-2.5}$ exposure. There is also evidence from CHE (Byrd et al., 2016; Zhong et al.; Brook et al., 2014; Bellavia et al., 2013), epidemiologic panel (Zhao et al., 2015) and animal toxicological (Aztatzi-Aguilar et al., 2015) studies that short-term exposure to $PM_{10-2.5}$ is associated with increases in BP. Similarly, there is evidence from epidemiologic panel studies for indicators of arrhythmia (Bartell et al., 2013; Hampel et al., 2010) following short-term $PM_{10-2.5}$ exposure. This is important given that increases in BP (e.g., through shear stress induced thrombosis) and arrhythmia may worsen IHD and set the stage for HF.

Taken together, there are plausible pathways by which short-term exposure to $PM_{10-2.5}$ may worsen IHD or HF as well as contribute to the development of MI or stroke (Figure 6-30). These proposed pathways also provide biological plausibility for ED visits and hospital admissions following short-term $PM_{10-2.5}$ exposure. That said, the evidence supporting most of the individual events in these pathways is quite limited. This information will be used to inform a causal determination, which is discussed later in the chapter (Section 6.3.13).

6.3.2 Ischemic Heart Disease and Myocardial Infarction

As noted above, (Section 6.1.2) IHD is characterized by reduced blood flow to the heart. The majority of IHD cases are caused by atherosclerosis (Section 6.2.4), which can result in the blockage of the coronary arteries and restrict of blood flow to the heart muscle. Also noted above (Section 6.1.2), an MI occurs as a consequence of IHD, resulting in insufficient blood flow to the heart that overwhelms myocardial repair mechanisms and leads to muscle tissue death. Additional information on IHD and MI can be found in Section 6.1.2.

As detailed below, recent studies add to existing evidence from the 2009 PM ISA that increases in $PM_{10-2.5}$ concentrations are associated with increases in ED visits and hospital admissions for IHD. However, results from copollutant models provide limited evidence that the observed associations are independent of other examined copollutants, including $PM_{2.5}$. Moreover, exposure measurement error remains an important uncertainty. There were no CHE or animal toxicological studies examining the relationship between short-term exposure to $PM_{10-2.5}$ and indicators of IHD or MI.

6.3.2.1 Emergency Department Visits and Hospital Admissions

The 2009 PM ISA reviewed a handful of studies that considered the association between $PM_{10-2.5}$ and IHD ED visits and hospital admissions that reported generally positive associations. A multicity study in France observed a 6.4% (95% CI: 1.6, 11.4%) increase in hospital admissions for IHD at lag 0-1 (Host et al., 2007). Associations were also recorded in single-city studies in Detroit (Ito, 2003) and Toronto (Burnett et al., 1999). On the other hand, one study in Atlanta observed no evidence of an association (Metzger et al., 2004). Additionally, one study examined $PM_{10-2.5}$ concentrations in relation to MI, and observed a positive but imprecise (i.e., wide 95% CI) association (Peters et al., 2001).

Several recent studies provide additional evidence for a positive association between short-term $PM_{10-2.5}$ exposure and IHD ED visits and HA. Specifically, $PM_{10-2.5}$ exposure was associated with IHD hospital admissions among U.S. Medicare beneficiaries in a multicity MCAPS study (Powell et al., 2015), as well as in single-city studies of IHD hospital admissions in Hong Kong, China and Kaohsiung, Taiwan (Chen et al., 2015b; Qiu et al., 2013). In the MCAPS study, $PM_{10-2.5}$ exposure was associated with a 0.74% (95% CI: 0.29, 1.20%) increase in hospital admissions for IHD on the same day (Powell et al., 2015). The association was unchanged in copollutant models adjusting for $PM_{2.5}$. Qiu et al. (2013) also observed a positive association, which persisted but lost precision after adjustment for $PM_{2.5}$. In Kaohsiung, Taiwan, Chen et al. (2015b) considered nearly 23,000 hospital admissions for IHD and reported positive associations on cool and warm days. The observed associations were generally robust to adjustment for NO_2, SO_2, CO, and O_3 in copollutant models. One additional important uncertainty across the available studies remains exposure measurement error for $PM_{10-2.5}$. All studies used an indirect measure of $PM_{10-2.5}$ (the difference between county- or area-averaged PM_{10} and $PM_{2.5}$ measurements or

the difference between concentrations measured at single PM_{10} and $PM_{2.5}$ monitors). Chen et al. (2015b) indicate the monitors were collocated, though it was unclear if these authors relied on the difference from collocated monitors before the spatial averaging was done, or if the spatial averaging of the PM_{10} and $PM_{2.5}$ monitors was done first, and then the difference was taken. Overall, it remains unclear how exposure measurement error may be affected by differing approaches for assigning $PM_{10-2.5}$ exposure in these studies (Section 3.3.1).

6.3.3 Heart Failure and Impaired Heart Function

As noted above (Section 6.1.3), HF refers to a set of conditions in which the heart's pumping action is weakened. In congestive heart failure (CHF), the flow of blood from the heart slows, failing to meet the oxygen demands of the body, and returning blood can back up, causing swelling or edema in the lungs or other tissues (typically in the legs and ankles). Additional information on HF can be found in Section 6.1.3.

As detailed below, recent studies add to existing evidence from the 2009 PM ISA that increases in $PM_{10-2.5}$ concentrations are associated with increases in ED visits and hospital admissions for HF. However, results from copollutant models provide limited evidence that the observed associations are independent of other examined copollutants, including $PM_{2.5}$. Moreover, exposure measurement error remains an important uncertainty. There were no CHE or animal toxicological studies examining the relationship between short-term exposure to $PM_{10-2.5}$ and indicators of HF included in the 2009 PM ISA.

6.3.3.1 Emergency Department Visits and Hospital Admissions

The 2009 PM ISA reviewed one study examining the association between $PM_{10-2.5}$ and ED visits and hospital admissions for heart failure. In the Atlanta-based SOPHIA study, Metzger et al. (2004) observed weak and imprecise positive associations between coarse PM concentrations and ED visits for congestive heart failure (CHF). Since the release of the 2009 PM ISA, few recent studies are available for review. In the 110-county national Medicare cohort (MCAPS) study, Powell et al. (2015) reported a 0.40% (95% CI: -0.06, 0.87%) increase in heart failure hospitalizations associated with $PM_{10-2.5}$ concentrations on the same day (measured by the difference of collocated PM_{10} and $PM_{2.5}$ monitors). The association was attenuated in magnitude and precision, but still positive, in a two-pollutant model adjusting for $PM_{2.5}$. In a much smaller study in Taipei, Taiwan, Chen et al. (2015b) also observed positive associations between $PM_{10-2.5}$ (measured by the difference of collocated PM_{10} and $PM_{2.5}$ monitors) and CHF hospitalizations on both warm and cold days. The associations were robust in copollutant models adjusting for SO_2, and attenuated but still positive in two-pollutant models adjusting for NO_2, CO, and O_3. Overall, recent studies provide limited evidence supporting an association between $PM_{10-2.5}$ and ED visits and hospital admissions for heart failure. Results from copollutant models also provide limited evidence

that the observed associations are independent of other examined copollutants; however, additional studies would be useful in providing more certainty regarding the nature of the association and addressing potential exposure measurement error from $PM_{10-2.5}$ measurements.

6.3.3.2 Toxicology Studies of Impaired Heart Function

There were no animal toxicological studies in the 2009 PM ISA (U.S. EPA, 2009) that examined the effect of short-term exposure to $PM_{10-2.5}$ on heart function. Since the publication of that document, Aztatzi-Aguilar et al. (2015) did not find an appreciable difference relative to control animals in expression of alpha skeletal actin (Acta1), or collagen-3 (Col3a1), two genes know to respond during pathological states of cardiac damage. Thus, this study does not provide evidence of potential decreases in heart function following short-term $PM_{10-2.5}$ exposure. More information on this recently published study can be found in Table 6-55 below.

Table 6-55 Study specific details from toxicological studies of short-term $PM_{10-2.5}$ exposure and impaired heart function.

Study	Study Population	Exposure Details	Endpoints Examined
(Aztatzi-Aguilar et al., 2015)	Adult Sprague-Dawley rats, M, n = 4 per treatment group	$PM_{10-2.5}$: 107 µg/m^3 collected from a high traffic and industrial area north of Mexico City in early summer. 5 h/day for 3 days. Animals were sacrificed 24 h after final exposure.	Acta1 and Col3a1 gene expression

d = day, h = hour, n = number, f = female, M = male, Acta1 = skeletal alpha-actin, Col3a1 = collagen Type 3 alpha

6.3.4 Cardiac Electrophysiology, Arrhythmia, and Cardiac Arrest

Experimental and epidemiologic panel studies typically use surface ECGs to measure electrical activity in the heart resulting from depolarization and repolarization of the atria and ventricles. The *P* wave of the ECG represents atrial depolarization, while the QRS represents ventricular depolarization and the T wave, ventricular repolarization. See Section 6.1.4 for more information on ECG, arrhythmia, and experimental measures of conduction abnormalities.

In the 2009 PM ISA, the evidence for arrhythmia related to short-term exposures to $PM_{10-2.5}$ was limited to a study reporting no associations between short-term $PM_{10-2.5}$ exposure and the risk of hospitalization for arrhythmia, and a panel studies demonstrating positive associations for ventricular arrhythmias. Since the 2009 PM ISA, there have been a few epidemiologic studies examining the

relationship between short-term PM 10-2.5 exposure and arrhythmia related HA. Although these studies generally show positive associations, uncertainties with respect to copollutant confounding and exposure measurement error remain. In addition, two panel epidemiologic studies only provide limited evidence of associations between short-term exposure to $PM_{10-2.5}$ and indicators of arrhythmia.

With respect to cardiac arrest, there were no studies included in the 2009 PM ISA and studies published since the last review are limited and inconsistent. That is, there are only a few studies that examined this endpoint, and the results of those few studies are not in agreement.

6.3.4.1 Emergency Department Visits and Hospital Admissions for Arrhythmia and Out-of-Hospital Cardiac Arrest

A number of studies based on administrative databases evaluate the association between short-term $PM_{10-2.5}$ concentrations and the risk of hospital admissions for cardiac arrhythmias (also known as dysrhythmias). In these studies, a primary discharge diagnosis of ICD-9 427 has typically been used to identify hospital admissions for cardiac arrhythmias. ICD-9 427 includes a heterogeneous group of arrhythmias including paroxysmal ventricular or supraventricular tachycardia, atrial fibrillation and flutter, ventricular fibrillation and flutter, cardiac arrest, premature beats, and sinoatrial node dysfunction.

As reported in the 2009 PM ISA, Halonen et al. (2009) did not observe a positive association between $PM_{10-2.5}$ and risk of hospital admissions for arrhythmias in Helsinki, Finland. Since the 2009 PM ISA, there have been few recent studies published on the association between $PM_{10-2.5}$ exposure and arrhythmia. In a large national Medicare cohort (MCAPS) study, Powell et al. (2015) found a positive association between $PM_{10-2.5}$ and arrhythmia-related hospital admissions (ERR: 0.94% [95% CI: 0.40, 1.48%] associated with $PM_{10-2.5}$ concentrations on the same day, measured by the difference of collocated PM_{10} and $PM_{2.5}$ monitors). The association was robust to adjustment for $PM_{2.5}$ in a two-pollutant model. In Kaohsiung, Taiwan, Chen et al. (2015b) reported positive associations between $PM_{10-2.5}$ (measured by the difference of collocated PM_{10} and $PM_{2.5}$ monitors) and hospital admissions for arrhythmias on cool days. In copollutant models, the observed association was robust to adjustment for SO_2, NO_2, and O_3, and attenuated but still positive after adjustment for CO.

6.3.4.1.1 Out-of-Hospital Cardiac Arrest

The majority of out-of-hospital cardiac arrests are due to cardiac arrhythmias. The 2009 PM ISA did not review any epidemiologic studies of ambient $PM_{10-2.5}$ concentrations and risk of OHCA. More recent evidence is limited and inconsistent. In two recent studies, Rosenthal et al. (2013) and Raza et al. (2014) did not observe positive associations between $PM_{10-2.5}$ (measured by the difference of collocated PM_{10} and $PM_{2.5}$ monitors) and OHCA in Helsinki, Finland and Stockholm, Sweden, respectively. In contrast, Dennekamp et al. (2010) and Wichmann et al. (2013) observed positive and imprecise

associations between $PM_{10-2.5}$ and OHCA. Dennekamp et al. (2010) reported a 1.7% (95% CI: -1.8, 5.3%) increase in hospital admissions on the same day in Melbourne, Australia, while Wichmann et al. (2013) observed a 9.0% (95% CI: -0.7, 19.5%) increase in hospital admissions at Lag 3 in Copenhagen, Denmark.

6.3.4.2 Panel Epidemiologic Studies for Arrhythmia and Conduction Abnormalities

The evidence for associations between arrhythmia and conduction abnormalities and $PM_{10-2.5}$ is very limited across the current review and in the 2009 PM ISA (U.S. EPA, 2009). Metzger et al. (2007) published a study demonstrating positive associations between ventricular arrhythmias and exposure to $PM_{10-2.5}$ in patients in Atlanta, GA, as described in the 2009 PM ISA (U.S. EPA, 2009). A recently published study by Bartell et al. (2013) used personal, size-fractionated PM measurements and found that 24-hour $PM_{10-2.5}$ was associated with ventricular tachyarrhythmia (RR = 1.20; 95% CI: 0.90, 1.59), but null associations were observed for 1-day (RR = 0.87; 95% CI: 0.71, 1.06) or 2-day lags (RR = 0.97; 95% CI: 0.66, 1.44). Hampel et al. (2010) reported positive associations between 24-47-hour average $PM_{10-2.5}$, determined using the difference method, with QTc (0.8%; 95% CI: 0.3%, 1.3%), but not for 0-23-hour averages or 3- to 5-day averages.

6.3.5 Cerebrovascular Disease and Stroke

Cerebrovascular disease typically includes conditions classified under ICD10 codes I60-I69 (ICD 9: 430-438) such as hemorrhagic stroke, cerebral infarction (i.e., ischemic stroke) and occlusion of the pre-cerebral and cerebral arteries. Ischemic stroke results from an obstruction within a blood vessel that supplies oxygen to the brain, potentially leading to infarction, and accounts for the majority of all strokes (Goldberger et al., 2008). Hemorrhagic stroke is less common but results to a disproportionate amount of fatalities. Additional information on cerebrovascular disease and stroke can be found in Section 6.1.5.

The 2009 PM ISA did not review any epidemiologic studies of short-term exposure to $PM_{10-2.5}$ emergency department visits and hospital admissions visits for cerebrovascular disease (CBVD). In the current review, a limited number of studies provide inconsistent evidence regarding the presence of an association. Moreover, there are uncertainties with respect to copollutant confounding and exposure measurement error.

6.3.5.1 Emergency Department Visits and Hospital Admissions

A limited number of recent studies provide inconsistent evidence regarding the presence of an association between short-term $PM_{10-2.5}$ exposure and ED visits and hospital admissions for CBVD.

Studies in Rome, Italy (Alessandrini et al., 2013) and Kaohsiung, Taiwan (Chen et al., 2015b) reported some evidence of an association between short-term $PM_{10-2.5}$ concentrations and ED visits and hospital admissions for CBVD. Alessandrini et al. (2013) considered 26,557 hospital admissions for CBVD in the context of Saharan dust outbreaks, and observed a 1.6% (95% CI: -0.6, 3.8%) increase in risk of hospital admissions associated with $PM_{10-2.5}$ concentrations measured on the same day. The association was larger in magnitude, but less precise (i.e., wide 95% CIs) on days with high Saharan dust levels, though effect measure modification by Saharan dust level was not statistically significant. Chen et al. (2015b) also evaluated approximately 25,000 hospitalizations for CBVD and reported associations with $PM_{10-2.5}$ concentrations on both warm and cool days, with a larger magnitude association observed on warm days. The observed association on warm days was robust to adjustment for SO_2 and O_3, and attenuated but still positive after adjustment for NO_2 and CO in copollutant models. Additional studies conducted in China reported inconsistent evidence of an association (Huang et al., 2016; Qiu et al., 2013). Huang et al. (2016) reported a positive association between $PM_{10-2.5}$ concentrations and stroke ED visits (lag 0) when adjusted for CO, or NO_2 in Beijing, China. Additionally, when examining ischemic and hemorrhagic stroke subtypes Huang et al. (2016) observed positive associations at lag 0, while associations were attenuated but still positive, or null, at longer lag periods (lag 1 to lag 3). Furthermore, the authors also reported consistently stronger associations across lag periods for ED visits on days when the temperature was greater than 13.5ºC. In contrast to the studies in Rome, Kaohsiung and Beijing, a study of over 100,000 ED visits in Hong Kong, China reported a null association between CBVD hospital admissions and $PM_{10-2.5}$ concentrations (Qiu et al., 2013). One additional important uncertainty across the available studies remains the use of an indirect measure of $PM_{10-2.5}$ and the potential for exposure measurement error for $PM_{10-2.5}$ (Section 3.3.1). Overall, there remains limited and inconsistent evidence of an association between $PM_{10-2.5}$ and CBVD.

6.3.6 Blood Pressure and Hypertension

High blood pressure results in the increased force on the artery walls and can damage the blood vessels and increase risk for cardiovascular disease and stroke. Hypertension typically develops over years and is the clinically relevant blood pressure outcome, defined as SBP above 140 mm hg or DBP above 90 mm hg. That being said, small population-level changes in blood pressure, even in the absence of clinical hypertension, can have large effects on clinical outcome prevalence (Rose, 1985). Additional information on blood pressure and hypertension can be found in Section 6.1.6 and Section 6.2.7.

There was a single epidemiologic panel study in the 2009 PM ISA finding a decrease in SBP following short-term $PM_{10-2.5}$ exposure (U.S. EPA, 2009). Since the publication of the 2009 PM ISA, an epidemiologic panel study and a few CHE studies provide some evidence of an effect of short-term PM 10-2.5 exposure on measurements of blood pressure. In addition, an animal toxicological study also reported that short-term exposure to $PM_{10-2.5}$ could result in changes in the blood pressure regulating renin-angiotensin system at the mRNA level. Thus, studies published since the completion of the 2009

PM ISA provide some additional evidence that short-term exposure to $PM_{10-2.5}$ may result in changes in BP.

6.3.6.1 Panel Epidemiologic Studies of Changes in Blood Pressure (BP)

For the 2009 PM ISA (U.S. EPA, 2009), a single study was evaluated (Ebelt et al., 2005) that examined the association between BP and $PM_{10-2.5}$. Ebelt et al. (2005) reported decreases in SBP relative to $PM_{10-2.5}$ determined using the subtraction method. A recent panel study examined cardiovascular effects among people with diabetes and short-term exposure to $PM_{10-2.5}$ (calculated by the subtraction method) in Shanghai where daily averages of $PM_{2.5}$ and $PM_{10-2.5}$ during the study period were 60 ug/m^3 and 19 ug/m^3, respectively. Specific lags of 0-2, 3-6, 7-12, and 13-24 hours were positively associated with DBP but associations with SBP and PP across lags were null (Zhao et al., 2015).

6.3.6.2 Controlled Human Exposure Studies of Changes in Blood Pressure (BP)

In the 2009 PM ISA (U.S. EPA, 2009), there were no CHE studies that examined the effect of $PM_{10-2.5}$ on blood pressure. Since the last review, there have been studies examining changes in blood pressure in response to short-term exposure to urban (Byrd et al., 2016; Bellavia et al., 2013), as well as rural (Brook et al., 2014) $PM_{10-2.5}$.

In response to urban $PM_{10-2.5}$, Bellavia et al. (2013) reported small, but significant ($p = 0.03$) elevations in SBP, but not DBP. These results are generally in agreement with an additional study of urban $PM_{10-2.5}$. Byrd et al. (2016) found exposure to urban $PM_{10-2.5}$ resulted in small (~1-3 mm hg), increases in SBP ($p < 0.001$), DBP ($p < 0.001$), and pulse pressure ($p = 0.03$) when compared to FA.

Changes in blood pressure were also demonstrated in a CHE study of rural $PM_{10-2.5}$. Brook et al. (2014) reported an increase in both SBP ($p = 0.021$) and DBP ($p = 0.05$) during the exposure period when compared to FA (results were reiterated in (Morishita et al., 2015b)). In addition, pooled blood pressure results from (Brook et al., 2014)and (Byrd et al., 2016) showed that changes in blood pressure in response to urban $PM_{10-2.5}$ were on average significantly greater throughout $PM_{10-2.5}$ exposure than those changes observed throughout the exposure to rural $PM_{10-2.5}$ (Byrd et al., 2016) ($p < 0.001$).

The CHE studies presented in the current ISA provide evidence of a small, but reproducible effect of urban and rural $PM_{10-2.5}$ exposure on BP elevation in healthy adults. Biological components present in PM may at least partially account for changes in BP. That is, Zhong et al. (2015) examined whether PM effects on BP were associated with endotoxin and β-1,3-d-glucan present in PM. After adjusting for total exposure mass, results indicated endotoxin was associated with increases in SBP 30-minutes post exposure, and DBP for up to 20 hours post exposure. β-1,3-d-glucan was only associated with an increase

in DBP 30 minutes post exposure. Finally, increases in BP could also be associated with hypomethylation. Bellavia et al. (2013) found Toll Like Receptor 4 (TLR4) hypomethylation (which can be a marker for increased inflammation) in response to $PM_{10-2.5}$ CAP exposure and an association between TLR4 hypomethylation and increases in SBP and DBP. More information on studies published since the 2009 ISA can be found in Table 6-56 below.

Table 6-56 Study-specific details from controlled human exposure (CHE) studies of short-term $PM_{10-2.5}$ exposure and blood pressure (BP).

Study	Population	Exposure Details (Concentration; Duration)	Endpoints Examined
Bellavia et al. (2013)	Healthy adults n = 8 M, 7 F 18-60 yr old 27.7 ± NA	~200 µg/m^3 $PM_{10-2.5}$ for 130 min at rest PM collected from a busy street in Toronto, Canada	BP: 10 min pre, 5 min post DNA methylation: 1 h post
Byrd et al. (2016)	Healthy adults 20 M, 9 F; 18-50 yrs 30 ± 8.2,	164.2 ± 80.4 µg/m^3 $PM_{10-2.5}$ CAP for 2 h CAP from urban Dearborn, MI	BP: every 7 min during exposure, post, 2 h post Vascular function: post, 2 h post
Brook et al. (2014)	Healthy adults n = 16 M, 16 F; 18-46 yr 25.9 ± 6.6,	76.2 ± 51.5 µg/m^3 $PM_{10-2.5}$ for 2 h CAPs from rural Dexter, MI	BP: every 10 min during exposure, post, and 2 h post
Morishita et al. (2015b)	Healthy adults n = 16 M, 16 F; 18-46 yr 25.9 ± 6.6	76.2 ± 51.5 µg/m^3 $PM_{10-2.5}$ CAP for 2 h CAP from rural Dexter, MI	Relationship between $PM_{10-2.5}$ components and changes in BP
Zhong et al. (2015)	Healthy adults n = 23 M, 27 F; 18-60 yr	Endotoxin and B-1,3-d-glucan associated with 200 µg/m^3 $PM_{10-2.5}$ CAP exposure for 130 min at rest CAP collected from a heavy-traffic 4-lane street in Toronto	BP: pre, 0.5 h and 20 h post

Note: SD = standard deviation, M = male, F = female, n = number, h = hour, yr = year, CAP = concentrated ambient particle, BP = blood pressure.

6.3.6.3 Toxicology Studies of Changes in Blood Pressure (BP)

There were no animal toxicological studies in the 2009 PM ISA examining the effect of $PM_{10-2.5}$ CAP exposure on measures of BP. Since the publication of that document, Aztatzi-Aguilar et al. (2015) exposed rats to $PM_{10-2.5}$ and reported that Ace and B1r, but not At1r mRNA levels in the heart were increased ($p < 0.05$). Thus, there is limited evidence at the mRNA level that exposure to $PM_{10-2.5}$ can result in changes to the renin-angiotensin system which could then, effect blood pressure. More information on this study can be found in Table 6-57 below.

Table 6-57 Study specific details from toxicological studies of short-term $PM_{10-2.5}$ exposure and blood pressure (BP).

Study	Study Population	Exposure Details	Endpoints Examined
(Aztatzi-Aguilar et al., 2015)	Adult Sprague-Dawley rats, M, n = 4 per treatment group	Inhalation of 107 µg/m^3 $PM_{10-2.5}$ for 5 h/day for 3 days	angiotensin and bradykinin system gene expression

Notes: n = number, h = hour, d = day, M = male

6.3.7 Emergency Department Visits and Hospital Admission Studies of Cardiovascular-Related Effects

Many epidemiologic studies consider the composite endpoint of ED visits and hospital admissions for all cardiovascular diseases, including diseases of the circulatory system. This endpoint generally encompasses ED visits and hospital admissions for ischemic heart disease, MI, PVD, heart failure, arrhythmia, CBVD and stroke, and diseases of pulmonary circulation. A smaller body of studies examines the endpoint of cardiac diseases, a subset of CVD that specifically excludes hospitalizations for cerebrovascular disease, peripheral vascular disease, and other circulatory diseases not involving the heart or coronary circulation. The 2009 PM ISA reviewed a limited number of studies on $PM_{10-2.5}$ and CVD ED visits and HA. In 108 U.S. counties with collocated PM_{10} and $PM_{2.5}$ monitors, Peng et al. (2008) reported a 0.8% (95%: 0.6, 1.0%) increase in risk of CVD hospital admissions among Medicare beneficiaries associated with $PM_{10-2.5}$ concentrations on the same day. A positive association was also observed in six French cities, but the association was much less precise (Host et al., 2008). Tolbert et al. (2007) did not find evidence of an association between $PM_{10-2.5}$ exposure and CVD ED visits and hospital admissions in Atlanta, Georgia. Recent multicity studies focus on overall CVD visits and provide some evidence that $PM_{10-2.5}$ may be associated with increased risk of cardiovascular-related HA, while results from single-city studies are inconsistent (Table 6-58).

Table 6-58 Epidemiologic studies of short-term $PM_{10-2.5}$ exposure and hospital admission and emergency department visits for cardiovascular disease.

Studies are listed in the order that they are discussed in the text. †Studies published since the 2009 PM ISA. Effect estimates are standardized to a 10 $\mu g/m^3$ for 24-h avg. $PM_{2.5}$.

Several multicity studies provide evidence of an association between $PM_{10-2.5}$ concentrations and cardiovascular-related HA. In the U.S. MCAPS study, Powell et al. (2015) observed increases in same-day (lag 0) $PM_{10-2.5}$ concentrations were associated with a 0.69% (95% CI: 0.45%, 0.92%) higher rate of cardiovascular-related hospital admissions among Medicare beneficiaries. The association was diminished when longer lag periods were evaluated, and was unchanged after adjustment for $PM_{2.5}$ in copollutant models. The authors did not observe differences in associations between study regions in the observed associations when stratifying counties into Eastern and Western regions. The MED-PARTICLES study reported a similar positive association between $PM_{10-2.5}$ concentrations (lag 0-1) and cardiovascular-related hospital admissions in eight southern European cities (Stafoggia et al., 2013b). Similar to the findings from the U.S. MCAPS study, the association was not present at longer lags (0-5 and 2-5). The observed association was attenuated but still positive in copollutant models adjusted for $PM_{2.5}$ and NO_2. Conversely, in a study of five cities in Central and Eastern Europe, Lanzinger et al. (2016b) reported a positive association with a wide confidence interval for $PM_{10-2.5}$ concentrations averaged over a longer lag period (0-5), though no evidence of an association at a shorter lag period (0-1). In city-specific analyses, while effect estimates had wider confidence intervals, there was evidence of a higher-magnitude association in Augsburg, Germany compared to the other four cities (Lanzinger et al., 2016c).

Results from single-city studies have shown less consistent evidence for the relationship between short-term $PM_{10-2.5}$ exposure and cardiovascular-related ED visits and HA. In Rome, Italy, Alessandrini et

al. (2013) considered 26,557 hospital admissions for CVD in the context of Saharan dust outbreaks, and observed a 3.6% (95% CI: 1.5, 5.9%) increase in risk of hospitalization at lag 0-1. There was no evidence of effect modification by Saharan dust level. In another European study, Atkinson et al. (2010) reported a null association between $PM_{10-2.5}$ exposure and cardiovascular-related hospital admissions in London, England. In Dona Ana County, New Mexico, Rodopoulou et al. (2014) reported a positive association with ED visits (RR: 1.015, 95% CI: 0.993, 1.039, lag 1). A study in Hong Kong, China considered $PM_{10-2.5}$ concentrations in relation to cardiac diseases (Qiu et al., 2013). Qiu et al. (2013) observed a positive association, but the association attenuated to the null after adjustment for $PM_{2.5}$.

Overall, several recent studies report positive association between $PM_{10-2.5}$ and cardiovascular-related ED visits and HA; however, there is limited evidence to support that this association is independent of copollutant confounding. Based on limited evidence from these studies, observed associations tend to be most pronounced on the same day or previous day, with diminishing associations at longer lags. Results from recent single-city studies provide inconsistent evidence of an association. Additionally, it remains unclear how exposure measurement error may be affected by how $PM_{10-2.5}$ exposure is being assigned in these studies (Section 3.3.1).

6.3.8 Epidemiologic Studies of Cardiovascular Mortality

Studies that examine the association between short-term $PM_{10-2.5}$ exposure and cause-specific mortality outcomes, such as cardiovascular mortality, provide additional evidence for $PM_{10-2.5}$-related cardiovascular effects, specifically whether there is evidence of an overall continuum of effects. In the 2009 PM ISA, the majority of studies evaluated consisted of single-city studies, with only one U.S. based multicity study (Zanobetti and Schwartz, 2009) that examined the relationship between short-term $PM_{10-2.5}$ exposure and cardiovascular mortality. Across studies there was evidence of consistent positive associations with cardiovascular mortality even though studies used a variety of approaches to estimate $PM_{10-2.5}$ concentrations. Overall there was a limited evaluation of the potential confounding effects of gaseous pollutants and the influence of model specification on the associations observed.

Recent multicity epidemiologic studies provide additional evidence of consistent positive associations between short-term $PM_{10-2.5}$ exposure and cardiovascular mortality with the majority of evidence at lags 0-1 days. Unlike the studies evaluated in the 2009 PM ISA, some recent studies have also further evaluated the $PM_{10-2.5}$-cardiovascular mortality relationship by examining cause-specific cardiovascular mortality outcomes (e.g., stroke, heart failure, IHD) (Pascal et al., 2014; Samoli et al., 2014), but overall these studies are still limited in number. As a result, this section focuses on studies that examine the combination of all cardiovascular mortality outcomes and address uncertainties and limitations in the relationship between short-term $PM_{10-2.5}$ exposure and cardiovascular mortality, specifically: potential copollutant confounding, lag structure of associations, and effect modification by season and temperature.

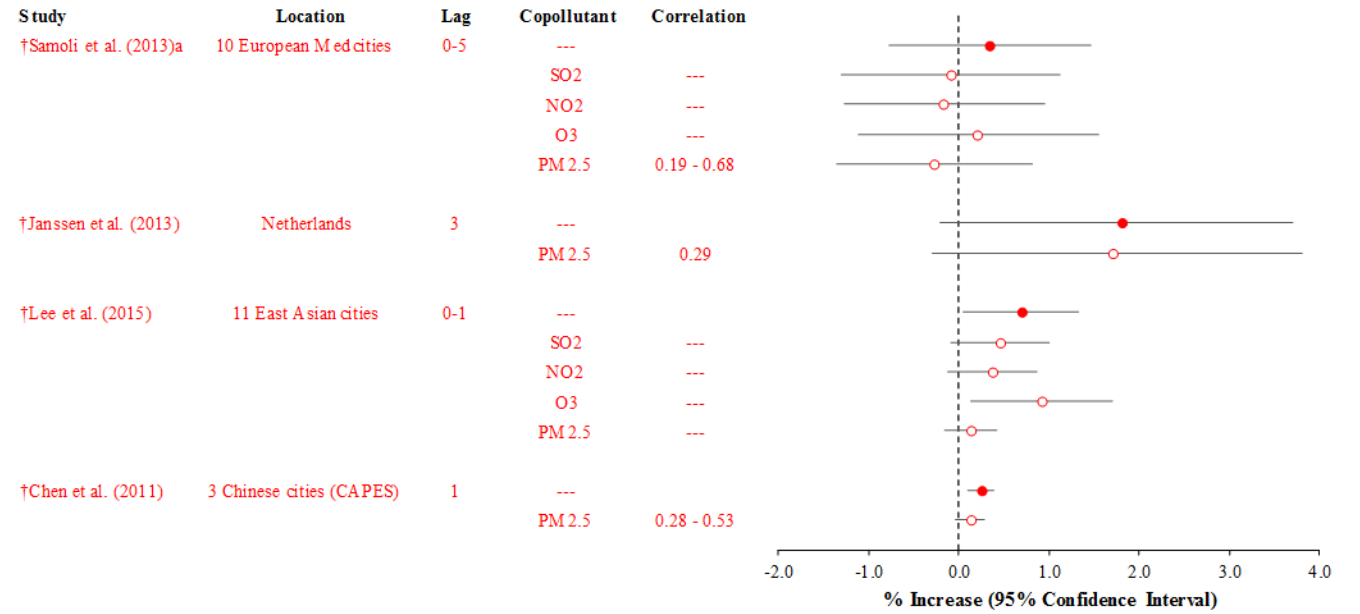
Characterizing the $PM_{10-2.5}$ Cardiovascular Mortality Relationship

Recent epidemiologic studies conducted additional analyses that address some of the uncertainties and limitations of the $PM_{10-2.5}$ – cardiovascular mortality relationship identified in the 2009 PM ISA. Specifically, recent studies provide additional information on copollutant confounding, lag structure of associations, and seasonal associations. However, similar to those studies evaluated in the 2009 PM ISA, the approaches used to estimate $PM_{10-2.5}$ concentrations varies across studies and it remains unclear if the level of exposure measurement error varies by each approach (see Table 11-9, Section 11.3). Overall, these studies provide initial evidence that: $PM_{10-2.5}$-cardiovascular mortality associations remain positive, but may be attenuated in copollutant models; $PM_{10-2.5}$ effects on cardiovascular mortality tend to occur within the first few days of exposure (i.e., lags 1 to 3 days), and associations are larger in magnitude during warmer months.

Copollutant Confounding

Consistent with the evaluation of total (nonaccidental) mortality, the studies evaluated in the 2009 PM ISA provided limited information on the potential confounding effects of gaseous pollutants and $PM_{2.5}$ on the relationship between short-term $PM_{10-2.5}$ exposure and cardiovascular mortality. Recent multicity studies (Lee et al., 2015a; Pascal et al., 2014; Janssen et al., 2013; Samoli et al., 2013; Malig and Ostro, 2009) and a meta-analysis (Adar et al., 2014) provide additional information concerning the role of copollutants on the $PM_{10-2.5}$-cardiovascular mortality relationship.

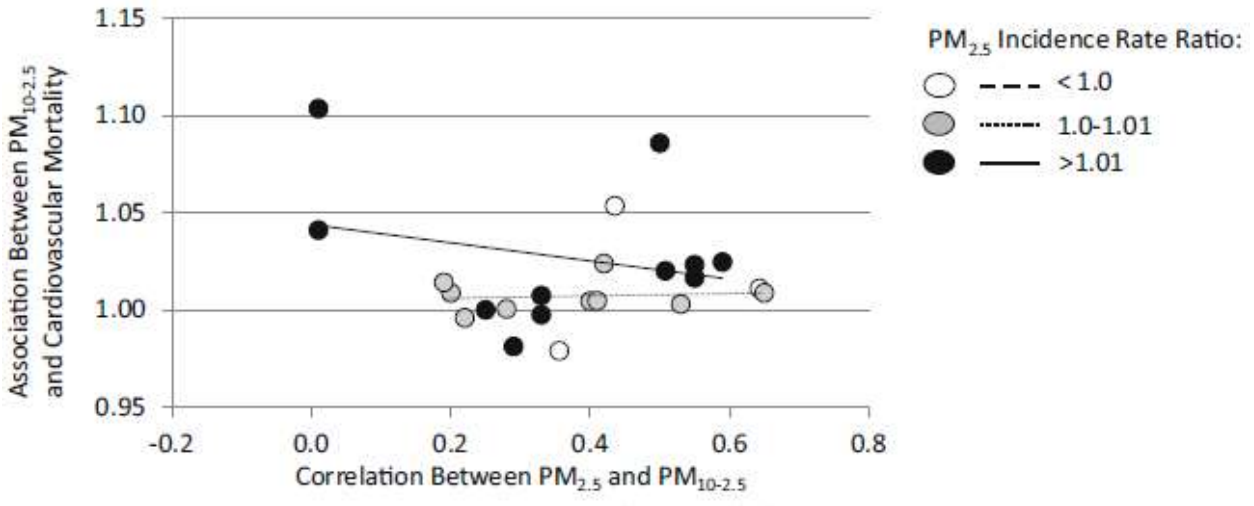
When focusing on potential copollutant confounding of the $PM_{10-2.5}$-cardiovascular mortality relationship by $PM_{2.5}$, there is evidence that the association generally remains positive, but is attenuated in some instances (Figure 6-31). Within the U.S., Malig and Ostro (2009) in a study of 15 California counties examined copollutant confounding, but only by $PM_{2.5}$. The authors observed that the pattern and magnitude of associations over single-day lags of 0 to 2 days was relatively unchanged in both models (quantitative results not presented), which is supported by the low correlation between $PM_{2.5}$ and $PM_{10-2.5}$ observed in this study (r = -0.03 to 0.35). The copollutant model results with $PM_{2.5}$ in Malig and Ostro (2009) are consistent with Janssen et al. (2013) in a study conducted in the Netherlands and Chen et al. (2011) in the CAPS study. However, these results are inconsistent with Lee et al. (2015a) in a study of 11 east Asian cities and Samoli et al. (2013) in a study of 10 European Mediterranean cities within the MED-PARTICLES project (Figure 6-31). The interpretation of $PM_{2.5}$ copollutant model results in Lee et al. (2015a) and Samoli et al. (2013) is complicated by the lack of information on the correlation between $PM_{2.5}$ and $PM_{10-2.5}$, and the examination of a longer lag (i.e., lag 0-5 days), respectively.



Note: †Studies published since the 2009 PM ISA. a = Copollutant results only presented for a lag of 0-5 days. Corresponding quantitative results are reported in Supplemental Table S6-22 (U.S. EPA, 2018).

Figure 6-31 Percent increase in cardiovascular mortality for a 10 μg/m^3 increase in 24-hour average $PM_{10-2.5}$ concentrations in single- and copollutant models.

The studies that provide evidence of a $PM_{10-2.5}$-cardiovascular mortality association that remains positive in copollutant models with $PM_{2.5}$ is supported by analyses conducted by Adar et al. (2014) in the context of a meta-analysis. When examining studies that conducted copollutant models with $PM_{2.5}$, Adar et al. (2014) observed that the $PM_{10-2.5}$-cardiovascular mortality association was similar in magnitude to that observed in single-pollutant models (quantitative results not provided). The results from copollutant models were further supported when stratifying $PM_{10-2.5}$-mortality estimates by the correlation with $PM_{2.5}$ (low, $r < 0.35$; medium, $r = 0.35$ to < 0.5; high, $r > 0.5$). The authors observed evidence of positive associations for the low and high correlation categories that were similar in magnitude, but had wide confidence intervals. However, there was no evidence of an association for the medium correlations. Adar et al. (2014) further examined potential copollutant confounding by $PM_{2.5}$ through an analysis focusing on whether $PM_{10-2.5}$-mortality associations were present when the correlation between $PM_{2.5}$ and $PM_{10-2.5}$ increased and when $PM_{2.5}$ was also associated with mortality. As highlighted in Figure 6-32 there was evidence of positive $PM_{10-2.5}$-cardiovascular mortality associations at both low and high correlations as well as low and high magnitudes of the $PM_{2.5}$-cardiovascular mortality association (Figure 6-32).



Source: Permission pending, Adapted from (Adar et al., 2014)

Figure 6-32 Associations between short-term $PM_{10-2.5}$ exposure and cardiovascular mortality as a function of the correlation between $PM_{10-2.5}$ and $PM_{2.5}$ stratified by strength of the association with $PM_{2.5}$.

Compared to the examination of potential copollutant confounding by $PM_{2.5}$, fewer studies examined the potential confounding effects of gaseous pollutants. Across studies there remains a limited evaluation of copollutant models with gaseous pollutants and their impact on the $PM_{10-2.5}$ – cardiovascular mortality relationship remains unclear (Figure 6-31). Similar to the analysis of potential copollutant confounding by $PM_{2.5}$, the assessment of gaseous pollutants is complicated by the lack of correlation information and the lag examined (i.e., lag 0-5 days).

Collectively, the recent epidemiologic studies that examined potential copollutant confounding along with the analyses conducted by Adar et al. (2014) provide initial evidence that $PM_{10-2.5}$-cardiovascular mortality associations remain positive in copollutant models with $PM_{2.5}$, but in some cases there is evidence of no association. Additionally, the limited number of studies that examined potential copollutant confounding by gaseous pollutants along with the lack of information on the correlation between $PM_{10-2.5}$ and gaseous pollutants does not allow for an adequate assessment as to whether they confound the $PM_{10-2.5}$-cardiovascular mortality association.

Lag Structure of Associations

Multicity epidemiologic studies that examined cause-specific mortality in the 2009 PM ISA observed immediate effects on cardiovascular mortality attributed to short-term $PM_{10-2.5}$ exposure with consistent positive associations observed at lags ranging from 0 to 1 day. However, the majority of these

studies either examined single-day lags or selected lags a prior. Recent multicity studies have conducted more extensive examinations of the lag structure of associations by examining multiple sequential single-day lags, or examining whether there is evidence of immediate (i.e., lag 0-1 days), delayed (i.e., lag 2-5 days), or prolonged (i.e., lag 0-5 days) effects of short-term $PM_{10-2.5}$ exposure on cardiovascular mortality.

Across the studies that examined single-Lag days, most of the studies focused on lags within the range of 0 to 2 days. Although a few studies extended out to a longer duration, collectively the studies provided evidence that was generally in agreement with one another. In the lone U.S. study, Malig and Ostro (2009) in 15 California counties observed the largest association at lag 2 (0.7% [95% CI: 0.1, 1.5]). These results are consistent with two studies conducted in Europe, Janssen et al. (2013) in the Netherlands where the largest association in terms of magnitude and precision was observed for lag 3 (1.8% [95% CI: -0.2, 3.7]), and Samoli et al. (2013) in the MED-PARTICLES project where the largest associations were observed at lags 1 and 2 (quantitative results not presented). Additionally, in a study conducted in Asia (i.e., CAPES) Chen et al. (2011) observed the largest association at lag 1. While the previous studies focused on a narrower number of single-day lags, Stafoggia et al. (2017), in a study of 8 European cities, examined single-day lags ranging from 0 to 10 days. Although the authors reported an association largest in magnitude at lag 1, they also found evidence of positive associations at lags 2 and 3, but no evidence of an association at longer lags. Instead of focusing on multiple single-day lags, Lee et al. (2015a) when examining 11 east Asian cities, examined a series of multi-day lags ranging from 0 to 4 days. Although positive associations were observed across all combinations of lags, the strongest association in terms of magnitude and precision was observed at lag 0-2 days (quantitative results not presented). The results across the studies that examined a series of single- and multi-day lags is confirmed by the meta-analysis by Adar et al. (2014) where an examination of single-day lag risk estimates across studies found positive associations across lags ranging from 0 to 2 days with the strongest association in terms of magnitude and precision occurring at lag 2.

Along with the examination of single-day lags, some studies also focused on a priori multi-day lag structures defined to be representative of immediate, delayed, and prolonged effects. However, in light of the single-day lag results the a priori lag structures institute breakpoints that complicate the interpretation of the combination of single-day and multi-day lag results. Lanzinger et al. (2016a) in the UFIREG study observed positive associations across all lag structures, but the confidence intervals were large due to the short study duration (lag 0-1: 1.9 % [95% CI: -4.8, 9.4]; lag 2-5: 8.9% [95% CI: 0.85, 17.8]; lag 0-5: 9.1% [95% CI: -1.3, 20.4]). The magnitude of associations in Lanzinger et al. (2016a) is much larger and shows a different pattern of associations than that observed in Samoli et al. (2013) where results tended to indicate that the majority of the effect on cardiovascular mortality due to short-term $PM_{10-2.5}$ exposures is immediate (lag 0-1: 0.28% [95% CI: -0.37, 0.93]; lag 2-5 and lag 0-5: 0.33%). Additionally, as noted above when examining single-day lags through a polynomial distributed lag model, Samoli et al. (2013) observed that associations were largest at lag 1 and 2 days.

Overall, studies that examined the lag structure of associations generally support that short-term $PM_{10-2.5}$ exposure contributes to cardiovascular mortality effects within the first few days after exposure, ranging from 1 to 3 days. Even though studies of multi-day lags that examined the timing of effects provide some initial evidence for a potential longer duration between exposure and effect, an examination of single-day lags over the same multi-day lag does not support this initial observation.

Effect Modification

Season

An examination of potential seasonal differences in associations between short-term $PM_{10-2.5}$ exposure and cardiovascular mortality in the 2009 PM ISA was limited to one U.S. multicity study (Zanobetti and Schwartz, 2009) that provided initial evidence of associations being larger in magnitude in the spring and summer. Although still limited in number, some recent multicity studies conducted an examination of potential seasonal differences in associations (Lee et al., 2015a; Pascal et al., 2014; Samoli et al., 2013).

Pascal et al. (2014) in a study of nine French cities examined associations at lag 0-1 across the four seasons and reported the largest associations in the summer (4.6% [95% CI: 2.3, 6.9]) and fall (3.3% [95% CI: 1.3, 5.1]) with no evidence of an association in the winter and spring. Instead of examining each individual season, Samoli et al. (2013) in the MED-PARTICLES project only examined warm (April – September) and cold months (October – March). When examining lag 0-5 days, the authors only observed evidence of an association during the warm season (0.48% [95% CI: -1.2, 2.2]), but confidence intervals were wide.

Although the studies that examined European cities provide consistent evidence of $PM_{10-2.5}$-cardiovasculr mortality associations being larger in magnitude during warmer months (i.e., summer), a study conducted in 11 east Asian cities observed a different pattern of associations. Lee et al. (2015a) reported that $PM_{10-2.5}$ associations with cardiovascular mortality were larger in the cold season (1.0% [95% CI: 0.26, 1.8]) compared to the warm (0.30% [95% CI: -0.30, 0.91]). It is unclear why these results differ from the other studies, but mean $PM_{10-2.5}$ concentrations and mean temperature tended to be higher across the cities in Lee et al. (2015a) compared to the cities in the other studies evaluated in this section. Overall, across studies the evidence for seasonal associations remains limited, but results indicate potentially larger associations during the warmer months.

Temperature

In addition to examining whether there is evidence that warm temperatures modify the $PM_{10-2.5}$-cardivoascular mortality relationship by conducting seasonal analyses, a recent study also examined whether there is evidence that high temperature days modify the $PM_{10-2.5}$-cardiovascular mortality relationship. Pascal et al. (2014) examined the impact of temperature on the $PM_{10-2.5}$-cardiovascular

mortality relationship across 9 French cities by comparing associations on warm and non-warm days where warm days were defined as those days where the mean temperature exceed the 97.5th percentile of the mean temperature distribution. When calculating the interaction ratio, which estimated the extra PM effect due to warm days, the authors observed no evidence of a positive or negative modifying effect of warm days on cardiovascular mortality.

6.3.9 Heart Rate (HR) and Heart Rate Variability (HRV)

Measured by ECG, HRV represents the degree of difference in the inter-beat intervals of successive heartbeats, and is an indicator of the balance between the sympathetic and parasympathetic arms of the autonomic nervous system (Rowan III et al., 2007). More information on HRV and measures of HRV can be found in Section 6.1.10.

In the 2009 PM ISA, there was limited evidence examining the relationship between short-term exposure to $PM_{10-2.5}$ and measurements of HRV and HR. Since the last review, results from a CHE study provides limited evidence that rural, but not urban $PM_{10-2.5}$ may alter HR and HRV.

6.3.9.1 Epidemiologic Panel Studies of Heart Rate (HR) and Heart Rate Variability (HRV)

In the 2009 PM ISA (U.S. EPA, 2009), there was limited evidence with inconsistent results for changes in HRV relative to short-term exposures to $PM_{10-2.5}$. One additional study has recently been published and found no association was observed between $PM_{10-2.5}$ (calculated as the difference between co-located monitors) and heart rate in asthma and COPD patients in New York City and Seattle; HRV was not examined (Hsu et al., 2011).

6.3.9.2 Controlled Human Exposure Studies of Heart Rate (HR) and Heart Rate Variability (HRV)

In the previous ISA, there were no CHE studies examining the effect of $PM_{10-2.5}$ on heart rate. More recently, Brook et al. (2014) reported significant, but modest increases in HR in response to rural $PM_{10-2.5}$ exposures ($P < 0.0001$). However, similar results were not observed in response to urban $PM_{10-2.5}$ exposure (Byrd et al., 2016). In total, there is some evidence from CHE studies relating modest changes in HR to rural, but not urban $PM_{10-2.5}$ exposure.

With respect to HRV, in the 2009 PM ISA a controlled human exposure study reported decreased SDNN after exposure to $PM_{10-2.5}$ CAPs (Graff et al., 2009). In a study published since the 2009 PM ISA, Brook et al. (2014) reported a decrease in HF ($p = 0.006$) and an increase in the LF/HF ratio ($p = 0.007$)

during exposure to rural $PM_{10-2.5}$. Statistically significant changes in SDNN and LF were not observed. In an additional study, no changes in time or frequency HRV metrics were reported in response to urban $PM_{10-2.5}$ exposure (Byrd et al., 2016). Taken together, the above CHE studies provide limited evidence relating changes in HRV to rural, but not urban $PM_{10-2.5}$. More information on studies published since the 2009 ISA can be found in Table 6-59 below.

Table 6-59 Study-specific details from controlled human exposure (CHE) studies of short-term $PM_{10-2.5}$ exposure and heart rate (HR) and heart rate variability (HRV).

Study	Population N, Sex; Age (Mean ± SD)	Exposure Details (Concentration; Duration)	Endpoints Examined
Byrd et al. (2016)	Healthy adults 20 M, 9 F; 18-50 yrs 30 ± 8.2,	164.2 ± 80.4 µg/m^3 $PM_{10-2.5}$ CAP for 2 h from urban Dearborn, MI	HR: every 7 min during exposure, post, 2 h post HRV: during exposure
Brook et al. (2014)	Healthy adults n = 16 M, 16 F; 18-46 yrs 25.9 ± 6.6,	76.2 ± 51.5 µg/m^3 $PM_{10-2.5}$ for 2 h CAP from rural Dexter, MI	HR: every 10 min during exposure, post, and 2 h post HRV: during exposure, Vascular function: post, and 2h post

n = number, M = male, F = female, n = number, h = hour, CAP = concentrated ambient particle, HR = heart rate, HRV = heart rate variability

6.3.10 Systemic Inflammation and Oxidative Stress

As discussed in Section 6.1.1 and Section 6.1.11 systemic inflammation and oxidative stress have been linked to a number of cardiovascular-related outcomes. For example, circulating cytokines such as IL-6 can stimulate the liver to release inflammatory proteins and coagulation factors that can ultimately increase the risk of thrombosis and embolism. Similarly, oxidative stress can result in damage to healthy cells and blood vessels and a further increase in the inflammatory response. Thus, this section discusses the evidence for markers of systemic inflammation and oxidative stress following short-term $PM_{10-2.5}$ exposures.

In the previous review, one CHE study reported no change in plasma CRP following short-term $PM_{10-2.5}$ exposure. Since the last review, a few additional studies have examined this relationship and the results of these studies have largely been inconsistent. That being said, given the transient nature of markers of systemic inflammation (e.g., cytokine release) and the differences in methodological approaches across studies, this is to be expected.

6.3.10.1 Epidemiologic Panel Studies of Systemic Inflammation and Oxidative Stress

Wittkopp et al. (2013) and Huttunen et al. (2012) have recently published studies examining the relationship between $PM_{10-2.5}$ and biomarkers of inflammation and oxidative stress. Both studies included repeated measures in panels of older adults with pre-existing cardiovascular disease and reported that 1- to 5-day averages of $PM_{10-2.5}$ or 1- to 3-day lags of $PM_{10-2.5}$ were not associated with a number of biomarkers including CRP, IL12, IL8, IL6sR, and sTNFRII. While Wittkopp et al. (2013) conducted size-fractionated, residential monitoring for $PM_{10-2.5}$ at retirement communities where participants lived, Huttunen et al. (2012) used the difference method to estimate $PM_{10-2.5}$ from differentially located monitors, contributing to greater uncertainty in exposure measurement.

6.3.10.2 Controlled Human Exposure Studies of Systemic Inflammation and Oxidative Stress

Controlled human exposure studies from the 2009 PM ISA (U.S. EPA, 2009) examining systemic inflammation reported no change in plasma CRP levels following exposure to $PM_{10-2.5}$ CAPs with exercise (Graff et al., 2009).

A few recent CHE studies examined the potential for short-term exposure to $PM_{10-2.5}$ CAP to induce a variety of inflammatory markers such as white blood cells, cytokines, adhesion molecules, or blood markers of inflammation such as CRP. A couple of these studies did not find an association between $PM_{10-2.5}$ and the markers or inflammatory cells they examined (Liu et al., 2015a; Brook et al., 2013a). However, Behbod et al. (2013) reported increased leukocytes and neutrophils at 24 hours, but not 3-hours post exposure to urban $PM_{10-2.5}$ ($p < 0.05$). They also reported that increases in accompanying ambient endotoxin were associated with the increases in leukocytes. However, no changes in the inflammatory markers IL-6, or hs-CRP were reported.

In a different type of study, Maiseyeu et al. (2014) looked at the potential for exposure to $PM_{10-2.5}$ to result in increased inflammation and decreased anti-oxidant activity by impairing high density lipoprotein (HDL) function. Indeed, HDL plays an important role in vascular homeostasis through anti-inflammatory and anti-oxidant activities (Maiseyeu et al., 2014). Exposure to coarse CAP did not impair HDL function. Additional information on lipoproteins and lipedema can be found in the Metabolic Effects Chapter (CHAPTER 7).

Considered together, there is limited evidence that exposure to $PM_{10-2.5}$ may result in systemic inflammation. However, it should be noted that due to the transient nature of some of the inflammatory biomarkers analyzed, it is possible that different results would have been reported if samples had been analyzed at different time points.

With respect to oxidative stress, a single study since the 2009 PM ISA has addressed systemic oxidative stress after exposure to coarse PM. Liu et al. (2015a) studied the potential for exposure to $PM_{10-2.5}$ and endotoxin to change levels of biomarkers for lipid peroxidation (malondialdehyde [MDA]) or DNA oxidative damage (8-OHdG). Short-term exposure to $PM_{10-2.5}$ was not associated with levels of MDA in blood or in urine. However, exposure to $PM_{10-2.5}$ was associated with 8-OHdG levels in urine 1-hour post exposure. It was further noted that endotoxin present in the coarse fraction was also associated with 8-OHdG levels. Thus, there is limited evidence that short-term exposure to $PM_{10-2.5}$ and/or endotoxin can alter markers of oxidative stress. More information on studies published since the 2009 ISA can be found in Table 6-60 below.

Table 6-60 Study-specific details from CHE studies of short-term $PM_{10-2.5}$ exposure and inflammation and oxidative stress.

Study	Population N, Sex; Age Mean ± SD	Exposure Details (Concentration; Duration)	Endpoints Examined
Behbod et al. (2013)	Healthy adults N = 19 M; 16 F 18-60 yrs	~250 µg/m^3 fine CAP (0.1 to 2.5 microns) ~200 µg/m^3 course CAP (2.5 to 10 microns) For 130 min CAP from busy Toronto street Correlated effects with presence of endotoxin	Inflammatory cells and markers ~45 pre and 3h and 24 h after start of each exposure
(Brook et al., 2013a)	Healthy adults n = 16 M, 16 F; 18-50 yrs 25.9 ± 6.6,	76.2 ± 51.5 µg/m^3 $PM_{10-2.5}$ for 2 h CAPs from rural Dexter, MI	Inflammatory cells and markers of inflammation, circulating endothelial progenitor cells collected 2 and 20 h post
Liu et al. (2015a)	Healthy adults n = 50; 18-60 yrs 28 ± 9	238.4 ± 62.0 µg/m^3 fine cap 212.9 ± 52µg/m^3 course cap 135.8 ± 67.2 µg/m^3 ultrafine cap for 130 min individually	Inflammatory markers and Oxidative stress markers pre, 1 h, and 21 h post
Maiseyeu et al. (2014)	Healthy adults n = 16 M, 16 F; 18-46 yrs 25.9 ± 6.6	76.2 ± 51.5 µg/m3 $PM_{10-2.5}$ CAP for 2 h CAP from rural Dexter, MI	HDL lipoprotein function: post, 20 h post

Note: SD = standard deviation, M = male, F = female, n = number, h = hour, CAP = concentrated ambient particle, HDL = high density lipoproteins

6.3.11 Coagulation

Coagulation refers to the process by which blood changes from a liquid to a semi-solid state in order to form a clot. Increases in coagulation factors (e.g., fibrinogen) or decreases in anti-coagulation factors can promote clot formation, and thus, increase the potential for an embolism.

In the last review, there was limited and inconsistent evidence for coagulation following $PM_{10-2.5}$ exposure. Since the 2009 PM ISA, no new CHE studies have been published. However, there is limited evidence for coagulation following short-term $PM_{10-2.5}$ exposure across a few epidemiologic panel studies.

6.3.11.1 Panel Epidemiologic Studies of Coagulation

Overall, there is limited evidence examining associations between $PM_{10-2.5}$ and markers of coagulation in panel epidemiologic studies. There were no studies evaluated in the 2009 PM ISA, though there are some recently published studies. In a quasi-experimental study of 31 healthy volunteers in Utrecht assigned to different exposure locations, $PM_{10-2.5}$ was associated with a .22% increase in vWF (95% CI: 0.02, 0.41; per 13.50 μg/m^3) but not fibrinogen or platelet counts (Strak et al., 2013a). Another study examined associations between $PM_{10-2.5}$ in a panel of 52 older adult participants with ischemic heart disease and found positive associations between fibrinogen levels and 1-day lag of ambient $PM_{2.5}$-10 (Huttunen et al., 2012). Null associations were observed between short-term exposures to $PM_{10-2.5}$ and an array of circulating markers of coagulation among people with diabetes and short-term exposure to $PM_{10-2.5}$. Wang et al. (2015). These recently published studies all used $PM_{10-2.5}$ concentrations derived from the subtraction method, contributing to exposure measurement error.

6.3.11.2 Controlled Human Exposure Studies of Coagulation and Thrombosis

Thrombosis was discussed in one study from the 2009 PM ISA. Graff et al. (2009) reported a ~33% decrease in the clot dissolving protein tPA 20 hours post exposure per 10 μg/m^3 increase in $PM_{10-2.5}$ concentration (p = 0.01). However, levels of other clotting related proteins were unchanged in response to $PM_{10-2.5}$ exposure. Since the publication of the 2009 PM ISA, no additional CHE studies have examined the relationship between $PM_{10-2.5}$ exposure and coagulation or thrombosis.

6.3.12 Endothelial Dysfunction and Arterial Stiffness

Endothelial dysfunction is the physiological impairment of the inner lining of the blood vessels and is typically measured by FMD. Arterial stiffness is associated with a variety of cardiovascular risk

factors and outcomes (Laurent et al., 2006) and is best measured by pulse wave velocity (PWV). Both endothelial dysfunction and arterial stiffness are discussed in more detail in Section 6.1.13.

There were no studies from the 2009 PM ISA evaluating the relationship between short-term exposure to $PM_{10-2.5}$ and endothelial dysfunction or arterial stiffness. Since that document, CHE studies have examined measures of endothelial dysfunction following $PM_{10-2.5}$ exposure and found limited evidence of an effect only when evaluating biomarkers (i.e., no statistically significant effect was found on FMD). There was also no new evidence of arterial stiffness in recent studies examining the endpoint.

6.3.12.1 Controlled Human Exposure Studies of Impaired Vascular Function

In the current review there were studies that examined the relationship between short-term exposure to $PM_{10-2.5}$ and clinical measures of endothelial dysfunction, but no relationship was found (Byrd et al., 2016; Brook et al., 2014). In addition to these studies, there were a couple of CHE studies that examined biomarkers indicating the potential for endothelial dysfunction following short-term $PM_{10-2.5}$ exposure. Liu et al. (2015a) reported that exposure to $PM_{10-2.5}$ alone did not result in statistically significant increases in VEGF at 1-hour post-exposure in blood or urine. There were also no changes in blood for the biomarker ET-1. In an additional study, Brook et al. (2013a) reported an increase ($p = 0.008$) in endothelial progenitor cells (a potential indicator of vascular injury) at 20 hours relative to filtered air, but changes in neutrophils, lymphocytes, and VEGF levels at this time point were not statistically significant. Taken together there is limited evidence for an increase in biomarkers consistent with vascular dysfunction. However, in the studies that examined measures of dilation, no relationship was found. Thus, the relationship between endothelial dysfunction and short-term exposure to $PM_{10-2.5}$ remains uncertain.

Since the publication of the 2009 PM ISA, studies have examined whether $PM_{10-2.5}$ had appreciable effects on measures of arterial stiffness, but results were generally negative. More specifically, Byrd et al. (2016) found no changes in pulse wave velocity or the Aix. In addition, Brook et al. (2014) reported that exposure to rural coarse CAP resulted in no change in pulse wave velocity. More information on studies published since the 2009 ISA can be found in Table 6-61 below.

Table 6-61 Study-specific details from controlled human exposure (CHE) studies of short-term $PM_{10-2.5}$ exposure and impaired vascular function.

Study	Population N, Sex; Age Mean ± SD	Exposure Details Concentration; Duration	Endpoints Examined
Byrd et al. (2016)	Healthy adults 20 M, 9 F; 18-50 yrs 30 ± 8.2,	164.2 ± 80.4 µg/m^3 $PM_{10-2.5}$ CAPs for 2 h CAP from urban Dearborn, MI	Pulse wave analysis, pulse wave velocity, and pulse pressure: post, 2 h post
(Brook et al., 2013a)	Healthy adults n = 16 M, 16 F; 18-50 yrs 25.9 ± 6.6,	76.2 ± 51.5 µg/m^3 $PM_{10-2.5}$ for 2 h CAPs from rural Dexter, MI	VEGF and markers and circulating Endothelial progenitor cells from blood collected 2 and 20 h post
Brook et al. (2014)	Healthy adults n = 16 M, 16 F; 18-46 yrs 25.9 ± 6.6,	76.2 ± 51.5 µg/m^3 $PM_{10-2.5}$ for 2 h CAPs from rural Dexter, MI	Flow mediated dilation: post, and 2h post
Liu et al. (2015a)	Healthy adults n = 50; 18-60 yrs 28 ± 9	212.9 ± 52µg/m^3 $PM_{10-2.5}$ for 130 min	VEGF: 1 h and 21 h post

Note: SD = standard deviation, M = male, F = female, n = number, h = hour, CAP = concentrated ambient particle, VEGF = vascular endothelial growth factor

6.3.13 Summary and Causality Determination

The 2009 PM ISA found that the available evidence for short-term $PM_{10-2.5}$ exposure and cardiovascular effects was "suggestive of a causal relationship." This conclusion was based primarily on several epidemiologic studies reporting positive associations between short-term $PM_{10-2.5}$ exposure and cardiovascular effects including IHD hospitalizations, supraventricular ectopy, and changes in HRV. In addition, dust storm events resulting in high concentrations of crustal material were linked to increases in cardiovascular disease ED visits and hospital admissions. However, the 2009 PM ISA noted concerns with respect to the potential for exposure measurement error and copollutant confounding in these epidemiologic studies. In addition, there was limited evidence of cardiovascular effects from a small number of experimental studies that examined short-term $PM_{10-2.5}$ exposures. Thus, in the last review, key uncertainties included the potential for exposure measurement error, copollutant confounding, and limited evidence of biological plausibility for cardiovascular effects following inhalation exposure.

The evidence relating short-term $PM_{10-2.5}$ exposure and cardiovascular outcomes has expanded since the last review and now includes additional epidemiologic studies reporting positive associations with IHD, HA, and arrhythmia. However, key uncertainties related to copollutant confounding and exposure measurement error remain. In addition, uncertainties remain with respect to the biological plausibility of ED visits and hospital admissions for IHD and arrhythmia. Thus, when considered as a whole, the epidemiologic, CHE and animal toxicological evidence continues to be suggestive but not sufficient to infer a causal relationship between short-term $PM_{10-2.5}$ exposure and cardiovascular effects. The evidence supporting this determination of causality is discussed below and summarized in Table 6-62, using the framework for causality determination described in the Preamble to the ISAs (U.S. EPA, 2015).

Studies published since the 2009 PM ISA provide additional evidence of an association between short-term exposure to $PM_{10-2.5}$ and ED visits and/or hospital admissions for IHD. In the MCAPS study, $PM_{10-2.5}$ concentrations were associated with an increase in hospital admissions for IHD on the same day (Powell et al., 2015) and the association was unchanged in copollutant models adjusting for $PM_{2.5}$. Qiu et al. (2013) also observed a positive association, which persisted but lost precision after adjustment for $PM_{2.5}$. In Kaohsiung, Taiwan, Chen et al. (2015b) considered nearly 23,000 hospital admissions for IHD and reported positive associations on cool and warm days. The observed associations were generally robust to adjustment for NO_2, SO_2, CO, and O_3 in copollutant models. Thus, there are a few studies using copollutant models that suggest an independent effect of $PM_{10-2.5}$ on IHD-related HA. However, uncertainties with respect to copollutant confounding remain due to the overall evidence base for an independent effect of $PM_{10-2.5}$ being quite limited.

There are also a limited number of studies providing evidence of an associations between short-term exposure to $PM_{10-2.5}$ and ED visits and hospital admissions for arrhythmia (Section 6.3.4). However, appreciable uncertainties in these results remain given that none of these studies examined the potential for copollutant confounding with other size fractions of PM, and gaseous copollutant results are from a small number of studies conducted in Asia. It is also important to note that the approaches used to estimate $PM_{10-2.5}$ concentrations vary across the epidemiologic studies mentioned above (both for arrhythmia and IHD). Methods include using the difference of county-level averages of PM_{10} and $PM_{2.5}$ and the difference of PM_{10} and $PM_{2.5}$ measured at co-located monitors. It remains unclear how exposure measurement error might be impacted by each of these approaches.

A small number of CHE, epidemiologic panel, and animal toxicological studies provides some biological plausibility for a sequence of events that could potentially lead to $PM_{10-2.5}$-related ED visit and hospital admissions (Section 6.3.1). However, the evidence supporting most of the individual events in these pathways is quite limited and some of the epidemiologic panel studies used to support these pathways have the same measurement error uncertainties mentioned above. Also, when the evidence is evaluated as a whole, with the exception of small reproducible changes in BP (Section 6.3.6), the results of experimental and epidemiologic panel studies are largely inconsistent, or only provided limited

evidence of a relationship between cardiovascular endpoints and short-term $PM_{10-2.5}$ exposure. Thus, while there is more evidence for biological plausibility than in the 2009 PM ISA, this body of evidence is still quite limited and important uncertainties remain.

In summary, there were a small number of epidemiologic studies reporting positive associations between short-term exposure to $PM_{10-2.5}$ and cardiovascular-related ED visits and HA. However, there was limited evidence to suggest that these associations were biologically plausible, or independent of copollutant confounding. It also remains unclear how the approaches used to estimate $PM_{10-2.5}$ concentrations in epidemiologic studies may impact exposure measurement error. Taken together, the **evidence is suggestive of, but not sufficient to infer, a causal relationship between short-term $PM_{10-2.5}$ exposures and cardiovascular effects.**

Table 6-62 Summary of evidence that is suggestive of, but not sufficient to infer, a causal relationship between short-term $PM_{10-2.5}$ exposure and cardiovascular effects.

Rationale for Causal Determination[a]	Key Evidence[b]	Key References[b]	$PM_{10-2.5}$ Concentrations Associated with Effects[c]
Evidence from multiple epidemiologic studies is generally supportive but not entirely consistent	Increases in ED visits and hospital admissions for IHD in multicity studies Increases in cardiovascular mortality in multicity studies conducted in the U.S., Europe, and Asia.	Powell et al. (2015); Section 6.3.2 Section 6.3.8	12.8 µg/m^3
Generally, consistent evidence from CHE studies	Small consistent changes in blood pressure	Section 6.3.6.2	~75.2-200 µg/m^3
Limited and supportive evidence from panel, controlled human exposure, and toxicological studies	Limited evidence for changes in HRV, systemic inflammation, coagulation factors, vascular function	Section 6.3.9 Section 6.3.10 Section 6.3.11 Section 6.3.12	See Tables in identified sections

Table 6-62 (Continued): Summary of evidence that is suggestive of, but not sufficient to infer, a causal relationship between short-term $PM_{10-2.5}$ exposure and cardiovascular effects.

Rationale for Causal Determination[a]	Key Evidence[b]	Key References[b]	$PM_{10-2.5}$ Concentrations Associated with Effects[c]
Epidemiologic evidence from copollutant models provides some support for an independent $PM_{10-2.5}$ association	$PM_{10-2.5}$ associations are generally robust, but there are some instances of attenuation in copollutant models with gaseous pollutants and $PM_{2.5}$. However, there is limited information on the correlation between $PM_{10-2.5}$ and gaseous pollutants complicating the interpretation of results. Copollutant analyses with cardiovascular mortality are limited to studies conducted in Europe and Asia and indicate that $PM_{10-2.5}$ associations generally remain positive, although attenuated in some instances. When reported, correlations with gaseous copollutants were primarily in the low (r < 0.4) to moderate (r ≥ 0.4 or < 0.7) range.	Powell et al. (2015); Qiu et al. (2013); Chen et al. (2015b) Figure 6-31	
Uncertainty regarding exposure measurement error	Across studies $PM_{10-2.5}$ concentrations are measured using a number of approaches (i.e., directly measured from dichotomous sampler, different between PM_{10} and $PM_{2.5}$ at collocated monitors, and difference of area-wide concentrations of PM_{10} and $PM_{2.5}$), which have not been compared in terms of whether they have similar spatial and temporal correlations.		
Limited evidence for biological plausibility of cardiovascular effects	Studies for a given health endpoint are largely inconsistent, or only provide limited evidence of a relationship between cardiovascular endpoints and $PM_{10-2.5}$ exposure. Some epidemiologic panel studies are also subject to the exposure measurement error discussed in this section.	Section 6.3.1 Figure 6-30

b = Describes the key evidence and references, supporting or contradicting, contributing most heavily to causal determination and, where applicable, to uncertainties or inconsistencies. References to earlier sections indicate where full body of evidence is described.

c = Describes the $PM_{2.5}$ concentrations with which the evidence is substantiated.

6.4 Long-Term $PM_{10-2.5}$ Exposure and Cardiovascular Effects

The evidence relating to the long-term effects of exposure to $PM_{10-2.5}$ on the cardiovascular system was characterized as "inadequate to infer the presence or absence of a causal relationship" in the 2009 PM ISA (U.S. EPA, 2009). A cause specific mortality study found a positive association with CHD

mortality among women enrolled in AHSMOG while another study of women (WHI) reported no association between $PM_{10-2.5}$ and cardiovascular events. Experimental studies demonstrating a direct effect of $PM_{10-2.5}$ on the cardiovascular system were lacking.

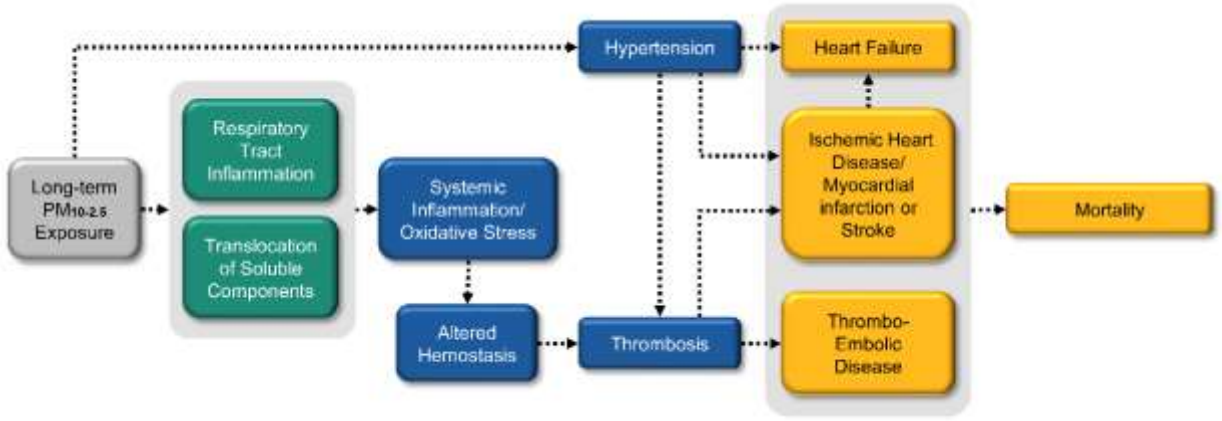
Evidence published since the completion of the 2009 PM ISA is also suggestive of a causal relationship between long-term exposures to $PM_{10-2.5}$ and cardiovascular effects. Since the publication of the 2009 PM ISA, the epidemiologic literature has grown and evidence is currently available on the relationship between exposure to long-term $PM_{10-2.5}$ and cardiovascular outcomes including MI and stroke, blood pressure and atherosclerosis. However, the overall epidemiologic evidence base is limited and uncertainties remain with respect to the potential for co-pollutant confounding. In addition, there continues to be a lack of toxicological evidence to support the associations reported in epidemiologic studies.

The subsections below provide an evaluation of the most policy relevant scientific evidence relating-long-tern $PM_{10-2.5}$ exposure to cardiovascular health effects. To clearly characterize and put this evidence into context, there is first a discussion of the biological plausibility of cardiovascular effects following long-tern $PM_{10-2.5}$ exposure (Section 6.4.1). Following this discussion, the health evidence relating long-tern $PM_{10-2.5}$ exposure and specific cardiovascular health outcomes is discussed in detail: ischemic heart disease and myocardial infarction (Section 6.4.2), heart failure and impaired heart function (Section 6.4.3), cerebral vascular disease and stroke (Section 6.4.4) atherosclerosis (Section 6.4.5), blood pressure and hypertension (Section 6.4.6), peripheral vascular disease (PVD), venous thromboembolism and pulmonary embolisms (Section 0) and cardiovascular-related mortality (Section 6.4.8). The evidence for an effect of $PM_{10-2.5}$ exposure on systemic inflammation and oxidative stress is also discussed (Section 6.4.9). Finally, the collective body of evidence is integrated across and within scientific disciplines[65], and the rationale for the causality determination is outlined in Section 6.4.10.

6.4.1 Biological Plausibility

This subsection describes the biological pathways that potentially underlie cardiovascular health effects resulting from long-term inhalation exposure to $PM_{10-2.5}$. Figure 6-33 graphically depicts these proposed pathways as a continuum of pathophysiological responses- connected by arrows- that may ultimately lead to the apical cardiovascular events observed in epidemiologic studies. This discussion of "how" long-term exposure to $PM_{10-2.5}$ may lead to these cardiovascular events also provides some biological plausibility for the epidemiologic results reported later in Section 6.4. In addition, most studies cited in this subsection are discussed in greater detail throughout Section 6.4.

[65] As detailed in the Preface, risk estimates are for a 5 $\mu g/m^3$ increase in annual $PM_{10-2.5}$ concentrations unless otherwise noted.



Note: the boxes above represent the effects for which there is experimental or epidemiologic evidence, and the dotted arrows indicate a proposed relationship between those effects. Shading around multiple boxes denotes relationships between groups of upstream and downstream effects. Progression of effects is depicted from left to right and color coded (grey, exposure; green, initial event; blue, intermediate event; orange, apical event). Here, apical events generally reflect results of epidemiologic studies, which often observe effects at the population level. Epidemiologic evidence may also contribute to upstream boxes. When there are gaps in the evidence, there are complementary gaps in the figure and the accompanying text below.

Figure 6-33 Potential biological pathways for cardiovascular effects following long-term exposure to $PM_{10-2.5}$.

When considering the available health evidence, there is a plausible pathway connecting long-term exposure to $PM_{10-2.5}$ to the apical events reported in epidemiologic studies (Figure 6-33). This pathway is described below and generally begins as respiratory tract inflammation leading to systemic inflammation.[66]

Long-term inhalation exposure to $PM_{10-2.5}$ may result in respiratory tract inflammation and oxidative stress (CHAPTER 5). Inflammatory mediators such as cytokines produced in the respiratory tract can potentially enter the circulatory system where they may cause distal pathophysiological responses such as changes in hemostasis (see Section 6.1.1). Thus, it noteworthy that following long-term exposure to $PM_{10-2.5}$, there is limited evidence from an epidemiologic study for systemic inflammation (Lanki et al., 2015) and altered hemostasis (Lanki et al., 2015). Therefore, thrombosis could conceivably occur, potentially contributing to the development of IHD, stroke, or thromboembolic disease elsewhere in the body (as previously described in Section 6.1.1). There is also evidence from epidemiologic studies that long-term exposure to $PM_{10-2.5}$ is associated with elevated blood pressure/hypertension risk (Chen et al., 2015a; Mu et al., 2014). Hypertension may also result in pathways that can contribute to the development of IHD, HF, stroke, or thromboembolic disease elsewhere in the body (as previously described in Section 6.1.1).

[66] It is also possible that soluble particle components can translocate directly into the circulatory system (Chapter 4) and lead to systemic inflammation, although the extent to which particle translocation occurs remains unclear.

Taken together, there is a small amount of evidence connecting long-term $PM_{10-2.5}$ exposure to cardiovascular health effects. That said, gaps in the proposed pathway exist. For example, there is a lack of evidence for how long-term $PM_{10-2.5}$ exposure may result in hypertension. Thus, there is only limited biological plausibility for the apical results reported in epidemiologic studies following long-term $PM_{10-2.5}$ exposure. This information will be used to inform a causal determination, which is discussed later in the chapter (Section 6.4.10).

6.4.2 Ischemic Heart Disease and Myocardial Infarction

Ischemic heart disease (IHD) is typically caused by atherosclerosis, which can result in the blockage of the coronary arteries and restriction of blood flow to the heart muscle potentially leading myocardial infarction (MI) or heart attack (Section 6.2.2). The evidence relating to the effect of $PM_{10-2.5}$ on the cardiovascular system included in the 2009 PM ISA was limited to a study of post-menopausal women enrolled in the WHI. The primary objective of this study (Miller et al., 2007) was to examine the cardiovascular health effects of long-term exposure to $PM_{2.5}$; however, results for $PM_{10-2.5}$ were also reported. No association between $PM_{10-2.5}$ and cardiovascular events was observed [HR: 0.99 (95%CI: 0.95, 1.03)]. Since the completion of the 2009 PM ISA, several epidemiologic studies reporting associations with $PM_{10-2.5}$, including some with comparable female populations, have been published. Among the limited number of studies currently available, positive associations were not consistently observed (Table 6-63, Figure 6-34).

Table 6-63 Characteristics of the studies examining the association between long-term $PM_{10-2.5}$ exposures and ischemic heart disease.

Study	Study Population	Exposure Assessment	Concentration µg/m³	Outcome	Copollutants Examined

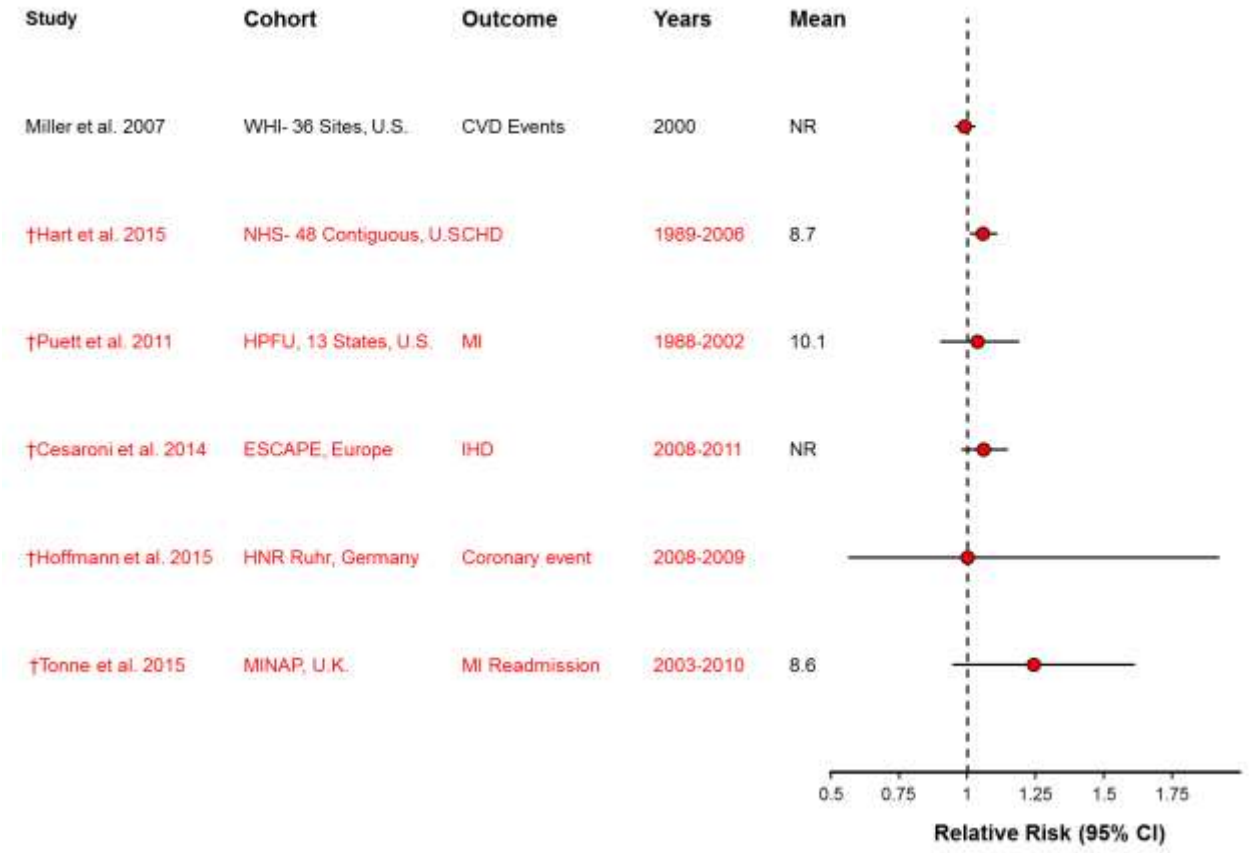
1

Hart et al. (2015b) examined data from the NHS, a cohort of women, 30-55 years old at enrollment, and observed positive associations of $PM_{10-2.5}$ with CHD [HR: 1.06 (95% CI: 1.01, 1.11)] Associations were less precise and somewhat attenuated in a sensitivity analysis restricted to exposure data that were relatively complete. Associations between $PM_{10-2.5}$ and CHD [HR: 1.07 (95%CI: 1.00, 1.14) vs. 0.96 (95%CI: 0.92, 1.0)] were present among women with diabetes, respectively. Effect modification by diabetes did not persist for CHD when analyses were restricted to the years with relatively complete exposure data. Larger associations of $PM_{10-2.5}$ with CHD were observed in the northeast compared to other regions. In a study of male health professionals Puett et al. (2011), a small increased risk for nonfatal MI was observed [HR: 1.04 (95%CI: 0.90, 1.19)]. There was no association after adjustment for $PM_{2.5}$, however [HR: 1.00 (95%CI: 0.85, 1.18)].

Cesaroni et al. (2014) reported an increased risk for the association between $PM_{10-2.5}$ and IHD [HR: 1.06 (0.98, 1.15)] in their meta-analysis of the 11 cohorts in the ESCAPE project. Heterogeneity in the effect estimates was observed across cohorts. In a separate analysis of one of the ESCAPE cohorts, Hoffmann et al. (2015) reported an inverse association of $PM_{10-2.5}$ exposure with coronary events [HR: 0.78 (95%CI: 0.33, 1.82)] in fully adjusted models that considered covariates including noise. Tonne et al. (2015) reported an association between $PM_{10-2.5}$ and readmission for MI in the MINAP study in the U.K. [HR: 1.24 (95%CI: 0.95, 1.61)].



†Studies published since the 2009 Integrated Science Assessment for Particulate Matter.

Figure 6-34 Associations between long-term exposure to $PM_{10-2.5}$ and ischemic heart disease. Associations are presented per 5 $\mu g/m^3$ increase in pollutant concentration.

6.4.3 Heart Failure and Impaired Heart Function

There were no studies of the effect of long-term exposure to $PM_{10-2.5}$ on heart failure or impaired heart function in the 2009 PM ISA (U.S. EPA, 2009).

6.4.3.1 Epidemiologic Studies

The E/E ratio is the ratio of peak early diastolic filling velocity to peak early diastolic mitral annulus velocity and a value less than eight indicates normal diastolic function and left atrial volume index (LAVI) is an indicator of diastolic function severity (Section 6.3.5). D'Souza et al. (2017) reported small imprecise increases in RV mass overall [0.91 g (95%CI: -2.95, 5.00] but larger increases were found among current smokers [2.05 g (95%CI: 0.23, 3.86] and those with emphysema [3.18 g [95%CI: 0.91, 5.68]. Ohlwein et al. (2016) conducted a cross-sectional analysis of the SALIA cohort to determine the association of long-term $PM_{10-2.5}$ with these two metrics. The mean ratios comparing 3rd to the 1st quartile of exposure for $PM_{10-2.5}$ were 1.03 (95%CI: 0.89, 1.18) for E/E and 1.06 (95%CI: 0.92, 1.21) for LAVI.

6.4.3.2 Toxicology Studies of Impaired Heart Function

In the 2009 PM ISA there was one study (Lemos et al., 2006) that reported heart muscle hypertrophy for Balb/c mice exposed to PM_{10} for 4 months. Since the 2009 PM ISA, Aztatzi-Aguilar et al. (2015) reported that short-term $PM_{10-2.5}$ exposure in rats resulted in thickening of the coronary artery wall ($p < 0.05$). However, the authors did not report increases in expression of two genes typically associated with cardiac damage: Acta1 and Col3a. Nonetheless, there is limited evidence from animal toxicological studies for the potential for decreases in heart function following long-term $PM_{10-2.5}$ exposure. More information on this recently published study can be found in Table 6-65 below.

Table 6-65 Study specific details from toxicological studies of long-term $PM_{10-2.5}$ exposure and impaired heart function impaired heart function.

6.4.4 Cerebrovascular Disease and Stroke

Cerebrovascular disease typically includes conditions such as hemorrhagic stroke, cerebral infarction (i.e., ischemic stroke) and occlusion of the pre-cerebral and cerebral arteries (Section 6.3.35). Only the WHI analysis reporting a positive association with stroke was available for inclusion in the 2009 PM ISA. Of the limited number of recent epidemiologic studies examining the relationship between $PM_{10-2.5}$ and stroke, there were some observations of positive associations (Table 6-66, Figure 6-35).

Table 6-66 Characteristics of the studies examining the association between long-term $PM_{10-2.5}$ exposures and stroke.

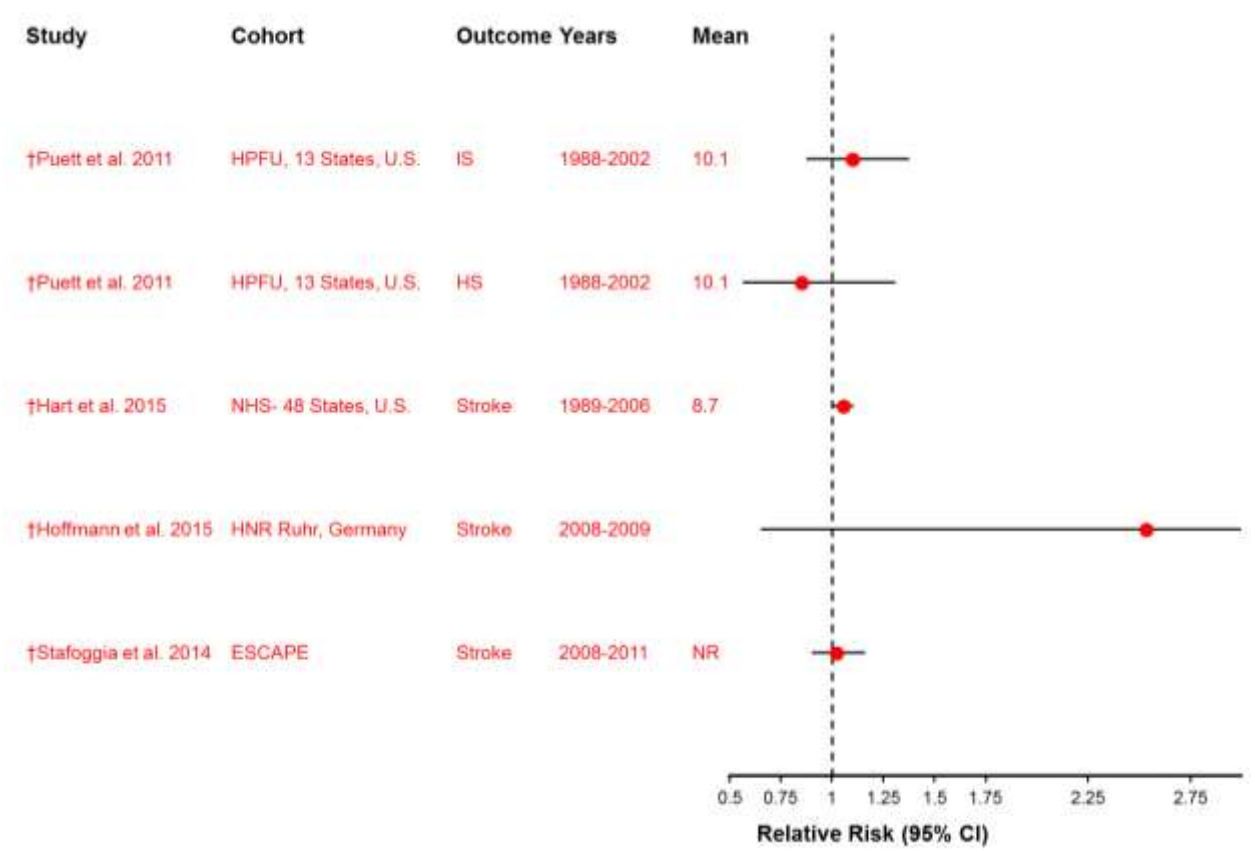
1

Hart et al. (2015b) examined data from women enrolled in the NHS and observed positive associations of $PM_{10-2.5}$ stroke [HR: 1.05 (95%CI: 1.00, 1.10)]. Larger associations between $PM_{10-2.5}$ and stroke [HR: 1.09 (95%CI: 1.00, 1.17)] were present among women with diabetes. Effect modification by diabetes persisted for stroke when analyses were restricted to the years with relatively complete exposure data. Larger associations of $PM_{10-2.5}$ with stroke were observed in the northeast compared to other regions, but not in the south. These strong associations in the northeast were even stronger in sensitivity analyses restricted to years with complete exposure data. Among male health professionals, Puett et al. (2011) reported an imprecise (n = 230 cases) increased risk for ischemic stroke [HR: 1.10 (95%CI: 0.88, 1.37and no association with hemorrhagic stroke [HR: 0.85 (95%CI: 0.56, 1.31)] in their basic model. A fully adjusted model that included comorbidities such as hypertension and diabetes returned similar results. The association between $PM_{10-2.5}$ and ischemic stroke strengthened after adjustment for $PM_{2.5}$ [HR: 1.31 (95%CI: 0.99, 1.72)]. Confidence intervals were wide due to small case numbers (N = 230 ischemic strokes), however.

No association of $PM_{10-2.5}$ was observed on incident stroke in the 11-cohort European Escape study [HR: 1.02 (95%CI: 0.90, 1.16)] (Stafoggia et al., 2014), although a separate analysis of one of the included cohorts (HNR) indicated a potential relationship between $PM_{10-2.5}$ and incident stroke. Although confidence intervals were wide Hoffmann et al. (2015), reported a strong positive association in this study [HR: 2.53 (95%CI: 0.65, 9.84)].

As shown in Figure 6-35, associations between $PM_{10-2.5}$ were not consistently observed in epidemiological of coronary events, CHD or stroke. Overall, the number of studies is limited and model performance is generally lower than the model performance for $PM_{2.5}$.



†Studies published since the 2009 Integrated Science Assessment for Particulate Matter.

Circles represent point estimates; horizontal lines represent 95% confidence intervals for $PM_{2.5}$. Black text and circles represent evidence included in the 2009 PM ISA; red text and circles represent recent evidence not considered in previous ISAs or AQCDs. Mean concentrations in $\mu g/m^3$. Hazard Ratios are standardized to a 5- $\mu g/m^3$ increase in $PM_{2.5}$ concentrations. Corresponding quantitative results are reported in Supplemental Table 6S-25 (U.S. EPA, 2018). HS = hemorrhagic Stroke, IS = Ischemic Stroke, HPFU = Health Professionals Follow-up Study, NHS = Nurses' Health Study, NHR = Heinz Nixdorf Recall, ESCAPE = European Study of Air Pollution Exposure.

Figure 6-35 Associations between long-term exposure to $PM_{10-2.5}$ and stroke. Associations are presented per 5 $\mu g/m^3$ increase in pollutant concentration.

6.4.5 Atherosclerosis

Atherosclerosis is the process of plaque buildup into lesions on the walls of the coronary arteries that can lead to narrowing of the vessel, reduced blood flow to the heart and IHD. The development of atherosclerosis is dependent on the interplay between plasma lipoproteins, inflammation, endothelial activation, and polymorphonucelar leukocyte attraction to the endothelium, extravasation, and lipid uptake. Additional information on atherosclerosis can be found in Section 6.2.4.

Increased cIMT is an indicator of atherosclerosis. An inverse cross-sectional association between long-term exposure to $PM_{10-2.5}$ and cIMT was observed in the ESCAPE study [-0.28% difference (95%CI: -1.16, 0.61)] (Perez et al., 2015) (Table 6-67).

6.4.6 Blood Pressure and Hypertension

High blood pressure is typically defined as a systolic blood pressure above 140 mm hg or a diastolic blood pressure above 90 mm hg with the clinically relevant consequence of chronically high blood pressure defined as hypertension (Section 6.2.7). There were no studies of the effect of $PM_{10-2.5}$ on blood pressure, hypertension or related effects on the renal system reviewed in the 2009 PM ISA.

6.4.6.1 Epidemiologic Studies

A limited number studies examined the relationship between $PM_{10-2.5}$ and blood pressure or hypertension among adults. Fuks et al. (2014) reported null associations with use of blood pressure lowering medication [OR: 0.99 (95%CI: 0.93, 1.05)] and hypertension [OR: 1.00 (95%CI: 0.94, 1.06)] in the ESCAPE cohort. Both small (relative to the size of the confidence interval) decreases and small increases in SBP and DBP were also observed in ESCAPE providing little support for an effect on blood pressure. A study conducted in Taiwan where mean $PM_{10-2.5}$ concentration was 21.2 $\mu g/m^3$ showed no effect on SBP but reported elevated DBP and an increased risk of hypertension in association with $PM_{10-2.5}$ (Chen et al., 2015a).

6.4.6.2 Toxicology Studies of Changes in Blood Pressure (BP)

There were no studies in the 2009 PM ISA exploring the relationship between long-term inhalation exposure to $PM_{10-2.5}$ and changes in BP. Since the publication of that review, a toxicological study has reported no changes in mRNA levels of angiotensin or bradykinin related genes after long-term exposure to $PM_{10-2.5}$ (Aztatzi-Aguilar et al., 2015). However, the authors did report an increase in AT_1R protein levels following exposure ($p < 0.05$). Thus, there is limited evidence from this study that exposure to $PM_{10-2.5}$ may effect BP through changes in the renin-angiotensin system. More information on this recently published study can be found in Table 6-68 below.

Table 6-68 Study-specific details from toxicological studies of long-term $PM_{10-2.5}$ exposure and blood pressure (BP).

Study	Study Population	Exposure Details	Endpoints Examined

6.4.7 Peripheral Vascular Disease (PVD), Venous Thromboembolism, Pulmonary Embolism

2 Pulmonary emboli (PE) are common subtypes of venous thromboembolism (VTE)
3 (Section 6.3.8). Pun et al. (2015) reported a positive association between long-term exposure to $PM_{10-2.5}$
4 and PE [HR: 1.09 (95%CI: 1.00, 1.19)] (Table 6-69). The association was stronger with idiopathic PE,
5 i.e., cases for which there was no underlying medical condition. Although confidence intervals were
6 wider, these associations were not substantially attenuated after adjustment for $PM_{2.5}$.

Avg = average, IQR = interquartile range, N, n = number of subjects, NR = not reported, NHS = Nurses' Health Study, PE = pulmonary embolism.

6.4.8 Cardiovascular Mortality

7 In the 2009 PM ISA, there was limited evidence for an association between long-term $PM_{10-2.5}$
8 exposure and cardiovascular mortality for women, but not for men Chen et al. (2005). Several recent U.S.

cohort studies (Table 6-70) examined the association between long-term $PM_{10-2.5}$ exposure and cardiovascular mortality in occupational cohorts. Puett et al. (2009) examined the association between long-term $PM_{10-2.5}$ exposure and CHD mortality among a cohort of female nurses in the Nurses' Health Study from 13 states in the northeast and Midwest from 1992 through 2002. Spatio-temporal models were used to assign exposure to $PM_{2.5}$ and PM_{10} and the $PM_{10-2.5}$ concentrations were derived via subtraction. The authors observed positive associations with CHD mortality, though the associations were attenuated to below the null value in copollutant models that include $PM_{2.5}$. Using a design similar to that of the Nurses' Health Study, Puett et al. (2011) investigated the effect of long-term $PM_{10-2.5}$ (derived by subtraction of $PM_{2.5}$ from PM_{10}) exposure and mortality CHD among men enrolled in the Health Professionals cohort. Near null associations were observed for CHD mortality in this cohort.

A pooled-analysis of the European ESCAPE cohort combined data from 22 existing cohort studies and evaluated the association between long-term $PM_{10-2.5}$ exposure and cardiovascular mortality (Beelen et al., 2014). LUR models were used to assign exposure to $PM_{2.5}$ and PM_{10} and the $PM_{10-2.5}$ concentrations were derived via subtraction. The authors applied a common statistical protocol to data from each of the 22 cohorts, from 13 different European countries, in the first stage of the analysis and combined the cohort-specific effects in a second stage. The authors observed a near-null association between long-term $PM_{10-2.5}$ exposure and cardiovascular mortality (Beelen et al., 2014). The strongest association was observed for the subset of cardiovascular deaths attributable to cerebrovascular disease (HR: 1.17, 95% CI: 0.90, 1.52), though copollutant models with $PM_{2.5}$ were not reported for this comparison. Using the same exposure models used for the pooled cohort study, Dehbi et al. (2016) assigned $PM_{10-2.5}$ exposure to two British cohort studies that were pooled together to examine CVD mortality. The British cohorts included follow-up between 1989 and 2015, though $PM_{10-2.5}$ exposure estimates were available for 2010-2011. The authors observed a negative association when exposure was considered on the continuous scale, but positive associations for each quartile when exposure was categorized. However, the confidence intervals were wide and overlapping for all of the results, and the inconsistency may indicate generally null results, but instability in the model. In a separate European cohort, Bentayeb et al. (2015) used the CHIMERE chemical transport model to estimate PM_{10} and $PM_{2.5}$, and then subtracted to estimate long-term $PM_{10-2.5}$ exposure. The authors observed positive association with cardiovascular mortality.

While there are more studies available in this review that examine the association between long-term $PM_{10-2.5}$ exposure and cardiovascular mortality, the body of evidence remains limited, especially when compared to the body of evidence available for $PM_{2.5}$. In addition, to date all of the studies that have examined the relationship between long-term $PM_{10-2.5}$ exposure and mortality have used the difference method to derive concentrations for $PM_{10-2.5}$, contributing to the uncertainty associated with these effect estimates. Overall, there is no consistent pattern of associations for cardiovascular mortality (Table 11-8). In the instances where positive associations were observed for long-term $PM_{10-2.5}$ exposure and mortality, and $PM_{2.5}$ copollutant model results were reported, the $PM_{10-2.5}$ effect estimates were often attenuated but still positive after adjusting for $PM_{2.5}$.

6.4.9 Systemic Inflammation and Oxidative Stress

As discussed in Section 6.1.1 and Section 6.1.11, systemic inflammation and oxidative stress have been linked to a number of CVD related outcomes. Thus, this section discusses the evidence for markers of systemic inflammation and oxidative stress following long-term PM10-2.5 exposures.

6.4.9.1 Epidemiologic Studies

Increased levels of C-reactive protein (CRP) can indicate systemic inflammation (Section 6.3.12) and fibrinogen is a marker of coagulation (Section 6.3.13). (Lanki et al., 2015) provides little support for an association (% difference) between long-term exposure to $PM_{10-2.5}$ and CRP (3.0% [95%CI: -.7, 6.8]) or fibrinogen (1% [95%CI: -1.2, 0.9]).

6.4.9.2 Toxicology Studies

There were no studies in the 2009 PM ISA exploring the relationship between long-term inhalation exposure to $PM_{10-2.5}$ CAP and systemic inflammation/oxidative stress. Since the publication of the 2009 PM ISA, Aztatzi-Aguilar et al. (2015) reported that rats exposed to coarse PM had no change in IL-6 or HO-1 protein levels in the heart following long-term exposure to $PM_{10-2.5}$. More information on this recently published study can be found in Table 6-71 below.

Table 6-71 Study specific details from toxicological studies long-term $PM_{10-2.5}$ exposure and of systemic inflammation.

Study	Study Population	Exposure Details	Endpoints Examined
(Aztatzi-Aguilar et al., 2015)	Adult Sprague-Dawley rats, M, n = 4 per group	Inhalation of 32 µg/m^3 $PM_{10-2.5}$ for 5 h/day, 4 days/week, for 8 week	Markers of inflammation in heart tissue collected 24 h post-exposure

Note: n = number, M = male, h = hour, d = day, week = week

6.4.10 Summary and Causality Determination

In the 2009 PM ISA (U.S. EPA, 2009), the evidence describing the relationship between long-term exposure to $PM_{10-2.5}$ and cardiovascular effects was characterized as "inadequate to infer the presence or absence of a causal relationship." The limited number of epidemiologic studies reported contradictory results and animal toxicological evidence demonstrating an effect of $PM_{10-2.5}$ on the cardiovascular system was lacking. The literature base has expanded but remains limited although some

epidemiologic studies report positive associations of cardiovascular mortality and other outcomes with long-term exposure to $PM_{10-2.5}$. More recent evidence describing the relationship between long-term exposure to $PM_{10-2.5}$ and cardiovascular effects is discussed below and summarized in Table 6-72, using the framework for causality determinations described in the Preamble to the ISAs (U.S. EPA, 2015).

The evidence relating long-term exposure to $PM_{10-2.5}$ to cardiovascular mortality remains limited. Overall, there is no consistent pattern of associations for cardiovascular mortality (Table 6-70). In the instances where positive associations were observed for long-term $PM_{10-2.5}$ exposure and mortality, and $PM_{2.5}$ copollutant model results were reported, the $PM_{10-2.5}$ effect estimates were often attenuated but still positive after adjusting for $PM_{2.5}$. The epidemiologic studies examining the relationship between $PM_{10-2.5}$ and other cardiovascular outcomes including MI and stroke, atherosclerosis, VTE, and blood pressure has grown. Some studies report positive associations with these outcomes. Specifically, single pollutant associations of long-term exposure to $PM_{10-2.5}$ with IHD were observed in the NHS (Hart et al., 2015b), ESCAPE (Cesaroni et al., 2014), and MINAP (recurrent MI) (Tonne et al., 2015) while no association was observed in the HPFU after adjusting for $PM_{2.5}$ in copollutant models (Puett et al., 2011). After adjusting for noise, Hoffmann et al. (2015) reported an inverse association with IHD in the HNR study, which is one of the cohorts included in ESCAPE. Evidence of an association between long-term exposure to $PM_{10-2.5}$ and stroke was similarly inconsistent with a positive association observed in the NHS (Hart et al., 2015b) and little evidence of an effect in HPFU (Puett et al., 2011) or ESCAPE (Stafoggia et al., 2014). No evidence of an association with cIMT in the only available study, an ESCAPE meta-analysis, was reported(Perez et al., 2015). An association between long-term $PM_{2.5}$ exposure and pulmonary embolism was reported in the NHS (Pun et al., 2015). An inconsistent pattern of results relating to the effect of $PM_{10-2.5}$ on increased blood pressure and hypertension was reported in a limited number of studies (Chen et al., 2015a; Fuks et al., 2014). To date the studies that have examined the relationship between long-term $PM_{10-2.5}$ exposure and mortality have used the difference method to derive concentrations for $PM_{10-2.5}$, contributing to the uncertainty associated with these effect estimates.

The toxicological evidence related to long-term $PM_{10-2.5}$ exposures was overall lacking and represents a substantial data gap in the present collection of literature. There was a study demonstrating that short-term $PM_{10-2.5}$ exposure in rats resulted in thickening of the coronary artery wall (Section 6.4.3.2). The same study also reported limited evidence of altered protein expression related to renal function and blood pressure, (Section 6.4.6.2) and no evidence for changes in markers of systemic inflammation or oxidative stress (Section 6.4.9). In addition, as evidenced in Section 6.4.1, there are important gaps in biological plausibility in part, due to the overall lack of experimental evidence.

There are individual high-quality epidemiologic studies that report positive associations with cardiovascular morbidity and mortality outcomes, but the evidence in not entirely consistent. Associations are sometimes attenuated in copollutant models and there is uncertainty stemming from the use of the subtraction method to estimate exposure. Furthermore, evidence from experimental animal studies is of insufficient quantity to establish biological plausibility. Based largely on the observation of positive

associations in some high-quality epidemiologic studies, the **evidence is suggestive of, but not sufficient to infer, a causal relationship between long-term $PM_{10-2.5}$ exposure and cardiovascular effects.**

Table 6-72 Summary of evidence indicating that the evidence is suggestive of, but not sufficient to infer a causal relationship between long-term $PM_{10-2.5}$ exposure and cardiovascular effects.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{10-2.5}$ Concentrations Associated with Effects[c]
Some epidemiologic studies report positive associations at relevant concentrations	Positive associations between long-term $PM_{10-2.5}$ exposure and cardiovascular mortality in some studies; however, lack of consistency across studies. Some high-quality studies report associations with IHD, stroke, or pulmonary embolism	Section 6.5.138 (Hart et al., 2015b) Cesaroni et al. (2014) Tonne et al. (2015) Pun et al. (2015) Miller et al. (2007)	8.7 7.3-31 8.2-8.6
Uncertainty regarding exposure measurement error	Studies rely on subtraction method to estimate exposure to $PM_{10-2.5}$ adding uncertainty to the interpretation of effect estimates	Section 3.5	
Uncertainty regarding the independent effect of $PM_{10-2.5}$	Limited number of epidemiologic studies evaluate copollutant confounding Null association with IHD after adjustment for $PM_{2.5}$ in HPFU Inverse association with IHD in HNR study after adjustment for noise	Puett et al. (2011) Hoffmann et al. (2015)	
Limited evidence of coherence across lines of evidence	A study reporting some indications of impaired heart function, and potentially changes in BP. No changes in markers of inflammation or oxidative stress were reported	(Aztatzi-Aguilar et al., 2015)	~30 µg/m^3
Biological plausibility	Overall, biological plausibility is extremely limited with important gaps in the potential pathways identified in Section 6.4.1.		

$PM_{2.5}$ = particulate matter with a nominal aerodynamic diameter less than or equal to 2.5 µm; $PM_{10-2.5}$ = particulate matter with a nominal aerodynamic diameter less than or equal to 10 µm and greater than a nominal diameter of 2.5 µm

[a]Based on aspects considered in judgments of causality and weight of evidence in causal framework in Tables I and II of the Preamble.

[b]Describes the key evidence and references contributing most heavily to causal determination and, where applicable, to uncertainties or inconsistencies. References to earlier sections indicate where the full body of evidence is described.

[c]Describes the $PM_{10-2.5}$ concentrations with which the evidence is substantiated.

6.5 Short-Term UFP Exposure and Cardiovascular Effects

The 2009 ISA concluded the available evidence for short-term ultrafine particle (UFP) exposure and cardiovascular effects was "suggestive of a causal relationship." There was a relatively large body of evidence from controlled human exposure studies of fresh diesel exhaust (DE), which is typically dominated by UFPs, demonstrating effects of UFP on the cardiovascular system. In addition, cardiovascular effects were demonstrated by a limited number of laboratories in response to UF carbon black, urban traffic particles and CAPs. Responses included altered vasomotor function, increased systemic oxidative stress and HRV parameters. Studies using UF CAPs, as well as wood smoke and DE, provided some evidence of changes in markers of blood coagulation, but findings were not consistent. Toxicological studies conducted with UF TiO_2, CB, and DE demonstrated changes in vasomotor function as well as in HRV. Effects on systemic inflammation and blood coagulation were less consistent. PM-induced cardiac oxidative stress was noted following exposure to gasoline exhaust. Notably, the few epidemiologic studies of UFPs conducted did not provide strong support for an association of UFPs with effects on the cardiovascular system.

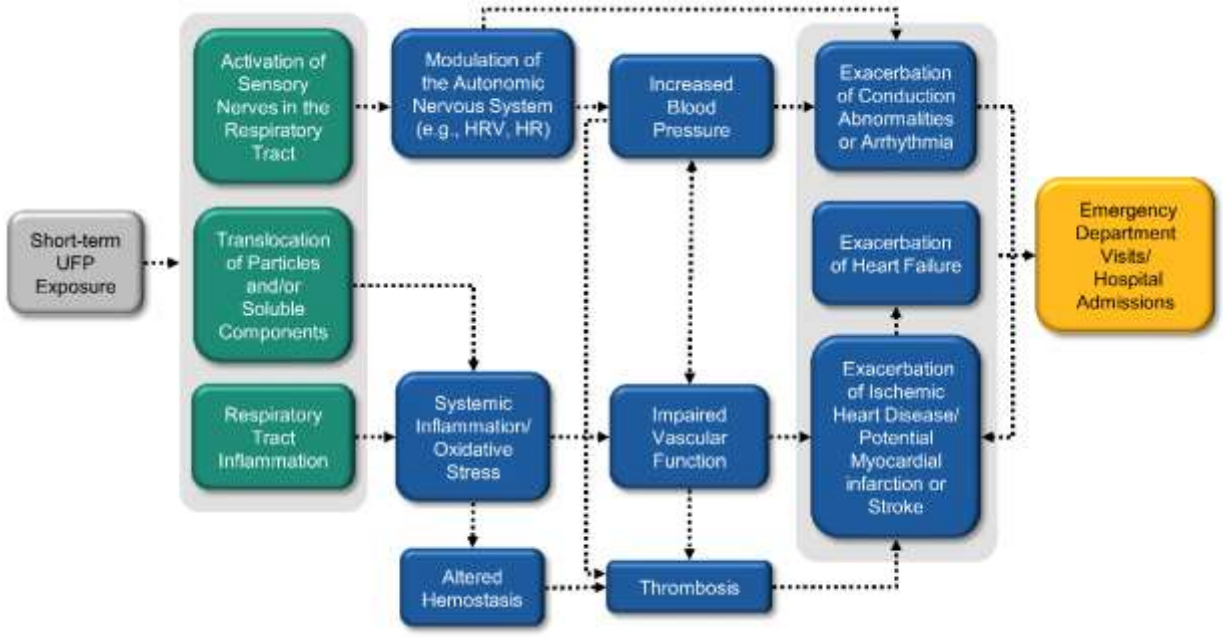
Recent evidence continues to be suggestive of a causal relationship between short-term exposures to UFPs and cardiovascular effects. Relatively speaking, the strongest evidence for cardiovascular-related effects following UFP exposure is for measures of HRV and coagulation. A small number of epidemiologic panel studies have reported associations between short-term exposure to UFPs and measures of HRV. This includes a well conducted epidemiologic panel study that found increases in SDNN with well-characterized 3 hour exposures. In addition, there was some evidence for positive associations between UFP exposure and markers of coagulation from epidemiologic panel studies, and evidence from a CHE study indicating decreases in the anticoagulant proteins plasminogen and thombomodulin in a subset of individuals with metabolic syndrome who express the GSTM1 null allele. In addition to changes in HRV and markers of coagulation, there was also limited evidence from CHE and epidemiologic panel studies for endothelial dysfunction, blood pressure, and systemic inflammation following UFP exposure.

The subsections below provide an evaluation of the most policy relevant scientific evidence relating-short-term UFP exposure to cardiovascular health effects. To clearly characterize and put this evidence into context, there is first a discussion of the biological plausibility of cardiovascular effects following short-term UFP exposure (Section 6.5.1). Following this discussion, the health evidence relating short-term UFP exposure and specific cardiovascular health outcomes is discussed in detail: ischemic heart disease and myocardial infarction (Section 6.5.2), heart failure and impaired heart function (Section 6.5.3) cardiac electrophysiology and arrhythmia (Section 6.5.4), cerebrovascular disease and stroke (Section 6.5.5), increased blood pressure and hypertension (Section 6.5.6), aggregated

cardiovascular outcomes (Section 6.5.7), and cardiovascular-related mortality (Section 6.5.8). The evidence for an effect of UFP exposures on endpoints such as changes in heart rate variability (HRV) and endothelial function are discussed (Section 6.5.9, Section 6.5.10, Section 6.5.11, and Section 6.5.12). Finally, considering the all of the information presented above, summary and causal determinations are presented (Section 6.5.13).

6.5.1 Biological Plausibility

This subsection describes the biological pathways that potentially underlie cardiovascular health effects resulting from short-term inhalation exposure to UFPs. Figure 6-36 graphically depicts these proposed pathways as a continuum of pathophysiological responses- connected by arrows- that may ultimately lead to the apical cardiovascular events observed in epidemiologic studies (i.e., ED visits and hospital admissions). This discussion of "how" short-term exposure to UFPs may lead to these cardiovascular events also provides at least some biological plausibility for the epidemiologic results reported later in Section 0. In addition, most studies cited in this subsection are discussed in greater detail throughout Section 0.



Note: the boxes above represent the effects for which there is experimental or epidemiologic evidence, and the dotted arrows indicate a proposed relationship between those effects. Shading around multiple boxes denotes relationships between groups of upstream and downstream effects. Progression of effects is depicted from left to right and color coded (grey, exposure; green, initial event; blue, intermediate event; orange, apical event). Here, apical events generally reflect results of epidemiologic studies, which often observe effects at the population level. Epidemiologic evidence may also contribute to upstream boxes.

Figure 6-36 Potential biological pathways for cardiovascular effects following short-term exposure to ultrafine particle (UFP).

When considering the available health evidence, plausible pathways connecting short-term exposure to UFPs to the apical events reported in epidemiologic studies are proposed in Figure 6-36. The first pathway begins as respiratory tract inflammation that leads to systemic inflammation[67]. The second pathway involves activation of sensory nerve pathways in the respiratory tract that leads to modulation of the autonomic nervous system. Once these pathways are initiated, there is evidence from experimental and observational studies that short-term exposure to UFPs may result in a series of pathophysiological responses that could lead to cardiovascular events such as ED visits and hospital admissions for IHD and HF.

Short-term inhalation exposure to UFPs may result in respiratory tract inflammation (CHAPTER 5). Inflammatory mediators such as cytokines produced in the respiratory tract have the potential to enter the circulatory system where they may cause distal pathophysiological responses that contribute to overt cardiovascular disease (see Section 6.1.1). There is limited evidence from CHE studies that following short-term UFP exposure, systemic inflammation (Liu et al., 2015a; Devlin et al., 2014) may occur. Importantly, systemic inflammation may result in altered hemostasis which may then increase the potential for thrombosis and possibly worsen IHD and HF. In addition, systemic inflammation may result in impaired vascular function that could potentially lead to rupture of existing plaques (Halvorsen et al., 2008). Dislodged plaques may then obstruct blood flow to the heart or stimulate intravascular clotting (Karoly et al., 2007), both of which could result in worsening of IHD and set the stage for HF. Thus, it is important to note that there is some evidence from CHE (Devlin et al., 2014) and epidemiologic panel studies (Wang et al., 2016; Rich et al., 2012; Hildebrandt et al., 2009; Peters et al., 2009) for altered hemostasis following short-term UFP exposure. Similarly, a CHE (Devlin et al., 2014) and an epidemiologic panel study (Ljungman et al., 2014) provide some evidence for impaired vascular function.

There is also evidence that short-term exposure to UFPs could potentially lead to these outcomes through activation of sensory nerves in the respiratory tract (CHAPTER 5). Once activated, autonomic nervous system modulation could exacerbate IHD and HF through proposed pathways that include increases in BP and/or exacerbation of conduction abnormalities or arrhythmia (Figure 6-36). Thus, it is important to note that CHE (Devlin et al., 2014; Samet et al., 2009) and epidemiologic panel studies (Hampel et al., 2014; Rich et al., 2012) report modulation of the autonomic nervous system (as evidenced by changes in HRV) following short-term UFP exposure. Similarly, evidence for increases in blood pressure can be found in epidemiologic panel studies (Chung et al., 2015; Kubesch et al., 2014; Liu et al., 2014b; Weichenthal et al., 2014a), while CHE (Devlin et al., 2014; Samet et al., 2009) and an additional

[67] It is also possible that UFP or soluble particle components can translocate directly into the circulatory system (Chapter 4) and lead to systemic inflammation, although the extent to which particle translocation occurs remains unclear.

epidemiologic panel (Link et al., 2013) study report conduction abnormalities or indicators of arrhythmia following short-term UFP exposure.

When considering the available evidence, there are potential pathways connecting short-term exposure to UFPs to cardiovascular health effects (Figure 6-36). More specifically, there exist potential pathways by which short-term exposure to UFPs may worsen IHD or HF, as well as contribute to the development of MI or stroke, potentially resulting in ED visits and hospital admissions. That said, the evidence supporting most of the individual events in these potential pathways is quite limited. This information will be used to inform a causal determination, which is discussed later in the chapter (Section 6.5.13).

6.5.2 Ischemic Heart Disease and Myocardial infarction

As noted above in Section 6.1.2, ischemic heart disease (IHD) is characterized by reduced blood flow to the heart. The majority of IHD cases are caused by atherosclerosis (Section 6.2.4), which can result in the blockage of the coronary arteries and restrict of blood flow to the heart muscle. A myocardial infarction (MI) or heart attack occurs as a consequence of IHD, resulting in insufficient blood flow to the heart that overwhelms myocardial repair mechanisms and leads to muscle tissue death.

There was no evidence in the 2009 PM ISA with respect to IHD, MI and short-term exposure to UFPs. In the current review, there are a few ED visit and hospital admission studies as well as a single epidemiologic panel study. Overall these studies do not suggest a relationship between short-term exposure to UFPs and IHD or MI.

6.5.2.1 Emergency Department Visits and Hospital Admissions

In Rome, Italy, Belleudi et al. (2010) considered nearly 23,000 ED visits for acute coronary syndrome and observed null associations with UFP exposure (particle number concentrations from a single, fixed-site monitor) at individual lags from 0 to 6 days. Gardner et al. (2014) also reported a null association between two subtypes of MI (ST segment elevation MI and non-ST segment elevation MI) and UFP (particle number concentration, 10-100 nm, from a fixed-site monitor) in a MI registry study in Rochester, NY. Conversely, in a MI registry study in Augsburg, Germany, Wolf et al. (2015a) observed a positive, albeit imprecise (i.e., wide 95% CI), association between same-day UFP exposure (particle number concentration, 10-2000 nm, from a fixed-site monitor) and MI. Additionally, Wolf et al. (2015a) observed a positive increase in recurrent MI events with UFP exposure averaged over a longer, multiday lag period (6.0%, 95% CI: 0.6%, 11.7%, lag 0-4 per 6,800 particles/cm^3 increase). Registry studies are advantageous because they are thought to lessen the degree of outcome misclassification generally seen in studies that rely on administrative data.

6.5.2.2 Panel Epidemiologic Studies of ST Segment Depression

There were no studies evaluating ST-segment depression available for the 2009 ISA and there is only a singly study in the recently published literature. Delfino et al. (2011) conducted a repeated measures study among older adults with coronary artery disease living in retirement communities in Los Angeles and did not find evidence for associations between average PNC of 1-hour up to 4-days and ST-segment depression.

6.5.3 Heart Failure and Impaired Heart Function

As first noted in Section 6.1.3, heart failure (HF) refers to a set of conditions including congestive heart failure (CHF) in which the heart's pumping action is weakened. With CHF the flow of blood from the heart slows, failing to meet the oxygen demands of the body, and returning blood can back up, causing swelling or edema in the lungs or other tissues.

There were no studies in the 2009 PM ISA with respect to short-term UFP exposure and heart function. In the current review, a hospital admission study showed a positive association that was lag dependent. However, relative to control animals, a toxicological study did not find an increase in markers consistent with cardiac damage following short-term exposure to $PM_{10-2.5}$.

6.5.3.1 Emergency Department Visits and Hospital Admissions

The 2009 PM ISA did not review any epidemiologic studies of ambient UFPs and ED visits and hospital admissions for heart failure. Recently, Belleudi et al. (2010) reported positive associations between ambient UFP exposure (particle number concentration from a single fixed-site monitor) and hospital admissions for heart failure in Rome, Italy. The authors examined individual lags from 0 to 6 days, and observed the highest magnitude associations at lag 0 (1.80% [95% CI: 0.39, 3.24%] per 9,392 particles/cm^3 increase) and lag 2 (1.65% [95% CI: 0.32, 3.00%]), with null associations at lags 5 and 6.

6.5.3.2 Toxicology Studies of Impaired Heart Function

There were no animal toxicological studies in the last review examining markers of potential heart failure following short-term UFP exposure. Since that document, Kurhanewicz et al. (2014) reported that short-term exposure to UFPs resulted in no appreciable change in LVDP or contractility. In addition, (Aztatzi-Aguilar et al., 2015) did not report statistically significant cardiac gene expression consistent with cardiac damage following short-term exposure to UFPs. More information on this recently published study can be found in Table 6-73 below.

Table 6-73 Study specific details from toxicological studies of short-term UFP exposure and impaired heart function.

Study	Study Population	Exposure Details	Endpoints Examined
(Aztatzi-Aguilar et al., 2015)	Adult male Sprague-Dawley rats (n = 4 per group)	Inhalation of UFP (107 $\mu g/m^3$) for 5 h/day, for 3 days	Acta1 and Col3a gene expression
(Kurhanewicz et al., 2014)	Adult, female C57BL/6 mice (10-12 week), n = 5-8/group	Inhalation of 138 $\mu g/m^3$ UFP for 4 h	LVDP and contractility (dP/dt) Tissue collected 24h post exposure.

Note: d = day, h = hour, n = number, f = female, M = male, LVDP = left ventricular developed pressure, Acta1 = skeletal alpha-actin, Col3a1 = collagen Type 3 alpha, post = post exposure

6.5.4 Cardiac Electrophysiology, Arrhythmia, and Cardiac Arrest

Electrical activity in the heart is measured using electrocardiography (ECG). The pattern of depolarization and repolarization in the heart can indicate various forms of arrhythmia and distinguish those arising in the ventricle from those arising in the atria. See Section 6.1.4 for more information on arrhythmia and measures of conduction abnormalities.

The 2009 PM ISA had a single epidemiologic study of ambient UFPs and arrhythmia-related ED visits and HA. In addition, there was a single CHE study that reported a shortening of the QT interval following short-term exposure to UFPs. Since the last review, one epidemiologic study reported a null association for arrhythmia related hospital admissions, but a CHE study did report conduction abnormalities by ECG that could indicate the potential for increased risk of arrhythmia following short-term UFP exposure.

With respect to OHCA, one study in the 2009 PM ISA that found a positive association between short-term UFP exposure and OHCA. Since the 2009 PM ISA, no new studies of OHCA have been reviewed.

6.5.4.1 Emergency Department Visits and Hospital Admissions for Arrhythmia and Out-of-Hospital Cardiac Arrest

A number of studies based on administrative databases have sought to evaluate the association between short-term fluctuations in ambient UFP concentrations and the risk of hospitalization for cardiac arrhythmias (also known as dysrhythmias). In these studies, a primary discharge diagnosis of ICD-9 427 has typically been used to identify hospitalized patients. ICD-9 427 includes a heterogeneous group of

arrhythmias including paroxysmal ventricular or supraventricular tachycardia, atrial fibrillation and flutter, ventricular fibrillation and flutter, cardiac arrest, premature beats, and sinoatrial node dysfunction.

The 2009 PM ISA did not review any epidemiologic studies of ambient UFPs and arrhythmia-related ED visits and HA. Recently, Anderson et al. (2010) examined the association between UFP exposure (particle number concentration, single fixed-site monitor) and atrial fibrillation in London, England. The authors reviewed records of implantable cardioverter defibrillators activations and reported a null association with UFP (OR: 1.00, 95% CI: 0.96, 1.05, per 1,000 particles/cm^3 increase, lag 0-5).

The majority of out-of-hospital cardiac arrests are due to cardiac arrhythmias. The 2009 PM ISA reviewed one study examining the association between UFP and OHCA. A study in Rome, Italy (Forastiere et al., 2005) reported positive associations between OHCA and UFPs. No studies published since the release of the 2009 PM ISA examined the association between UFP concentrations and OHCA.

6.5.4.2 Panel Epidemiologic Studies for Arrhythmia and Conduction Abnormalities

In the 2009 PM ISA, (Dockery et al., 2005b) reported a positive association for arrhythmias relative to 2-day averages of UFP. A handful of studies examined the relationship between short-term exposure to UFPs and changes in arrhythmia or cardiac conduction and generally reported null results. While Link et al. (2013) found a positive association between arrhythmia and 2-hour averages of NCs measured at the clinic site in a panel of adults with ICDs, null associations were reported for 24-hour averages. Positive associations for ventricular tachyarrhythmia with NCs in the prior 24-47 hours (0.5%; 95% CI: -0.1, 1.0; per 7,481/cm^3) were also reported by Bartell et al. (2013) in a study of ventricular tachyarrhythmia in older adults with coronary artery disease that used residential monitoring for NC (100-3,000nm); however, negative associations were reported with NCs in the prior 96-119 hours (-0.6%; 95% CI: -1.3, 0.1; per 7,481/cm^3) Hampel et al. (2010) and Rich et al. (2012) both examined QTc changes in relation to ambient NCs (10-100nm) among survivors of MI and cardiac rehabilitation patients, respectively. Hampel et al. (2010) used fixed site monitoring representative of urban background NCs in Dusseldorf, Germany. (Rich et al., 2012) conducted monitoring at the clinic site in Rochester, NY, located roughly 1,500 m from an interstate highway and within 19km of study participants. Neither study reported evidence of associations with 5-hour up to 5-day NC averages.

6.5.4.3 Controlled Human Exposure Studies for Arrhythmia and Conduction Abnormalities

In the 2009 ISA, a CHE study examined the relationship between ultrafine PM exposure and ventricular arrhythmia. Samet et al. (2009) reported a shortened QT interval. They also noted increased variance in the duration of QRS complexes under ultrafine CAP exposure in healthy, young individuals.

In the current ISA, an additional study examined the relationship between UFP CAP exposure and potential indicators of ventricular arrhythmia. Devlin et al. (2014) recently studied adults with metabolic syndrome, including a subgroup with the null allele for glutathione S-transferase (GSTM1- an important antioxidant gene). The GSTM1 null allele individuals had a small but significant increase in the QT interval one-hour post exposure (p = 0.0070) relative to FA, while a nonsignificant trend in increased QTc was reported for the entire study group. These GSTM1 null individuals also had an increased complexity of the QRS complex (possible indicator of increased risk of arrhythmia development) at both one-hour (p = 0.025) and 20 hours (p = 0.008) post exposure. More information on studies published since the 2009 ISA can be found in Table 6-74 below.

Table 6-74 Study-specific details from CHE studies of short-term UFP exposure and conduction abnormalities.

Study	Population N, Sex; Age (mean ± SD)	Exposure Details (Concentration; Duration)	Endpoints Examined
(Devlin et al., 2014)	Adults with metabolic syndrome n = 13 M; 21 F 27-70, average 15 of which carried the null allele for GSTM1	98 µg/m^3 UFPs (73% of which are <0.1 µm) 16,000–564,000 particles/cm^3 for 2 h at rest particles from Chapel Hill, NC	Measures of conduction abnormalities including QT interval: from continuously worn halter data

Note: SD = standard deviation, M = male, F = female, n = number, GSTM1 = Glutathione S-transferase Mu 1, ECG = electrocardiogram QT = time interval between from beginning of the Q-wave to end of the T-wave

6.5.4.4 Toxicological Studies for Arrhythmia and Conduction Abnormalities

In the 2009 ISA, there were no toxicological studies that examined the effect of UFP CAP exposure on indicators of arrhythmia or conduction abnormalities. In the current review, Kurhanewicz et al. (2014) reported that short-term exposure to UFPs resulted in no appreciable change in ECG measurements. More information on this recently published study can be found in Table 6-75 below.

Table 6-75 Study specific details from toxicological studies of short-term ultrafine particle (UFP) exposure and conduction abnormalities.

Study	Study Population	Exposure Details	Endpoints Examined
(Kurhanewicz et al., 2014)	Adult, female C57BL/6 mice (10-12 week), n = 5-8/group	Inhalation of 138 μg/m^3 UFP CAP for 4h.	QRS, QT interval, *P*-wave,

d = day, h = hour, n = number, f = female, M = male, ECG = electrocardiogram, QT = time interval between from beginning of the Q-wave, to end of the T-wave, c = corrected for heart rate

6.5.5 Cerebrovascular Disease and Stroke

Cerebrovascular disease typically includes conditions such as hemorrhagic stroke, cerebral infarction (i.e., ischemic stroke) and occlusion of the pre-cerebral and cerebral arteries. Ischemic stroke results from an obstruction within a blood vessel that supplies oxygen to the brain, potentially leading to infarction. Hemorrhagic stroke is less common but results to a disproportionate amount of fatalities.

There were no studies in the last review with respect to short-term UFP exposure and stroke. The current review has a single hospital admission study that generally found a positive association between short-term UFP exposure and stroke.

6.5.5.1 Emergency Department Visits and Hospital Admissions

The 2009 PM ISA did not review any epidemiologic studies of UFP concentrations and ED visits and hospital admissions for CBVD/stroke. Andersen et al. (2010) recently studied 7,485 incident hospital admissions for stroke in Copenhagen, Denmark from 1995 to 2003. Data from a national stroke registry allowed the authors to consider stroke type (ischemic vs. hemorrhagic), stroke severity (mild vs. severe), and ischemic stroke subtype (with atrial fibrillation vs. without atrial fibrillation) in relation to UFP exposure (particle number concentration (10-700 nm) measured by fixed-site monitors at two urban locations). Andersen et al. (2010) observed increases in odds of hospital admissions for ischemic stroke, mild stroke, ischemic stroke without atrial fibrillation, and mild ischemic stroke without atrial fibrillation over the previous five days (lag 0-4). The associations were generally imprecise (i.e., wide 95% CIs), especially for the subgroup analyses. The association with the highest magnitude was observed between UFP exposure and hospital admissions for mild ischemic stroke without atrial fibrillation (OR: 1.21, 95% CI: 1.04, 1.41, per 3,918 particles/cm^3 increase, lag 0-4). The observed association was robust to adjustment for PM_{10}, NO_X, and CO in copollutant models.

6.5.6 Blood Pressure and Hypertension

High blood pressure results in the increased force on the artery walls and can damage the blood vessels and increase risk for cardiovascular disease and stroke. Hypertension is characterized by persistently elevated blood pressure. Additional information on blood pressure and hypertension can be found in Section 6.1.6.

In the 2009 PM ISA, a handful of epidemiologic panels studies and a single CHE study reported that exposure to UFPs did not result in increases in BP. In the current review, an additional CHE studies also reported that exposure to UFPs did not result in increases in BP. However, panel epidemiologic studies in the current review do provide some evidence for increases in blood pressure following UFP exposure. Thus, across disciplines evidence is both limited and inconsistent.

6.5.6.1 Emergency Department Visits and Hospital Admissions

Hypertension, a medical condition characterized by persistently elevated blood pressure, is a leading risk factor for myocardial infarction, heart failure, and cerebrovascular diseases. The 2009 PM ISA did not review any epidemiologic studies of ambient UFPs and ED visits and hospital admissions for hypertension. In the only recent study available, Franck et al. (2011) observed positive associations between short-term UFP exposure (measured by particle number concentration, < 100 nm, single fixed-site monitor) and emergency calls for hypertensive crisis in Leipzig, Germany. The authors examined individual lags from 0 to 10 days, and observed positive associations at every lag except for 0, 1, and 10. The authors presented their results graphically; detailed effect estimates were not provided. Additionally, when using alternative exposure metrics based on surface area and volume concentrations, Franck et al. (2011) reported cardiovascular effects were not "significantly correlated" with UFP exposure (quantitative results not presented).

6.5.6.2 Panel Epidemiologic Studies of Changes in Blood Pressure (BP)

Limited evidence was available for the 2009 PM ISA (U.S. EPA, 2009) examining exposures to UFP and changes in BP, though several recently published studies are available. Weichenthal et al. (2014a), Kubesch et al. (2014), and Liu et al. (2014b) all conducted studies that were quasi-experimental in design and provide some evidence for associations between $PM_{2.5}$ and SBP and DBP. Weichenthal et al. (2014a) and Liu et al. (2014b) both used personal monitoring for NCs (10-100nm) with differential exposure scenarios (sites with high and low pollution). Weichenthal et al. (2014a) reported positive associations between 2-hour averages of NCs with SBP measurements taken 3 hours post-exposure, but associations with SBP were null. In contrast, Liu et al. (2014b) reported a decrease in DBP and NCs with a 1-day lag (-0.78 mm hg; 95% CI: -1.40, -0.16; per 10256/cm^3). Chung et al. (2015) and Kubesch et al.

(2014) both utilized differential exposures to traffic. Kubesch et al. (2014) measured SBP and DBP in participants following a 2 hour exposure to high or low traffic and found positive associations personal average NCs (100-1000nm) and SBP, but not DBP. Chung et al. (2015) also included participants with differential traffic exposures and reported positive associations between NC and SBP, but not DBP, though there is greater uncertainty in NCs in this study do to fixed-site monitoring. Rich et al. (2012) also examined associations between BP and exposures to UFPs in a panel of cardiac rehabilitation patients that lived within 19 km of the clinic where NCs (10-100 nm) were measured. Associations between NCs and DBP were positive across exposure periods ranging from 23-hours up to 4-days, though a decrease in DBP was associated with 5-day averages of NCs; positive associations were also observed for SBP with 1- to 5-day average NCs (Rich et al., 2012). Overall, these recent studies provide some evidence of a relationship between exposure UFPs and BP that is in contrast to evidence for exposures to $PM_{2.5}$, but the evidence base is still quite small for UFP exposures compared to $PM_{2.5}$.

6.5.6.3 Controlled Human Exposure Toxicology Studies of Changes in Blood Pressure (BP)

In studies from the 2009 ISA, BP was not found to be affected by exposure to UF carbon particles (Frampton, 2001), UF EC (Shah et al., 2008; Routledge et al., 2006), or UF ZnO (Beckett et al., 2005). In the current ISA, no changes in BP were reported by Devlin et al. (2014) in metabolic syndrome patients (including those with GSTM1 null allele) exposed to UFP CAPs. In addition, in healthy men, Mills et al. (2011) found an increase in BP following exposure to DE (Table 6-76), however the increase was not attenuated following exposure to particle-filtered DE. Thus, there is no evidence from CHE studies to suggest an effect of UFP exposure on BP. More information on studies published since the 2009 ISA can be found in Table 6-76 below.

Table 6-76 Study specific details from CHE studies of short-term ultrafine particle (UFP) exposure and blood pressure (BP).

Study	Population N, Sex; Age (mean ± SD)	Exposure Details (Concentration; Duration)	Endpoints Examined
(Devlin et al., 2014)	Adults with metabolic syndrome n = 13 M; 21 F 27-70, average 15 of which carried the null allele for GSTM1	98 µg/m^3 UF CAPs (73% of which are <0.1 µm) 16,000–564,000 particles/cm^3 for 2 h at rest particles from Chapel Hill, NC	BP: pre, during, 1 h post

Study	Population N, Sex; Age (mean ± SD)	Exposure Details (Concentration; Duration)	Endpoints Examined
(Mills et al., 2011)	Healthy M N = 16 18- 32 yr	300 µg/m^3 UFP Particles generated with diesel engine passed through 0.1 µm filter 15-minute rest and cycling intervals during exposure Particle filtered exposures had UFP removed	BP: 6 h post

Note: SD = standard deviation, M = male, F = female, n = number, h = hour, CAP = concentrated ambient particle, DE = diesel exhaust; GSTM1 = Glutathione S-transferase Mu 1, BP = blood pressure

6.5.6.4 Toxicological Studies of Changes in Blood Pressure (BP)

There were no animal toxicology studies in the 2009 PM ISA exploring the relationship between short-term exposure to UFP and the angiotensin system. Since the publication of that review, a study has reported that short-term exposure to UFP can result in statistically significant increases in Ace and B1r, but not At1r mRNA in rat heart tissue (Aztatzi-Aguilar et al., 2015). However, in mice Kurhanewicz et al. (2014) reported that short-term exposure to UFPs resulted in no appreciable change in Ace serum levels compared to filtered air exposure. More information on these studies can be found in Table 6-77 below.

Table 6-77 Study specific details from toxicological studies of short-term ultrafine particle (UFP) exposure and blood pressure (BP).

Study	Study Population	Exposure Details	Endpoints Examined
(Aztatzi-Aguilar et al., 2015)	Adult male Sprague-Dawley rats (n = 4 per group)	Inhalation of UFP 107 µg/m^3 for 5 h/day, for 3 days	Renin-angiotensin gene expression. Heart tissue harvested 24 h post exposure
(Kurhanewicz et al., 2014)	Adult, female C57BL/6 mice (10-12 weeks), n = 5-8/group	Inhalation of 138 µg/m^3 UFP for 4 h	ACE serum levels 24-h post exposure.

Note: d = day, h = hour, n = number, f = female, M = male, ACE = angiotensin converting enzyme

6.5.7 Emergency Department Visits and Hospital Admission Studies of Cardiovascular-Related Effects

Many epidemiologic studies consider the composite endpoint of ED visits and hospital admissions for all cardiovascular diseases, including diseases of the circulatory system. This endpoint generally encompasses ED visits and hospital admissions for ischemic heart disease, MI, PVD, heart failure, arrhythmia, CBVD and stroke, and diseases of pulmonary circulation. A smaller body of studies examine the endpoint of cardiac diseases, a subset of CVD that specifically excludes hospitalizations for cerebrovascular disease, peripheral vascular disease, and other circulatory diseases not involving the heart or coronary circulation. The 2009 PM ISA did not review any epidemiologic studies of ambient UFPs and ED visits and hospital admissions for CVD or cardiac disease. Several recent studies are available for review provide emerging evidence of an association between UFP concentrations and ED visits and hospital admissions for CVD.

In a study in London, England, Atkinson et al. (2010) reported that cardiovascular-related hospital admissions were positively associated with UFP exposure (particle number concentration measured at a single fixed-site monitor for lag 1 and lag 0-1; quantitative results not reported; results presented graphically). In another study in London, England using a single fixed-site monitor, Samoli et al. (2016) reported null associations for cardiovascular-related hospital admissions and UFP exposure (particle number count, upper size limit of 3,000 nm, lag 1). Samoli et al. (2016) also examined associations between UFPs exposure (source apportionment, particle number size distribution, particles < 600 nm). The authors reported positive, but imprecise, associations with UFP linked to urban background and traffic sources, though not for particles attributed to regional nucleation or secondary particle formation. Similarly, in a study of five cities in Central and Eastern Europe, Lanzinger et al. (2016b) reported null associations for UFP (number count, 100 nm; particle number concentration, 800nm) across individual lags (lag 0 to lag 7) and multi-day averaged lags. In city-specific analyses, results did not substantially differ based on the exposure metric used, and results for UFP (NC100nm) were robust to adjustment for $PM_{2.5}$ or NO_2 both in pooled and city-specific estimates. A delayed association was observed in Beijing, China (Liu et al., 2013). Liu et al. (2013) reported a 7.2% (95% CI: 1.1, 13.7%) increase in cardiovascular-related ED visits corresponding to a 9,040 particle/cm^3 increase in 11-day moving average of UFP concentrations (measured by number concentration, particles 3-100 nm, single fixed-site monitor). Liu et al. (2013) also reported attenuated associations with 2-day moving averages based on number concentration (1.1%, 95% CI: -3.0%, 5.3%; 10,340 particle/cm^3, particles 3-100 nm), particularly Aitken mode particles. In Prague, Czech Republic, Braniš et al. (2010) assessed associations between submicron particles (particles 14.6 to 487 nm) measured from a single fixed-site monitor and cardiovascular-related HA. The authors reported positive associations with nucleation (14.6 to 48.7 nm) and Aitken (48.7 to 205 nm) mode particles, but the highest magnitude associations were observed with accumulation (205 to 487 nm) mode particles (e.g., RR 1.093, 95% CI: 1.019, 1.174, at lag 2 per 1,000 particles/cm^3 increase).

Overall, the evidence provides limited support for the presence of a positive association between UFP exposure and cardiovascular-related ED visits and HA. Evidence for this relationship is provided by a limited number of single-city studies conducted in Europe and Asia. The observed associations tend to be for delayed lags, with weak or null associations with UFP concentrations on the same day, and increasing associations thereafter; however, these studies relied on a single monitor to estimate UFP exposure. As detailed in CHAPTER 2 (Section 2.5.1.1.5, Section 2.5.1.2.4, and Section 2.5.2.2.3), the use of a single monitor does not adequately account for the spatial and temporal variability in UFP concentrations as well as the change in the particle size distribution that changes with distance from source. The range in measures used to represent UFP exposures also complicates the overall interpretation of results. Furthermore, the studies did not examine the potential for copollutant confounding.

6.5.8 Epidemiologic Studies of Cardiovascular Mortality

In the 2009 PM ISA, a small number of studies examined associations between short-term UFP exposure and cardiovascular mortality, providing some initial evidence of a positive association. Although the number of studies has increased, the total body of evidence remains small, as detailed in CHAPTER 11 (Section 11.4.1). Across studies that examined the UFP – cardiovascular mortality relationship, there is inconsistency in the particle size distribution that was used to represent UFP exposures with some studies measuring total number concentration (NC), while other studies measured NC with the upper end of the size distribution ranging from 100 – 3,000 nm. This disparity in the measurement of UFPs between studies complicates the overall interpretation of results.

The assessment of the relationship between short-term UFP exposure and cardiovascular mortality is limited to studies conducted in Europe (Stafoggia et al., 2017; Lanzinger et al., 2016a; Samoli et al., 2016) and China (Breitner et al., 2011). Focusing on NC, Breitner et al. (2011) reported evidence of a positive association, but confidence intervals were wide, whereas, the other studies evaluated reported no evidence of an association. Additionally, of the studies evaluated, (Breitner et al., 2011) also examined alternative exposure metrics, surface area concentration (SC) and mass concentration (MC), and reported positive associations that were imprecise (SC: 0.24% [95% CI: -2.72, 3.29], lag 0-4 per 12,060 cm^{-3}; MC: 0.13% [95% CI: -2.87, 3.23], lag 0-4 per 14.0 $\mu g/m^{3)}$. Although there is some evidence of a positive association between short-term UFP exposure and cardiovascular mortality, within each study only a single monitor was used to estimate exposure to UFPs (Table 11-9, UFP studies in mortality chapter). As detailed in CHAPTER 2 (Section 2.5.1.1.5, Section 2.5.1.2.4, and Section 2.5.2.2.3), the use of a single monitor does not adequately account for the spatial and temporal variability in UFP concentrations as well as the change in the particle size distribution that changes with distance from source.

6.5.9 Heart Rate (HR) and Heart Rate Variability (HRV)

Measured by ECG, heart rate variability (HRV) represents the degree of difference in the inter-beat intervals of successive heartbeats, and is an indicator of the balance between the sympathetic and parasympathetic arms of the autonomic nervous system. Additional information on HRV and HR can be found in Section 6.1.10.

In the 2009 PM ISA, there were a handful of epidemiologic panel and CHE studies that reported changes in metrics of HRV following short-term UFP exposure. Since the last review, an additional CHE study reported changes in HRV following UFP exposure. In addition to the CHE studies, several epidemiologic panel studies examined potential associations between metrics of HRV and short-term UFP exposure. The results of these studies were inconsistent with some studies showing positive associations while others did not. In addition, a single toxicological study did not find an effect of UFP exposure on HRV measures. Taken together, there is some evidence for an effect of short-term UFP exposure on HRV, but overall the evidence remains inconsistent within and across disciplines.

With respect to heart rate, a CHE and toxicological study did not find that UFP exposure resulted in changes in heart rate.

6.5.9.1 Epidemiologic Panel Studies of Heart Rate (HR) and Heart Rate Variability (HRV)

Limited evidence was available for the 2009 ISA, though some evidence indicated decreases in HRV relative to increases in PNC. Several recently published studies are available that examine associations between UFP concentrations and HRV (Hampel et al., 2014; Weichenthal et al., 2014a; Bartell et al., 2013; Rich et al., 2012; Schneider et al., 2010). Rich et al. (2012) reported reduced rMSSD and SDNN with 5-hour and 23-hour lagged exposures to NCs (10-100nm) in a panel of adults in a cardiac rehabilitation program living within 19km of the clinic where monitoring was conducted. Weichenthal et al. (2014a) conducted a quasi-experimental study with personal monitoring for NCs (10-100nm) during ambient exposure periods at different sites and reported positive associations between 2-hour averages of NCs with SDNN measured 3 hours post-exposure, but associations with rMSSD were null. Bartell et al. (2013) also found positive associations between SDNN and 5-day averages of NCs in a study of community-dwelling seniors (71 years of age or older) using residential monitoring for particles 100-3,000 nm in size. In contrast, Schneider et al. (2010) did not find associations between rMSSD or HF with NCs measured at a site representing urban background (10-100nm) in a panel of older adults with coronary artery disease. Overall, these recent studies provide some evidence for an association between exposure to UFP and changes in HRV, particularly SDNN among older adults and individuals with a history of cardiovascular disease.

6.5.9.2 Controlled Human Exposure Studies of Heart Rate (HR) and Heart Rate Variability (HRV)

The 2009 PM ISA discussed two studies that examined HRV, but no studies reporting potential changes in HR. Samet et al. (2009) demonstrated that healthy adults exposed to UF CAPs had an increase in both HF and LF frequency domains, but not in time domains. In addition, Gong et al. (2008) reported a small and transient decrease in LF in healthy and asthmatic adults.

Since the 2009 PM ISA, Mills et al. (2011) reported no difference in HR following exposure to DE (Table 6-78), or particle-filtered DE in healthy men. With respect to HRV, Devlin et al. (2014) exposed metabolic syndrome patients, including a subset with the GSTM1 null allele, to UFP CAP or FA. In the subset of patients expressing the GSTM1 null allele, decreases in HF ($p < 0.05$) and an increase in both LF ($p < 0.05$) and the LF/HF ratio ($p < 0.05$) was reported. Taken together, the is limited evidence of an UFP effect on HRV, but not HR. More information on studies published since the 2009 ISA can be found in Table 6-78 below.

Table 6-78 Study specific details from controlled human exposure (CHE) studies of short-term ultrafine particle (UFP) exposure and changes in heart rate (HR) and heart rate variability (HRV).

Study	Population N, Sex; Age (mean ± SD)	Exposure Details (Concentration; Duration)	Endpoints Examined
(Devlin et al., 2014)	Adults with metabolic syndrome n = 13 M; 21 F 27-70, average 15 of which carried the null allele for GSTM1	98 µg/m^3 UF CAPs (73% of which are <0.1 µm) 16,000–564,000 particles/cm^3 for 2 h at rest particles from Chapel Hill, NC	HRV time parameters: collected over 24 h HRV frequency domains: pre, 1 h post, 20 h post
(Mills et al., 2011)	Healthy men N = 16 18- 32 yr	300 µg/m^3 UFP Particles generated with diesel engine passed through 0.1 µm filter 15-min rest and cycling intervals during exposure Particle filtered exposures had UFP removed	HR: 6 h post

Note: SD = standard deviation, M = male, F = female, n = number, h = hour, CAP = concentrated ambient particle, DE = diesel exhaust; IQR = interquartile range, HRV = heart rate variability, GSTM1 = Glutathione S-transferase Mu 1

6.5.9.3 Toxicology Studies of Heart Rate (HR) and Heart Rate Variability (HRV)

Since the publication of the 2009 ISA, Kurhanewicz et al. (2014) reported that short-term exposure to UFPs resulted in no appreciable change in HR, SDNN, rMSSD, or LF/HF in mice. More information on this recently published study can be found in Table 6-79 below.

Table 6-79 Study specific details from toxicological studies of short-term UFP exposure and heart rate (HR) and heart rate variability (HRV).

Study	Study Population	Exposure Details	Endpoints Examined
(Kurhanewicz et al., 2014)	Adult, F C57BL/6 mice (10-12 week), n = 5-8/group	Inhalation of 138 µg/m^3 UFP for 4h.	HR, HRV time and frequency domains

n = number, h = hour, d = day, M = male, F = female HR = heart rate, HRV = heart rate variability.

6.5.10 Systemic Inflammation and Oxidative Stress

As discussed in Section 6.1.1 and Section 6.1.11, inflammation has been linked to a number of CVD related outcomes. For example, circulating cytokines such as IL-6 can stimulate the liver to release inflammatory proteins and coagulation factors that can ultimately increase the risk of thrombosis and embolism. Similarly, oxidative stress can result in damage to healthy cells and blood vessels and a further increase in the inflammatory response. Thus, this section discusses the evidence for markers of systemic inflammation and oxidative stress following short-term UFP exposures.

6.5.10.1 Epidemiologic Panel Studies of Systemic Inflammation and Oxidative Stress

Several recently published panel studies add to the limited evidence available for the 2009 ISA that provide some evidence for increases in systemic inflammation relative to UFP counts. In a panel study including 31 young, healthy adults exposed to air pollution at 5 different sites with intermittent exercise, Steenhof et al. (2014) reported mixed results for associations between UFPs and WBC counts; while decreases were observed for eosinophils and lymphocytes with PNCs at 2 and 18 hours post-exposure, respectively, increases in monocytes were observed and no changes were reported for neutrophils or total WBC counts. In this same panel, no associations were observed for PNC and CRP (Strak et al., 2013a).

In nursing home residents in Los Angeles, CA with ischemic heart disease, Wittkopp et al. (2013) did not find associations for CRP or soluble receptor for IL-6 with up to 5-day averages of PNC. In addition, other studies in panels with pre-existing cardiovascular disease generally did not find evidence for associations. While Rich et al. (2012) and Croft et al. (2017) found a positive association between CRP and 24-47-hour averages of UFPs. Associations were not found for other averaging times or with WBC counts (Rich et al., 2012) and negative associations between 12-96-hour lags of UFPs and myeloperoxidase were observed (Croft et al., 2017). In elderly with ischemic heart disease, PNC was associated with higher IL-12 but not CRP, IL-6, IL1B, IL-8, and IFNγ in 52 participants in Kotka, Finland (Huttunen et al., 2012).

In Heinz Nixdorf Recall study including approximately 4,000 participants, particle number concentration (PNC) based on a chemical transport model with a resolution of 1 × 1 km was associated with higher CRP in averaging periods from 2 up to 28 days with the largest effect estimates reported for 21-day average [7.1% (95% CI 1.9, 12.6) per IQR (4,580 particles x 104/ml)] (Hertel et al., 2010). Similarly, Karottki et al. (2014) reported associations between 48-hour PNC and CRP; no associations were observed for changes in WBCs.

6.5.10.2 Controlled Human Exposure Studies of Short-Term UFP Exposure and Systemic Inflammation and Oxidative Stress

Controlled human exposure studies from the 2009 PM ISA reported no change in plasma CRP levels following a 2-hour exposure to UFPs, although one study looked at and reported a significant increase in IL-8 (Samet et al., 2009; Gong et al., 2008). No change in plasma CRP was reported.

In the current review, Liu et al. (2015a) studied the potential for UFP exposure and endotoxin to associate with the biomarkers for inflammation IL-6 and CRP-. no associations were found. Devlin et al. (2014) also found no differences in sICAM-1 or sVCAM-1 (as well as no differences in neutrophils, lymphocytes, monocytes, platelets) in patients with metabolic syndrome, including a subset with the GSTM1 null allele. However, 20 hour post exposure, CRP was elevated (30.4 ± 11.9%, $p = 0.016$), as was the acute phase inflammatory marker SAA (77.5 ± 37.2%, $p = 0.043$). With respect to filtered diesel exhaust, in healthy men Mills et al. (2011) reported no statistical difference in leukocytes, neutrophils, or lymphocytes following exposure to DE (Table 6-80) or particle-filtered DE. In total, there is limited evidence from one CHE study indicating a systemic inflammatory response in metabolic syndrome patients.

With respect to markers of oxidative stress, Liu et al. (2015a) examined the potential for UF CAP exposure to increase levels of the biomarker of lipid peroxidation MDA and the DNA oxidative damage biomarker 8-OHdG. Ultrafine CAP exposure did not result in an increase in blood or urine levels of MDA. However, urine sampling revealed increases in 8-OHdG (0.69 ng/mg creatinine; 95% CI: 0.09, 1.29) at one hour but not 21 hours post-exposure. Thus, there is only limited evidence to suggest that UFP

exposure effects markers of oxidative stress. More information on studies published since the 2009 ISA can be found in Table 6-80 below.

Table 6-80 Study specific details from controlled human exposure (CHE) studies of short-term UFP exposure and systemic inflammation.

Study	Population N, Sex; Age (mean ± SD)	Exposure Details (Concentration; Duration)	Endpoints Examined
(Devlin et al., 2014)	Adults with metabolic syndrome n = 13 M; 21 F 27-70, average 15 of which carried the null allele for GSTM1	98 µg/m^3 UF CAPs (73% of which are <0.1 µm) 16,000–564,000 particles/cm^3 for 2 h at rest particles from Chapel Hill, NC	Markers of systemic inflammation and pre,1 h post, 20 h post
(Liu et al., 2015a)	Healthy adults n = 50; 18-60 yrs 28 ± 9	135.8 ± 67.2 µg/m^3 ultrafine cap for 130 min from Toronto, Canada	Markers of inflammation and oxidative stress measured pre, 1 h, and 21 h post
(Mills et al., 2011)	Healthy men N = 16 18- 32 yr	300 µg/m^3 UFP Particles generated with diesel engine passed through 0.1 µm filter 15-min rest and cycling intervals during exposure Particle filtered exposures had UFP removed	Markers of coagulation

Note: SD = standard deviation, M = male, F = female, n = number, h = hour, GSTM1 = glutathione S-transferase Mu 1, CAP = concentrated ambient particle

6.5.10.3 Toxicological Studies of Short-Term Ultrafine Particle (UFP) Exposure and Systemic Inflammation and Oxidative Stress

In the 2009 PM ISA, there were no animal toxicological studies examining the effects of short-term UFP exposure on markers of systemic inflammation or oxidative stress. Since the publication of that document, Kurhanewicz et al. (2014) reported that short-term exposure to UFPs did not result in a change in CRP levels or potential markers of oxidative stress relative to FA control animals. More information on studies published since the 2009 ISA can be found in Table 6-81 below.

Table 6-81 Study specific details from controlled human exposure (CHE) studies of short-term UFP exposure and systemic inflammation.

Study	Study Population	Exposure Details	Endpoints Examined
(Kurhanewicz et al., 2014)	Adult, F C57BL/6 mice (10-12 week), n = 5-8/group	Inhalation of 138 μg/m^3 UFP for 4h.	CRP, markers of oxidative stress in serum 24h post -exposure

Note: n = number, h = hour, d = day, M = male, F = female CRP = c-reactive protein

6.5.11 Coagulation

Coagulation refers to the process by which blood changes from a liquid to a semi-solid state in order to form a clot. Increases in coagulation factors (e.g., fibrinogen) or decreases in anti-coagulation factors can promote clot formation, and thus, increase the potential for an embolism.

In the 2009 PM ISA, CHE studies examined whether exposure to UFPs could result in changes in markers of coagulation. In general, results from these studies were negative. Since the 2009 PM ISA, a couple of additional CHE studies have reported inconsistent results, with one study showing changes in markers of coagulation, while the other study did not. Similarly, results from epidemiologic panel studies also report limited evidence of an associations between UFP concentrations and changes in markers of coagulation.

6.5.11.1 Panel Epidemiologic Studies

In the 2009 PM ISA (U.S. EPA, 2009), no studies were available that examined associations between short-term exposure to UFPs and biomarkers of coagulation, though a handful of studies have been published since. Among the recently published studies is one that used a quasi-experimental study design, including personal monitoring at five different locations in Utrecht, the Netherlands allowing for increased exposure contrast and reduced correlations between PM characteristics. Results from this study demonstrate that NCs (7-3000 nm) measured at the five different exposure sites were not associated with platelet counts or fibrinogen (Strak et al., 2013a). However, average NCs for the five-hour exposure periods, particularly those from the outdoor sites, were associated with reduced lag time in FXII-mediated (intrinsic) thrombin generation in a single pollutant model and several two-pollutant models, including those with PM_{10}, $PM_{2.5}$, OC, NO_3-, and SO_4^{2}-. These measures indicated hypercoagulability via the intrinsic pathway, but there was little evidence to suggest changes in the extrinsic pathway (tissue-factor mediated) (Strak et al., 2013b).

Other panel studies have examined fibrinogen and a number of other biomarkers as well. Hildebrandt et al. (2009) conducted a study to examine blood markers in a panel of adults with chronic pulmonary disease and reported positive associations with 1- (2.5%; 95% CI: 0.2, 4.9) and 3-day (2.5%; 95% CI: 0.2, 4.9 and 3.3; 95% CI: 1.0, 5.6, respectively, per 3827/cm^3 increase) lagged NCs (10-100nm) as well as 5-day averages (3.1%; 95% CI: 0.2, 6.0; per 2918/cm^3 increase). However, other study results included a negative association between 3-day lagged NCs and fibrinogen, negative associations between vWF and D-dimer for a number of lags, and null associations for prothrombin fragment 1+2 (Hildebrandt et al., 2009). Fibrinogen was also positively associated with 24- to 47-hour average NCs (10-100nm) in cardiac rehabilitation patients in Rochester, NY (Wang et al., 2016; Rich et al., 2012) and with 12 up to 96 hour averages of NCs (10-100 nm) in adults with acute coronary syndrome (Croft et al., 2017). In contrast, associations with fibrinogen were not observed in a study of older adult participants with ischemic heart disease (Huttunen et al., 2012) or a panel of individuals with a history of MI (Peters et al., 2009), though exposure measurement, including NC size range, was not described in these studies. Brüske et al. (2011) examined associations between lipoprotein-associated phospholipase A2, which has recently been shown to be an independent predictor of coronary heart disease events, and NCs (<100nm; measured at a fixed-site representing urban background) and found negative associations at 0- to 2-day lags but positive associations for 4-5-day lags in a prospective panel study of MI survivors.

6.5.11.2 Controlled Human Exposure Studies

The 2009 PM ISA included a study of healthy and asthmatic adults exposed to UFP CAPs from CA(Gong et al., 2008). No significant changes were reported for D-dimer, vWF, PAI-1, factors VII and IX, fibrinogen, plasminogen, or TPA levels. In an additional study, healthy adults were exposed to UFPs from NC while alternating between 15-minute rest/exercise sessions. Increases in D-dimer concentration, but not in PAI-1, vWF, tPA, fibrinogen, plasminogen, or factors IX or VII, were found (Samet et al., 2009).

In the current review, Devlin et al. (2014) examined the effects of UFP exposure on markers of fibrinolysis in metabolic syndrome patients, including a subgroup (n = 15) carrying the null allele for GSTM1. The anticoagulant proteins plasminogen (p = 0.022) and thombomodulin (p = 0.048) had a statistically significant decrease when examining the entire study population at 20 hours but not one hour post exposure. There were no statistically significant changes in a number of other measured markers including tPA, D-dimer, and vWF. Moreover, in healthy men Mills et al. (2011) reported no difference in t-PA and PAI-1 antigen or activity or platelets following exposure to either DE or filtered-DE.

Taken together, there is some evidence from a single CHE study for changes in biomarker levels that would be indicative of increased risk of thrombosis and coagulation in patients with metabolic syndrome. More information on studies published since the 2009 ISA can be found in Table 6-82 below.

Table 6-82 Study specific details from controlled human exposure (CHE) studies of short-term UFP exposure and coagulation and thrombosis.

Study	Population N, Sex; Age (mean ± SD)	Exposure Details (Concentration; Duration)	Endpoints Examined
(Devlin et al., 2014)	Adults with metabolic syndrome n = 13 M; 21 F 27-70, average 15 of which carried the null allele for GSTM1	98 µg/m^3 UF CAPs (73% of which are <0.1 µm) 16,000–564,000 particles/cm^3 for 2 h at rest particles from Chapel Hill, NC	Markers of coagulation: pre,1 h post, 20 h post
(Mills et al., 2011)	Healthy men N = 16 18- 32 yr	300 µg/m^3 UFP Particles generated with diesel engine passed through 0.1 µm filter 15-min rest and cycling intervals during exposure Particle filtered exposures had UFP removed	Markers of coagulation

Note: SD = standard deviation, M = male, F = female, n = number, h = hour, GSTM1 = glutathione S-transferase Mu 1, CAP = concentrated ambient particle

6.5.12 Endothelial Dysfunction and Arterial Stiffness

Endothelial dysfunction is the physiological impairment of the inner lining of the blood vessels and is typically measured by FMD. Arterial stiffness is associated with a variety of cardiovascular risk factors and outcomes (Laurent et al., 2006) and is best measured by pulse wave velocity (PWV). More information on measures of endothelial dysfunction and arterial stiffness can be found in Section 6.1.13.

There were no studies in the 2009 PM ISA examining the relationship between exposure to UFPs and endothelial dysfunction or arterial stiffness. Since publication of the 2009 PM ISA, a single epidemiologic panel and a few CHE studies have examined the potential for UFP exposure to result in changes in measures in endothelial dysfunction. Taken together, these studies provide some evidence that exposure to UFPs can result in endothelial dysfunction.

6.5.12.1 Panel Epidemiologic Studies

There were no studies in the 2009 ISA examining associations between short-term exposures to UFPs and measures of endothelial dysfunction, and only a single study is available from the recently published literature. Ljungman et al. (2014) examined associations between UFPs and peripheral arterial tonometry, a measure of microvessel dilation, and pulse wave amplitude in the Framingham Heart Study and found positive associations for 1 to 7-day averages.

6.5.12.2 Controlled Human Exposure Studies

In the current review, BAD and FMD were both examined following UFP exposure in metabolic syndrome patients, including a subgroup with the GSTM1 null allele (Devlin et al., 2014). No effects of UFPs were observed following reactive hyperemia or nitroglycerin administration when compared to FA. In contrast, Mills et al. (2011) found that the vasodilation response to bradykinin ($p = 0.005$), acetylcholine ($p = 0.008$), and sodium nitroprusside ($p < 0.001$) were attenuated following exposure to DE (Table 6-83) relative to FA, but not following exposure to particle-filtered DE.

With respect to protein markers of endothelial dysfunction, Liu et al. (2015a) examined whether short-term exposure to UFPs increased levels of and ET-1 or VEGF. There were no increases in blood ET-1 or urine VEGF levels, but the authors did report a statistically significant ($p < 0.05$) increase in blood VEGF levels at 21 hours, but not one hour post exposure.

Taken together, the studies presented above provide some evidence of impaired vasomotor function following short-term exposure to UFPs present in diesel exhaust, but very little evidence following short-term exposure to UFP CAPs. More information on studies published since the 2009 ISA can be found in Table 6-83 below.

Table 6-83 Study specific details from controlled human exposure (CHE) studies of short-term UFP exposure and impaired vascular function.

Study	Population N, Sex; Age (mean ± SD)	Exposure Details (Concentration; Duration)	Endpoints Examined
(Devlin et al., 2014)	Adults with metabolic syndrome n = 13 M; 21 F 27-70, average 15 of which carried the null allele for GSTM1	98 µg/m^3 UF CAPs (73% of which are <0.1 µm) 16,000–564,000 particles/cm^3 for 2 h at rest particles from Chapel Hill, NC	Vascular function: pre, 1 h post, 20 h post

Table 6-83 (Continued): Study specific details from controlled human exposure (CHE) studies of short-term UFP exposure and impaired vascular function.

Study	Population N, Sex; Age (mean ± SD)	Exposure Details (Concentration; Duration)	Endpoints Examined
(Liu et al., 2015a)	Healthy adults n = 50; 18-60 yrs 28 ± 9	135.8 ± 67.2 µg/m^3 ultrafine cap for 130 min	Biomarkers of vascular function measured pre, 1 h, and 21 h post
(Mills et al., 2011)	Healthy men N = 16 18- 32 yr	300 µg/m^3 UFP Particles generated with diesel engine passed through 0.1 µm filter 15-min rest and cycling intervals during exposure Particle filtered exposures had UFP removed	Vascular function: 6-8 h post

Note: SD = standard deviation, M = male, F = female, n = number, h = hour, GSTM1 = glutathione S-transferase Mu 1, CAP = concentrated ambient particle

6.5.13 Summary and Causality Determination

In the 2009 PM ISA (U.S. EPA, 2009), the evidence from toxicological studies predominantly using DE exposures was suggestive of a causal relationship between short-term UFP exposure and cardiovascular effects. Cardiovascular effects included altered endothelial function, increased systemic oxidative stress, and altered HRV parameters. In addition, studies using UF CAPs, as well as wood smoke and DE, provided some evidence of changes in markers of blood coagulation, but results were not consistent across studies. The few epidemiologic studies of UFPs in the last review did not provide support for an association of UFPs with effects on the cardiovascular system. More recent evidence describing the relationship between short-term UFP exposure and cardiovascular effects is discussed below and summarized in Table 6-84, using the framework for causality determinations described in the Preamble to the ISAs (U.S. EPA, 2015).

Since the publication of the 2009 PM ISA, there have been a limited number of studies describing the relationship between short-term UFP exposure and cardiovascular effects. That being said, there is at least some evidence for cardiovascular effects following short-term exposure to UFPs. A small number of epidemiologic panel studies have observed positive associations between short-term exposure to UFPs and measures of HRV (Section 6.5.9.1) and markers of coagulation (Section 6.5.11.1), although there are also studies that did not report UFP-related effects. In addition, there is evidence from a single CHE study indicating decreases in the anticoagulant proteins plasminogen and thombomodulin in individuals with metabolic syndrome (Section 6.5.11.2). There was also inconsistent evidence from CHE and

epidemiologic panel studies for endothelial dysfunction, changes in blood pressure, and systemic inflammation following exposure to UFPs. Notably, there was little evidence of an effect when considering short-term UFP exposure on other cardiovascular endpoints or epidemiologic outcomes such as ED visits or hospital admissions. However, when considered as a whole, the evidence presented in Section 0 is **suggestive of, but not sufficient to infer, a causal relationship between short-term exposure to UFPs and cardiovascular effects.**

Table 6-84 Summary indicating that evidence is suggestive of, but not sufficient to infer, a causal relationship between short-term UFP exposure and cardiovascular effects.

Rationale for Causal Determination[a]	Key Evidence[b]	Key References[b]	UFP Concentrations Associated with Effects[c]
Evidence from a limited number of epidemiologic panel studies and a controlled human exposure study is generally supportive	Some evidence of positive associations in epidemiologic panel studies of HRV and coagulation A single CHE study indicating decreases in the anticoagulant proteins plasminogen and thombomodulin in individuals with metabolic syndrome.	Section 6.5.10 Section 6.5.11 Section 6.5.12 Section 6.5.13 Devlin et al. (2014)	See tables in identified sections
Limited and inconsistent epidemiologic evidence for ED visits and hospital admissions	Limited evidence does not support association with ED visits and hospital admissions for IHD Limited evidence supports association with ED visits and hospital admissions for aggregate CVD	Section 6.5.2.1 Section 6.5.7	
Uncertainty regarding potential confounding by copollutants	Single study provides limited evidence that UFP association is robust to PM_{10} and gaseous copollutants in study of stroke ED visits. Panel studies did not evaluate potential copollutant confounding	Andersen et al. (2010)	
Uncertainty regarding exposure metric and UFP size fraction	Inconsistency in the UFP metric used (i.e., NC, SC, and MC) and UFP size fraction examined complicating interpretation of results across studies.		
Uncertainty regarding exposure measurement error	Single study used personal UFP monitoring. Most studies relied on 1 monitor to measure UFPs, which is inadequate based on limited data demonstrating both that there is greater spatial variability in UFPs (i.e., NC) and that the particle size distribution changes with distance from source. Additionally, there is limited information on the temporal variability in UFP concentrations.	Hampel et al. (2014)	

Table 6-84 (Continued): Summary indicating that evidence is suggestive of, but not sufficient to infer, a causal relationship between short-term UFP exposure and cardiovascular effects.

Rationale for Causal Determination[a]	Key Evidence[b]	Key References[b]	UFP Concentrations Associated with Effects[c]
Little evidence from animal toxicological studies	The few animal toxicological studies that examined the relationship between UFP CAP exposure and CVD endpoints reported mostly negative results	(Aztatzi-Aguilar et al., 2015) Kurhanewicz et al. (2014)	
Limited evidence for biological plausibility of cardiovascular effects	There were very few studies on which to base biologically plausible pathways for the few epidemiologic studies reporting positive associations between UFP exposure and ED visits or hospital admissions	Section 6.5.1 Figure 6-36	

a = Based on aspects considered in judgments of causality and weight of evidence in causal framework in Table I and Table II of the Preamble to the ISAs (U.S. EPA, 2015).

b = Describes the key evidence and references, supporting or contradicting, contributing most heavily to causal determination and, where applicable, to uncertainties or inconsistencies. References to earlier sections indicate where full body of evidence is described.

c = Describes the UFP concentrations and metric (i.e., number concentration [NC], surface area concentration [SC], mass concentration [MC]) with which the evidence is substantiated.

1

6.6 Long-Term UFP Exposure and Cardiovascular Effects

The evidence pertaining to the effect of long-term exposure to ultrafine particles (UFPs) on the cardiovascular system reviewed in the 2009 PM ISA comprised a small number of toxicological studies that indicated the potential for long-term exposure UFP to lead to atherogenic changes. The evidence provided by these studies was characterized as "inadequate to infer the presence or absence of a causal relationship" (U.S. EPA, 2009).

The subsections below provide an evaluation of the most policy relevant scientific evidence relating-long-term UFP exposure to cardiovascular health effects. To clearly characterize and put this evidence into context, there is first a discussion of the biological plausibility of cardiovascular effects following long-term UFP exposure (Section 6.6.1). Following this discussion, the health evidence relating long-term UFP exposure and specific cardiovascular health outcomes is discussed in detail: atherosclerosis (Section 6.6.2) heart failure and impaired heart function (Section 6.6.3) increased blood pressure and hypertension (Section 6.6.4), and systemic inflammation and oxidative stress (Section 6.6.5). Considering all of the information presented above, summary and causal determinations are then presented (Section 6.6.6).

6.6.1 Biological Plausibility

There continues to be a lack of evidence for health effects following long-term exposure to UFPs. As a result, there is very little evidence for biological plausibility of health effects in humans, and thus, a biological plausibility figure was not constructed for this size fraction. However, as noted below, there is limited toxicological evidence for atherosclerosis (Li et al., 2013), impaired heart function (Aztatzi-Aguilar et al., 2015), systemic inflammation (Aztatzi-Aguilar et al., 2015) and changes in the renin-angiotensin system (Aztatzi-Aguilar et al., 2015).

6.6.2 Atherosclerosis

In the 2009 PM ISA, ultrafine CAPs derived from traffic were demonstrated to increase plaque size in ApoE$^{-/-}$ mice (Araujo et al., 2008). Since the 2009 PM ISA, Aguilera et al. (2016) reported a 2.1% increase (95%CI: 0.03, 4.10) per interdecile increase in PN and 2.3% increase (95% CI: 0.23, 4.4) per interdecile increase in Lung Deposited Surface Area (LDSA). NC (10-300 nm) concentration was measured directly with diffusion classifier for use in LUR model in this study. More information on this recently published study can be found in Table 6-85.

Table 6-85 Characteristics of the epidemiologic study examining the association of UFP with circulating markers of inflammation and coagulation.

Study	Study Population	Exposure Assessment	Concentration	Outcome	Copollutants Examined
†(Aguilera et al., 2016) 4 Cities, Switzerland Cross-sectional PNC: 2011/22 Outcome: 2010/2011	SAPALDIA N = 1,503	2 yr avg estimated at residence using LUR PNC Model R^2 = 0.85 miniature diffusion classifier (10-300 nm)	PNC Mean 11,184 (SD: 4,862) particles/cm^3	cIMT	PNC with $PM_{2.5}$ last yr r = 0.88, $PM_{2.5}$ 2001-2011 r = 0.86; $PM_{2.5}$ vehicular r = 0.86; $PM_{2.5}$ crustal 0.83

LDSA = Lung Deposited Surface Area, PNC = particle number concentration; SAPALDIA = Swiss study on Air Pollution and Lung Disease in adults; Hs-CRP = high sensitivity C-reactive Protein; cIMT = carotid intima media thickness; NR = Not reported

†Studies published since the 2009 Integrated Science Assessment for Particulate Matter.

6.6.3 Heart Failure and Impaired Heart Function

Since the 2009 PM ISA, Aztatzi-Aguilar et al. (2015) reported that long-term UFP exposure in rats resulted in thickening of the coronary artery walls. These authors also found that long-term exposure to UFP resulted in a statistically significant increase in two genes typically associated with cardiac damage in heart tissue: Acta1 and Col3a. Thus, there is limited evidence from animal toxicological studies of potential decreases in heart function following long-term UFP exposure. More information on this study can be found in Table 6-86.

Table 6-86 Study-specific details from toxicological studies of long-term UFP exposure and impaired heart function.

Study	Population N, Sex; Age (mean ± SD)	Exposure Details (Concentration; Duration)	Endpoints Examined
(Aztatzi-Aguilar et al., 2015)	Adult male Sprague-Dawley rats (n = 4 per group)	Inhalation of ultrafine PM (107 µg/m^3) for 5 h/day, 4 days/week, for 8 weeks	Coronary wall thickness, Acta 1 and Col3a1 mRNA

Note: n = number, h = hour, d = day, week = week, M = male, f = female, Acta1 = skeletal alpha-actin, Col3a1 = collagen Type 3 alpha

6.6.4 Blood Pressure and Hypertension

There were no animal toxicology studies in the 2009 PM ISA exploring the relationship between long-term exposure to UFP and the angiotensin system. Since the publication of that review, long term exposure to UFP has been reported to significantly increase mRNA levels in the heart of At2R and At1R ($p < 0.05$), but not Ace, or b1R (Aztatzi-Aguilar et al., 2015). More information on this recently published study can be found in Table 6-87 below.

Table 6-87 Study-specific details from toxicological studies of long-term UFP exposure and blood pressure (BP).

Study	Population N, Sex; Age Mean ± SD	Exposure Details Concentration; Duration	Endpoints Examined
(Aztatzi-Aguilar et al., 2015)	Adult male Sprague-Dawley rats (n = 4 per group)	Inhalation of 107 μg/m^3 ultrafine PM for 5 h/day, 4 days/week, for 8 weeks	Angiotensin and bradykinin system gene and protein expression

m = male n = number, h = hour, week = week

6.6.5 Systemic Inflammation and Oxidative Stress

As discussed in Section 6.1.1 and Section 6.1.11, inflammation has been linked to a number of CVD related outcomes. Similarly, oxidative stress can result in damage to healthy cells and blood vessels and a further increase in the inflammatory response. Thus, this section discusses the evidence for markers of systemic inflammation and oxidative stress following short-term UFP exposures.

6.6.5.1 Epidemiologic Studies

The epidemiologic evidence continues to be limited. In a recent study, Viehmann et al. (2015) observed small longitudinal changes in hs-CRP [3.8 -0.6, 8.4], fibrinogen [1.0 0.0, 2.0], WCC [1.0 -0.1, 2.1] and platelets [0.6 -0.4, 1.7] in association with an IQR increase in 365 day moving average PNC concentration among participants in the HNR study in Germany. The mean PNC concentration was 88,000 in this study.

6.6.5.2 Toxicology Studies

Since the 2009 PM ISA, Aztatzi-Aguilar et al. (2015) reported that rats exposed to UFP had increased ($p < 0.05$) IL-6 and decreased ($p < 0.05$) HO-1 protein levels in heart tissue. More information on this recently published study can be found in Table 6-88 below.

Table 6-88 Study-specific details from toxicological studies of long-term UFP exposure and systemic inflammation and oxidative stress.

Study	Study Population	Exposure Details	Endpoints Examined
(Aztatzi-Aguilar et al., 2015)	Adult male Sprague-Dawley rats (n = 4 per group)	Inhalation of 107 µg/m^3 ultrafine PM collected from a high traffic and industrial area north of Mexico City in early summer and exposed for 5 h/day, 4 days/week for 8 weeks	Markers of systemic inflammation and oxidative stress in heart tissue

Notes: m = male n = number, h = hour, d = day, week = week

6.6.6 Summary and Causality Determination

In the 2009 PM ISA, there was evidence from an animal toxicological study of increased atherosclerotic plaque size in mice following long-term exposure to UFPs. Since the publication of the 2009 PM ISA, a small number of epidemiologic studies reporting positive associations between long-term exposure to UFPs and cIMT and markers of inflammation and coagulation have become available. In addition, a single recent animal toxicological study reported evidence of impaired heart function (Section 6.6.3), as well as changes in markers associated with systemic inflammation, oxidative stress (Section 6.6.5.2), and the renin-angiotensin system following long-term UFP exposure (Section 6.6.4). However, the overall toxicological evidence base examining the effects of long-term UFP exposure on cardiovascular endpoints remains extremely limited, and thus, there is little biological plausibility for the effects observed in the epidemiologic studies mentioned above. Therefore, as in the previous review, the evidence characterizing the relationship between long-term UFP exposure and cardiovascular effects is **inadequate to infer the presence or absence of a causal relationship.** The evidence for the relationship between long-term exposure to UFPs and effects on the cardiovascular system is summarized in Table 6-89, using the framework for causality determinations described in the Preamble to the ISAs (U.S. EPA, 2015).

Table 6-89 Summary of evidence that is inadequate to infer the presence or absence of a causal relationship between long-term UFP exposure and cardiovascular effects.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	UFP PM Concentrations Associated with Effects[c]
Limited epidemiologic evidence	Long-term exposure to UFPs associated with Increase in cIMT and markers of inflammation and coagulation; Overall few epidemiologic studies of UFP health effects are conducted.	Aguilera et al. (2016) Viehmann et al. (2015)	Mean: 11,184 particles/cm^3 Mean: 88,000 particles/ml
Limited animal toxicological evidence	Long-term exposure to UFPs increased coronary artery wall thickness, markers of systemic inflammation, and some markers in the renin-angiotensin system.	Aztatzi-Aguilar et al. (2015)	
Uncertainty regarding potential confounding by copollutants	PNC strongly correlated with $PM_{2.5}$ concentrations (r = 0.88)	Aguilera et al. (2016)	
Uncertainty regarding exposure measurement error	Potentially uncharacterized spatial and temporal variation of UFP concentration limits interpretation of epidemiologic evidence		
Uncertainty regarding biological plausibility	Lack of evidence to characterize the biological plausibility of health effects following long-term PM 2.5 exposure.		

$PM_{2.5}$ = particulate matter with a nominal aerodynamic diameter less than or equal to 2.5 µm; PM_{10} = particulate matter with a nominal aerodynamic diameter less than or equal to 10 µm; $PM_{10-2.5}$ = particulate matter with a nominal aerodynamic diameter less than or equal to 10 µm and greater than a nominal diameter of 2.5 µm; SO_2 = sulfur dioxide.

[a]Based on aspects considered in judgments of causality and weight of evidence in causal framework in Tables I and II of the Preamble.

[b]Describes the key evidence and references contributing most heavily to causal determination and, where applicable, to uncertainties or inconsistencies. References to earlier sections indicate where the full body of evidence is described.

[c]Describes the $PM_{2.5}$ concentrations with which the evidence is substantiated.

CHAPTER 7 METABOLIC EFFECTS

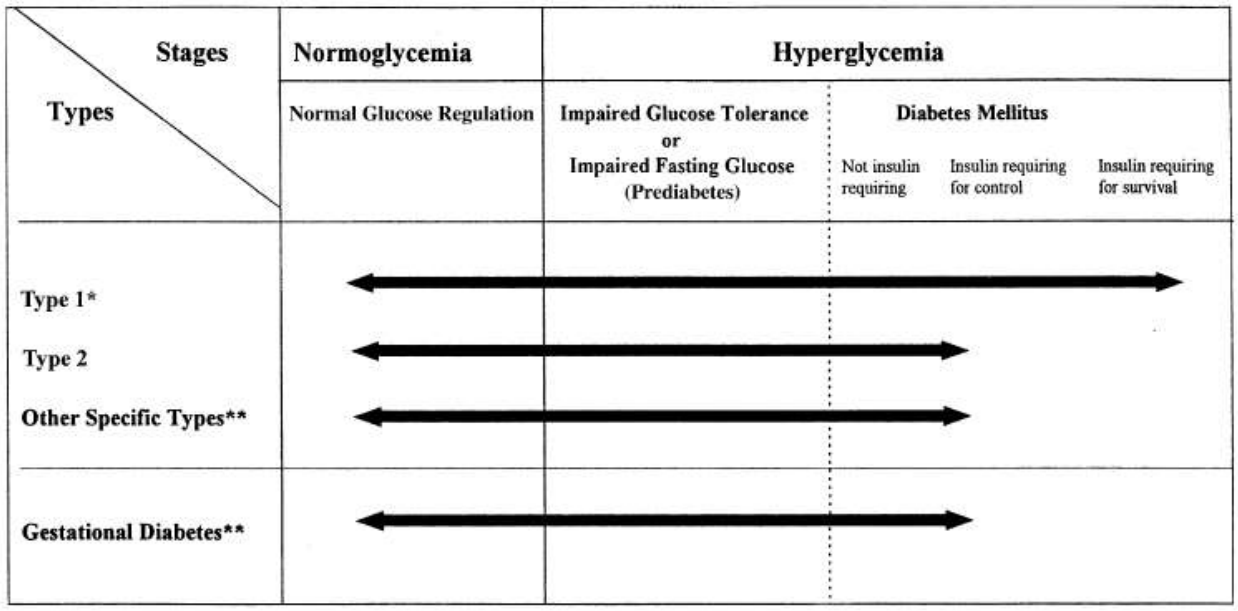
Summary of Causality Determinations for Short- and Long-Term Particulate Matter (PM) Exposure and Metabolic Effects

This chapter characterizes the scientific evidence that supports causality determinations for short- and long-term PM exposure and metabolic effects. The types of studies evaluated within this chapter are consistent with the overall scope of the ISA as detailed in the Preface (see Section P 3.1). In assessing the overall evidence, strengths and limitations of individual studies were evaluated based on scientific considerations detailed in the Appendix. More details on the causal framework used to reach these conclusions are included in the Preamble to the ISA (U.S. EPA, 2018).

Size Fraction	Causality Determination
Short-term exposure	
$PM_{2.5}$	Suggestive of, but not sufficient, to infer
$PM_{10-2.5}$	Suggestive of, but not sufficient, to infer
UFP	Inadequate
Long-term Exposure	
$PM_{2.5}$	Suggestive of, but not sufficient, to infer
$PM_{10-2.5}$	Suggestive of, but not sufficient, to infer
UFP	Inadequate

The evidence relevant to metabolic effects that was reviewed in the 2009 PM ISA included a small number of studies that examined the extent to which diabetes and metabolic syndrome-like phenotypes conferred susceptibility to PM-related health effects (U.S. EPA, 2009). Specifically, exaggerated insulin resistance, visceral adiposity and systemic inflammation in response to chronic exposure to CAPs was demonstrated in animals fed a high-fat diet. Epidemiologic studies reported some evidence for increased cardiovascular effects among people with diabetes or metabolic syndrome in association with PM_{10} exposure, providing preliminary evidence for pathophysiologic alterations experimentally demonstrated. There was no causal determination for metabolic effects in the 2009 ISA. The literature has expanded substantially with the bulk of evidence informing the relationship between long-term exposure to $PM_{2.5}$ and metabolic effects including glucose and insulin homeostasis and Type 2 diabetes (T2D).

The metabolic effects reviewed in this chapter include metabolic syndrome and its components (Table 7-1), diabetes (Table 7-2 and Figure 7-1), metabolic disease mortality as well as indicators of metabolic function that underlie metabolic and cardiovascular diseases. Studies that inform our understanding of whether people diagnosed with metabolic syndrome or diabetes are at increased risk of PM-related health effects are also discussed in CHAPTER 12, Section 12.3.2 (Populations and Lifestages Potentially at Increased Risk for PM Health Effects).



Note: *Even after presenting in ketoacidosis, these patients can briefly return to normoglycemia without requiring continuous therapy (i.e., "honeymoon" remission).

**In rare instances, patients in these categories (e.g., Vacor toxicity, Type 1 diabetes presenting in pregnancy) may require insulin for survival.

Figure 7-1 Disorders of glycaemia: etiologic types and stages.

Metabolic syndrome is a term used to describe a collection of risk factors that include high blood pressure, dyslipidemia (elevated triglycerides and low levels of high density lipoprotein [HDL] cholesterol), obesity (particularly central obesity), and increased fasting blood glucose (FBG) (Table 7-1) (Alberti et al., 2009). The presence of these risk factors may predispose one to an increased risk of T2D and cardiovascular disease (see CHAPTER 6).

Table 7-1 Criteria for clinical diagnosis of Metabolic Syndrome

Risk Factor	Threshold
Waist circumference	≥89 cm in women and ≥102 cm in males
Triglycerides[a]	≥150 mg/dL (1.7 mmol/L)
HDL-C1	<40 mg/dL (1.0 mmol/L in males); <50 mg/dL (1.3 mmol) in females
Blood pressure[b]	Systolic ≥130 and/or diastolic ≥85 mm Hg
Fasting glucose[c]	≥100 mg/dL (5.6 mmol/L)

[a]A person taking drugs used to lower triglycerides or raise HDL-C is considered to exceed the threshold.
[b]A person taking blood pressure medication is considered to exceed the threshold.
[c]A person taking glucose regulating medication is considered to exceed the threshold.
Source: Permission pending, Adapted from Alberti et al. (2009).

Diabetes is characterized by a continuum of hyperglycemia (i.e., elevated glucose level) resulting from defects in insulin signaling, secretion or both (Figure 7-1). Several types of diabetes have been classified by the American Diabetes Association (ADA) (ADA, 2014). Type 1 diabetes (T1D) is caused by β-cell dysfunction or destruction that leads to insulin deficiency (Section 7.2.7), while T2D is characterized by defects in insulin secretion in an insulin resistant environment (Section 7.2.4). Gestational diabetes mellitus (GDM) is generally diagnosed during the 2nd or 3rd trimester of pregnancy (Section 7.2.6). The diagnostic testing criteria for diabetes are listed in Table 7-2. The A1C, which is also known as the hemoglobin A1C, HbA1C, or glycohemoglobin, is a blood test that provides information about a person's average blood glucose over the past 3 months by measuring the percentage of hemoglobin (i.e., a blood protein with a 3-month lifespan) modified by glucose. In controlled human exposure, animal toxicological, and epidemiologic studies the homeostasis model assessment (HOMA) model has been widely used for the quantification of insulin resistance (HOMA-IR) and pancreatic beta cell (HOMA-β) function and used to infer diabetes risk. The HOMA-IR index is given by the product of basal insulin and glucose levels divided by 22.5, whereas the HOMA-β index is derived from the product of 20 and basal insulin levels divided by glucose concentration minus 3.5 (Wallace et al., 2004; Matthews et al., 1985).

Table 7-2 Criteria for clinical diagnosis of diabetes.

Test	Criteria
A1C	A1C ≥6.5%[a]
	OR
Fasting Plasma Glucose (FPG)	FPG ≥126 mg/dL (7 mmol/L). Fasting is defined as no caloric intake for at least 8 h.[a]
	OR
Oral Glucose Tolerance Test (OGTT)	Two-hour plasma glucose ≥200 mg/dL (11.1 mmol/L during OGTT). The test should be performed as described by the World Health Organization, using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water.[a.]
	OR
Random Glucose Test	In a person with classical symptoms of hyperglycemia or hyperglycemic crisis, a random plasma glucose ≥200 mg/dL (11.1 mmol/L).

[a]In the absence of unequivocal hyperglycemia, criteria 1–3 should be confirmed by repeat testing.

Diabetes test criteria were extracted from American Diabetes Association. Diagnosis and classification of diabetes mellitus. Diabetes Care 2014;37(Suppl. 1): S81–S90

Impaired insulin signaling is a pathophysiological effect leading to clinical outcomes including insulin resistance, increased blood glucose, and increased blood lipids. Specifically, insulin stimulates sensitive tissues to take up glucose, lipids, and amino acids. In muscle, insulin stimulates glucose oxidation or storage as glycogen and protein synthesis; in liver, insulin stimulates glycogen synthesis; and in adipose tissue, insulin stimulates lipid synthesis and storage. During a fast (overnight) plasma glucose (60–80 mg/dL) and insulin (3–8 μU/mL) levels are low; glucagon levels rise and lipids are mobilized from adipose tissue into the circulation; glycogenolysis and gluconeogenesis increase in the liver; and striated muscle metabolizes lipids and degrades proteins into amino acids (Boron and Boulpaep, 2017). When individuals do not respond properly to glucose and insulin levels (as in T2D mellitus), body fuels (glucose, lipid, and amino acid) are mobilized into the blood, putting a burden on liver, kidney, and vascular function. For example, lipid oversupply promotes hepatic steatosis, hepatic fibrosis, and atherosclerosis, which is a major contributor to cardiovascular disease (see Section 6.3.4).

7.1 Short-Term $PM_{2.5}$ Exposure and Metabolic Effects

There were no epidemiologic or toxicological studies of short-term exposure to $PM_{2.5}$ and metabolic syndrome or diabetes included in the 2009 PM ISA. In the present ISA, there are a limited

number of epidemiologic studies examining the effects of short-term $PM_{2.5}$ exposure on glucose tolerance, insulin sensitivity, and diabetes control (i.e., HbA1c levels). A small number of experimental animal studies that evaluate $PM_{2.5}$-mediated effects on glucose and insulin homeostasis are also available for review. A limited body of controlled human exposure and toxicological studies also provide some evidence that diet and genetic factors, as well as systemic and peripheral inflammation, may play a role in the $PM_{2.5}$ mediated metabolic disruption. Collectively, these studies indicate that short-term exposure to $PM_{2.5}$ may affect glucose and insulin homeostasis.

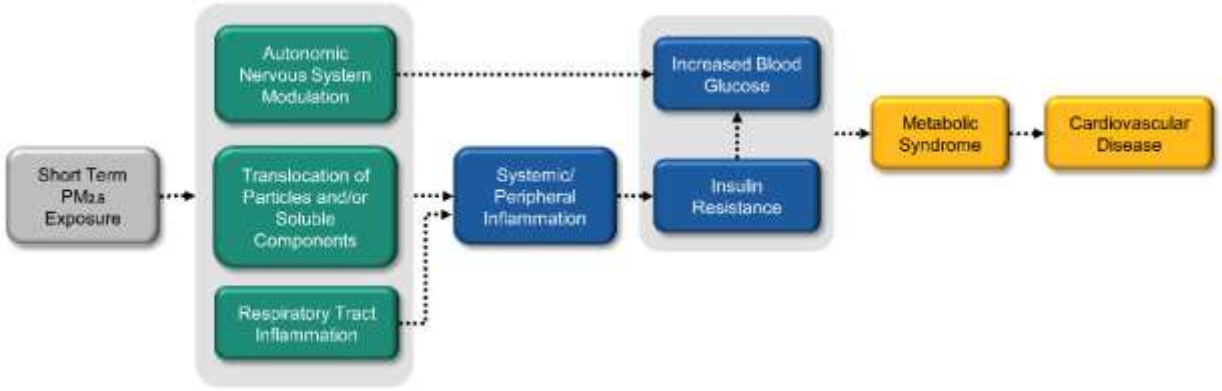
The discussion of short-term $PM_{2.5}$ exposure and metabolic effects opens with a discussion of biological plausibility (Section 7.1.1) that provides background for the subsequent sections in which groups of related endpoints are presented in the context of relevant disease pathways. These outcome groupings are glucose and insulin homeostasis (Section 7.1.2) and other indicators of metabolic function (Section 7.1.3). The collective body of evidence is integrated across and within scientific disciplines[68], and the rationale for the causality determination is outlined in Section 7.1.4.

7.1.1 Biological Plausibility

This section describes biological pathways that potentially underlie metabolic effects resulting from short-term exposure to $PM_{2.5}$. Figure 7-2 graphically depicts the proposed pathways as a continuum of upstream events, connected by arrows, that may lead to downstream events observed in epidemiologic studies. This discussion of "how" exposure to $PM_{2.5}$ may lead to metabolic health effects contributes to an understanding of the biological plausibility of epidemiologic results evaluated later in Section 7.1.

Progression from $PM_{2.5}$ exposure along the potential pathways depicted in Figure 7-2 are supported by experimental and observational evidence streams discussed below, as well as in other Chapters of the PM ISA including: dosimetry, respiratory, cardiovascular, and nervous system chapters (CHAPTER 4, CHAPTER 5, CHAPTER 6, and CHAPTER 8, respectively). CHAPTER 4 discusses the PM administered dose dependence on deposition, which is a function of particle size, intake, and physical chemistry as well as modifying factors such as lifestages and species. The available evidence for $PM_{2.5}$ is organized into potential pathways that include autonomic nervous system (ANS) modulation, translocation of soluble components and respiratory tract inflammation that converge upon systemic inflammation leading to insulin resistance and metabolic risk factors, metabolic syndrome, or comorbidities. Although the specific details underlying these proposed pathways are unclear, evidence from experimental and epidemiologic studies implicate relationships between short term $PM_{2.5}$ exposure and metabolic effects. Further, metabolic syndrome risk factors can lead to complications and comorbidities.

[68] As detailed in the Preface, risk estimates are for a 10 $\mu g/m^3$ increase in 24-hour avg $PM_{2.5}$ concentrations unless otherwise noted.



The boxes above represent the effects for which there is experimental or epidemiologic evidence, and the dotted arrows indicate a proposed relationship between those effects. Shading around multiple boxes denotes relationships between groups of upstream and downstream effects. Progression of effects is depicted from left to right and color-coded (grey, exposure; green, initial event; blue, intermediate event; orange, apical event). Here, apical events generally reflect results of epidemiologic studies, which often observe effects at the population level. Epidemiologic evidence may also contribute to upstream boxes. When there are gaps in the evidence, there are complementary gaps in the figure and the accompanying text below.

Figure 7-2 Potential biological pathways for metabolic effects following short-term $PM_{2.5}$ exposure.

The central nervous system (CNS) and ANS pathways have the potential for activation due to stimulation of sensory nerves that are further described in CHAPTER 4 and CHAPTER 8. Soluble components of $PM_{2.5,}$ and poorly soluble particles that are part of the $PM_{2.5}$ fraction and smaller than approximately 200 nm, may translocate into the systemic circulation and contribute to inflammatory or other processes in extrapulmonary compartments (CHAPTER 4). The extent to which translocation into the systemic circulation occurs is currently uncertain. A study from the 2009 PM ISA (Campbell et al., 2005) described a proinflammatory response in the brain that was accompanied by increases in cytokines TNFα and IL-1α that functionally stimulate and enhance the inflammatory response (see CHAPTER 8). More recent evidence describes promotion of inflammatory gene expression (Section 8.1.3.2), and it is possible that these immune signaling molecules may initiate an innate immune response transmitted through the circulation to other organs tissues. Furthermore, Balasubramanian et al. (2013) found that $PM_{2.5}$ increased the neurotransmitter norepinephrine and the endocrine hormone corticotrophin releasing hormone (CRH) in the hypothalamus. Although Balasubramanian et al. (2013) measured norepinephrine hours after exposure, an increase in the neurotransmitter may mobilize the ANS. The ANS may activate a "flight or fight" response that not only increases vasoconstriction, heart rate and blood pressure, but also mobilizes glucose into the blood stream. Similarly, CRH release stimulates glucocorticoid synthesis marked by a stress response that leads to mobilization of energy stores (i.e., glucose and lipids) into the blood stream (Section 7.1.2.2).

Respiratory tract inflammation leading to inflammatory mediator diffusion from the lung is another potential part of a pathway leading to systemic inflammation (see CHAPTER 5 and CHAPTER

6), systemic oxidative stress, and peripheral inflammation, as indicated by Kim et al. (2015) from human liver function measures (Section 7.1.4) and Sun et al. (2013) from rodent adipose tissue. Once in the circulation inflammatory mediators (such as cytokines, damage associated molecular patterns [DAMPs], and oxidized lipids) may further stimulate the immune response by interacting with endothelium leading to coordination of immune signaling from the circulatory system into peripheral tissues. Short term $PM_{2.5}$ exposure reduced the antioxidant and anti-inflammatory capacity of HDL particles (CHAPTER 6) (Hazucha et al., 2013). These collective responses can stimulate the migratory capacity and increase infiltration of inflammatory cells as demonstrated by Xu et al. (2013) (Section 7.1.3.1), but also interfere with insulin signaling by stimulating the nuclear factor kappa-light-chain-enhancer of activated B cells (NFκβ) pathway via toll-like receptor (TLR) activation (further discussed in Section 7.2.1). Of note, TLR activation interfered with insulin-mediated stimulation of the IRS/PI3K/Akt signaling pathway leading to impaired expression and/or function of insulin signaling components (de Luca and Olefsky, 2008). Further, Haberzettl et al. (2016) identified that short-term $PM_{2.5}$ exposure led to insulin resistance in aortas as measured by failure of insulin to stimulate Akt phosphorylation in mice. Collectively, these findings provide a potential pathway connecting systemic and peripheral inflammation to insulin resistance. Consistent with these experimental animal findings Brook et al. (2013b) reported an association of short-term exposure to $PM_{2.5}$ with increased glucose, insulin and HOMA-IR among healthy subjects and Zanobetti et al. (2014) reported a small increase in hospital admissions for diabetes in association with short-term exposure to $PM_{2.5}$.

As described here, there are proposed pathways by which short-term exposure to $PM_{2.5}$ could lead to metabolic health effects. One pathway involves CNS and ANS activation, translocation of soluble components, and pulmonary inflammation that may lead to systemic inflammation and inflammation of other peripheral organs that is linked to insulin resistance and metabolic syndrome comorbidities. ANS modulation that can also lead to activation of a "flight-or-fight" response increasing blood glucose that is linked to metabolic syndrome. While experimental studies involving animals contribute most of the evidence of upstream effects, epidemiologic studies found associations between short-term $PM_{2.5}$ exposure and both insulin resistance and cardiovascular disease endpoints. Together, these proposed pathways provide biological plausibility for epidemiologic results of metabolic health effects and will be used to support a causal determination, which is discussed later in the chapter (Section 7.1.4).

7.1.2 Glucose and Insulin Homeostasis

Insulin is secreted by β-cells within the pancreas in response to glucose levels. When glucose levels rise, depolarization of the pancreatic β-cells or modulation by other hormones stimulate insulin secretion. Thus, during feeding, blood insulin levels rise stimulating glucose uptake and replenishment of body fuel reserves in the form of triglycerides and glycogen. When insulin levels decrease (e.g., during fasting) fuels such as lipids from adipose tissue and amino acids from muscle are mobilized to the blood

stream where they are used by the liver to synthesize glucose (Section 7.1.1). Notably, the effects of short-term exposure to $PM_{2.5}$ on glucose and insulin homeostasis may be transient.

7.1.2.1 Epidemiologic Studies

Several epidemiologic studies examined the relationship of short-term exposure to $PM_{2.5}$ with indicators of glucose and insulin homeostasis (Table 7-3). Peng et al. (2016) found that short-term exposures (i.e., 1-, 7- and 28-day averages) were associated with increased FBG and a higher odds of impaired fasting glucose (IFG), defined as fasting blood glucose <100 mg/dL. These authors also reported that ICAM-1 promotor methylation mediated the association with 28-day average exposure to $PM_{2.5}$ and FBG. Brook et al. (2013b) reported increased glucose, insulin and HOMA-IR among healthy subjects exposed to $PM_{2.5}$ during 5-day exposure blocks. Lucht et al. (2018b) reported an increase in blood glucose level [0.80 mg/dL (95% CI: 0.33, 1.26)] in association with 28-day average $PM_{2.5}$ exposure among those without diabetes enrolled in the Heinz Nixdorf Recall (HNR) study. An association of HbA1c with 91-day average $PM_{2.5}$ exposure was also observed in this study (see Section 7.2.3). Results from a large retrospective cohort study in Israel did not report evidence to support associations of 24-hour or 7-day average $PM_{2.5}$ exposure with glucose level, glycated hemoglobin (HbA1c), or lipids, although a 3-month average exposure was associated with HbA1c and lipid level (Yitshak Sade et al., 2016) (see Section 7.2.3). Finally, Zanobetti et al. (2014) reported an increase in hospitalizations for diabetes in association with 2-day average concentrations of $PM_{2.5}$ (RR: 1.01 [95% CI: 1.00, 1.02]) most likely reflecting the risk of diabetes-related complications among those with diabetes. Overall, the small number of studies indicate that short-term exposure to $PM_{2.5}$ (1−7 days) may affect glucose and insulin levels among those without diabetes, and consequent increases in hospital admissions for conditions related to diabetes. None of these studies examined the extent to which confounding by copollutants may have influenced their findings.

Table 7-3 Epidemiologic studies of short-term exposure to $PM_{2.5}$ and effects on glucose and insulin homeostasis.

Study	Study Population	Exposure Assessment	Concentration $\mu g/m^3$	Outcome	Copollutants Examined

†Studies published since the 2009 PM ISA.

7.1.2.2 Toxicological Studies

Toxicological studies provided some evidence that $PM_{2.5}$ may impair the insulin signaling pathway leading to effects on glucose and insulin homeostasis (Table 7-4). Haberzettl et al. (2016) reported that insulin increased ($p < 0.05$) Akt phosphorylation, which is a marker of insulin sensitivity, in the aortas of mice breathing filtered air, whereas no insulin-stimulated phosphorylation of Akt was identified in short-term $PM_{2.5}$ CAPs exposed mice. This effect was also observed following long-term exposure to $PM_{2.5}$ (Section 7.2) and may precede changes in glucose tolerance or insulin resistance. When Haberzettl et al. (2016) treated mice with the insulin sensitizers metformin or rosiglitazone, aortic insulin signaling (also measured via Akt phosphorylation) was unaffected in exposed mice, whereas vascular insulin resistance and inflammation induced by $PM_{2.5}$ CAPs exposure were prevented (Section 7.1.3). Notably, treatment with or without the insulin sensitizers had no effect on blood glucose, plasma insulin levels, or the HOMA-IR or HOMA-β scores (Haberzettl et al., 2016). Liu et al. (2014b) reported insulin resistance (measured by HOMA-IR) at 1 and 3 weeks after $PM_{2.5}$ CAPs exposure. Balasubramanian et al. (2013) reported an acute increase ($p < 0.05$) in norepinephrine (NE) in the paraventricular nucleus and corticotrophin releasing hormone (CRH) in the median eminence of the hypothalamus of Lean Brown Norway rats 1 day, but not 3 days after $PM_{2.5}$ exposure. Norepinephrine increases suggest activation of the sympathetic nervous system, whereas increased CRH may activate the HPA stress axis leading to glucocorticoid release and mobilization of glucose, lipids, and amino acids to the blood stream (see CHAPTER 8).

Table 7-4 Study specific details from animal toxicology studies of metabolic homeostasis.

Study	Study Population	Exposure Details	Endpoints Examined
Balasubramanian et al. (2013)	Rat, male, adult Brown Norway or 4 or 8 mo. old JCR-LA (spontaneous obesity, hyperlipidemic, insulin resistant), n = 16	Grand Rapids, MI CAPs 519 μg/m^3 for 1 day and 595 μg/m^3 for 3 days; JCR/LA rats, Detroit, MI CAPs 291 μg/m^3 for 4 days; whole body inhalation. Study	Study Population	Exposure Details	Endpoints Examined
Haberzettl et al. (2016)	Mouse, male, C57BL/6J, ND or HFD, 8−12 weeks, n = 4−8	Louisville, KY CAPs $PM_{2.5}$; 30−100 µg/m^3 Group 1: exposed for 6 h/day for 9 days. Group 2: treated with daily dose of water, metformin (50 mg/kg dose 2 days before, 100 mg/kg dose 1 day before and 300 mg/kg at the time of $PM_{2.5}$ exposure), or 1 mg/kg rosiglitazone 2 mg/kg 2 days before 9 days CAP exposure in drinking water.	Body weight, fasting blood glucose and insulin, HOMA-IR, organ weights, blood lipids, liver clinical chemistry, insulin signaling pathway, circulating bone marrow derived stem cells, Blood triglycerides, HDL, LDL, HDL/LDL
Ito et al. (2008)	Adult male Wistar Kyoto rats	Yokahama City, Japan CAPs collected during May 2004 (1.3 mg/m^3 ± 0.1), November 2004 (1.0 mg/m^3 ± 0.3), and September 2005 (1.9 mg/m^3 ± 0.4). Rats were exposed 4 days (4.5 h/day) or to FA for 3 days and CAPs for 1 day or to FA for 4 days	Blood pressure, HR and mRNA markers from heart tissue of HO-1, TBARS, ETA, cardiovascular disease (ET-1, ETA, ACE, ANP, BNP, Tnfα, Il-1B)
Seagrave et al. (2008)	Adult male Sprague-Dawley rats, 8−10 weeks old	Nose-only inhalation, $PM_{2.5}$ road dust from New York City, Los Angeles, and Atlanta at low (306 µg/m^3) and high (954 µg/m^3), one 6 h exposure	Heart tissue, oxidative stress, TBARS
Sun et al. (2013)	Rat, male, Sprague Dawley, ND or high fructose, 8 weeks, n = 7−8	Dearborn, MI CAPs $PM_{2.5}$; 356 µg/m^3; 8 h/day, 5 day/week for 9 days over 2 weeks, whole body inhalation	Body weight, inflammation, adipose tissue gene expression, iNOS, mitochondrial area
Wagner et al. (2014a)	Rat, male, Sprague Dawley, ND or high fructose, n = 7−8 per group	Dearborn, MI CAPs $PM_{2.5}$; 356 ± 87 µg/m^3, 441 ± 65 µg/m^3 for O_3 and $PM_{2.5}$ or O_3 alone. O_3 average was 0.485 ± 0.042 ppm for 8 h/day for 9 consecutive weekdays (Week 1 M-F, Week 2 M-Th)	Heart rate, heart rate variability, blood pressure
Wagner et al. (2014b)	Rat, male, SH (spontaneously hypertensive), 12−13 weeks, n = 8	Dearborn, MI CAPs $PM_{2.5}$; Study 1: 415 ± 99 µg/m^3 $PM_{2.5}$ Study 2: 642 ± 294 µg/m^3 $PM_{2.5}$ Study 3: 767 ± 256 µg/m^3 $PM_{2.5}$ Study 4: 364 ± 58 µg/m^3 $PM_{2.5}$ 8 h exposure repeated for 4 consecutive days	Distribution of major components, heart rate, lnSDNN, lnRMSSD, MAP, systolic, diastolic, associations between components and cardiac responses
Xu et al. (2013)	Mouse, male, C57BL//6, n = 6/group, 4 weeks old	Columbus, OH CAPs $PM_{2.5}$; (143.8 µg/m^3), 6 h/day, 5 days/week for 5, 14 or 21 days	Adipose gene expression, adipose inflammation, inflammatory cell migration capacity

1

7.1.2.3 Summary

A limited body of epidemiologic and experimental animal studies provide evidence that short-term exposure to $PM_{2.5}$ may affect glucose and insulin homeostasis. However, effects may be transient, so the upstream consequences are somewhat uncertain.

7.1.3 Other Indicators of Metabolic Function

7.1.3.1 Inflammation

Inflammation plays a critical role in the development of T2D and atherosclerosis leading to CHD (Section 7.1.1, CHAPTER 6). As outlined in the Section 7.1.1 (Biological Plausibility), systemic inflammation may promote a peripheral inflammatory response in organs and tissues, such as liver and adipose tissues. Consistent with the 2009 PM ISA, the evidence for systemic inflammation following short-term exposure to $PM_{2.5}$ is limited with some studies reporting changes in markers of inflammation such as the cytokine IL-6 and inflammatory proteins such as CRP while other studies do not show changes in these and other markers. Acute inflammation is transient in nature, inflammatory response is dynamic, and there is technical difficulty in measuring cytokine levels that may be at or below baseline levels, however (Angrish et al., 2016b).

Recent experimental and epidemiologic studies (Section 6.1.11) report at least some evidence of $PM_{2.5}$ mediated effects on systemic inflammation. For example, Behbod et al. (2013) reported that exposure to $PM_{2.5}$ CAP resulted in healthy adults having increased blood leukocytes and neutrophils at 24 hour, but not 3 hour post exposure. In an additional study, Urch et al. (2010) used two different $PM_{2.5}$ CAP exposure levels and reported a statistically significant increase ($p < 0.05$) in blood IL-6 levels following CAP exposure at 3-hour, but not immediately after or the day after exposure. In contrast, Liu et al. (2015) did not report a statistically significant change in Il-6 or CRP. Results from animal toxicology studies reported $PM_{2.5}$ mediated increases in ROS, suggesting oxidative stress (Ito et al., 2008; Seagrave et al., 2008). Evidence in support of systemic inflammation was also provided by a study in which mice exposed to $PM_{2.5}$ CAPs had increased ($p < 0.05$) monocyte chemoattractant protein 1 levels, while Tnf α, and Il 12 were not significantly altered (Xu et al., 2013). Epidemiologic panel studies were similar to CHE and animal toxicology studies in that some of these analyses showed increases in markers of systemic inflammation while others did not (Section 6.1.11.1). Although the above results are seemingly inconsistent, markers of systemic inflammation such as cytokines are often transiently expressed, thus making it difficult to consistently find changes across studies using a variety of methodological approaches (see Section 6.1).

Inflammation of peripheral organs and tissues were reported in animal toxicology studies. Xu et al. (2013) evaluated adipose inflammation concurrently with systemic inflammation in mice exposed to Columbus, OH $PM_{2.5}$ CAPs for 5, 14, or 21 days. The investigators found that the mRNA levels of visceral adipose tissue *Il-6* was increased ($p < 0.05$) at 5 days after exposure, while, no change in *Nos2*, *Tnfα*, *Arg-1*, or *Il-10* were detected (Xu et al., 2013). Furthermore, there was an increase in in the number of macrophages in the epididymal adipose tissue of $PM_{2.5}$ exposed mice at 5 days ($p < 0.05$) and 21 days ($p < 0.001$) post exposure compared to filtered air controls. A migratory cell assay evaluated and found that the migratory capacity of macrophages ($p < 0.0001$) and neutrophils ($p < 0.05$) was increased, suggesting that $PM_{2.5}$ altered the chemokine composition in visceral adipose tissue (Xu et al., 2013). Sun et al. (2013) provided evidence that $PM_{2.5}$ may exacerbate pre-existing conditions. Specifically, the authors identified increased monocyte/macrophage infiltration in rat epicardial and perirenal adipose tissue that was exacerbated by high fructose diet feeding for 8 weeks prior to exposure as well as oxidative stress (measured by iNOS immunofluorescence) (Sun et al., 2013).

Overall, some studies report increased markers of systemic inflammation following, or in association with, short-term exposure to $PM_{2.5}$. Inconsistency across short-term exposure studies may be related to several factors including the transient nature of the effects. For example, CHE studies examined responses from blood after several hours whereas animal toxicology studies examine responses from blood and other tissues after several days. A limited number of studies provide additional evidence that short-term exposure to $PM_{2.5}$ may result in inflammation of the visceral or perirenal adipose tissue, which is particularly relevant to metabolic function and a risk factor for metabolic syndrome.

7.1.3.2 Liver Function

The liver, which is strategically situated between the portal and systemic circulation, is the site for primary energy and xenobiotic metabolism (Boron and Boulpaep, 2017). Another important liver function is synthesis and degradation of proteins, carbohydrates, and lipids for distribution to extrahepatic tissues depending on energy needs. Finally, the liver regulates whole body cholesterol balance via biliary excretion of cholesterol, cholesterol conversion to bile acids, and by regulating cholesterol synthesis (Boron and Boulpaep, 2017). Consequently, the liver is an essential regulator of whole body metabolism and energy homeostasis.

Acute-phase liver proteins, such as CRP, can act as sensors of liver function and were discussed in more detail in CHAPTER 6, Section 6.2.11. Specifically, there were several epidemiologic studies that found associations between CRP, a protein produced by the liver in response to acute systemic inflammation. These proteins, in combination with other liver enzymes can give information about overall health, including liver function. In a panel study of older adults in Seoul Korea. Kim et al. (2015) reported increases (1−2%) in γ-glutamyl transpeptidase (γ-GTP, a marker of cholestatic function), aspartate aminotransferase (AST, a marker of acute inflammation, not necessarily liver specific) and alanine

aminotransferase (ALT, a marker of liver injury) in association with short-term $PM_{2.5}$ exposure (lag day 3). The mean concentration was 23.2 µg/m^3 during the study. In contrast, Haberzettl et al. (2016) found no change in the liver enzymes (including AST and ALT) in an animal model.

7.1.3.3 Blood Lipids

7.1.3.3.1 Epidemiologic Studies

Epidemiologic studies of short-term exposure to $PM_{2.5}$ and changes in blood lipids are limited in number. Chen et al. (2016) examined lagged exposure periods from 0−90 days, selecting the period with the best model fit using Akaike Information Criterion (AIC). Short-term (up to 14−day cumulative averages) were associated with changes in HDL to LDL cholesterol ratio, total cholesterol and LDL that were consistent with reduced metabolic function.

7.1.3.3.2 Toxicological Studies

Controlled human exposure studies of metabolic homeostasis are described in Table 7-5. Ramanathan et al. (2016) reported an increasing trend in the HDL oxidant index (HOI) that became significant ($p < 0.05$) when compared to the baseline HOI at 1 hour, but not 20 hours post exposure. These results suggested that PM reduced the antioxidant and anti-inflammatory capacity of HDL particles (Section 6.2.11). Hazucha et al. (2013) identified specific effects on blood lipids and reported a 4.5 and 4.1% decrease ($p < 0.05$) in blood HDL 3 and 22 hours after controlled chamber exposure to $PM_{2.5}$ CAPs in ex- and lifetime smokers. In contrast, short term animal toxicology studies reported no $PM_{2.5}$-mediated effects on blood triglycerides, HDL, LDL, or HDL/LDL ratio (Haberzettl et al., 2016).

Table 7-5 Study specific details from controlled human exposure studies of metabolic homeostasis.

Study	Study Population	Exposure Details	Endpoints Examined
Hazucha et al. (2013).	Current and ex-smokers; n = 11; 3 M, 8 F 35−74 yr	Chapel Hill, NC, 108.7 ± 24.8 µg/m^3 $PM_{2.5}$ for 2 h at rest	Blood HDL
Ramanathan et al. (2016).	Healthy adults n = 13 M, 17 F; 18−50 yr 28 ± 9	Toronto, Ontario. 148.5 ± 54.4 µg/m^3 $PM_{2.5}$ (652,259 ± 460,843 particles ≥ 0.3 µm, 2,987 ± 1,918 particles ≥ 2.0 µm) 2 h exposure at rest	HDL antioxidant index

7.1.3.4 Blood Pressure

Short-term $PM_{2.5}$ mediated effects on blood pressure are discussed in detail in the Cardiovascular Chapter (CHAPTER 6, Section 6.1.6). Positive associations between short-term $PM_{2.5}$ exposures and changes in SBP or DBP were not consistently reported in epidemiologic studies. A few CHE studies indicated that $PM_{2.5}$ CAPs may affect BP, however, there were also studies that found no $PM_{2.5}$-mediated effect. Similarly, the animal toxicology studies found little to no $PM_{2.5}$-mediated effects on BP in healthy animals, whereas BP was increased ($p < 0.05$) in the SH rat model (Wagner et al., 2014b), but decreased ($p < 0.05$) in a metabolic disease model (Wagner et al., 2014a). A similar PM exposure mediated an acute decrease ($p < 0.05$) in BP in corpulent JCR rats (Balasubramanian et al., 2013).

7.1.4 Summary and Causality Determination

There were no studies of the effect of short-term $PM_{2.5}$ exposure and metabolic effects reviewed in the 2009 PM ISA (U.S. EPA, 2009). Recent studies provide some evidence supporting effects on glucose and insulin homeostasis and other indicators of metabolic function. Evidence pertaining to the relationship between short-term exposure to $PM_{2.5}$ and metabolic effects is summarized in Table 7-6, using the framework for causality determination described in the Preamble to the ISAs (U.S. EPA, 2015).

Recent epidemiologic studies have demonstrated increased FBG, insulin, and HOMA-IR (Lucht et al., 2018a; Peng et al., 2016; Brook et al., 2013b) in association with short-term $PM_{2.5}$ exposure. Yitshak Sade et al. (2016) found no association with blood glucose or lipids and $PM_{2.5}$ exposure, although a positive association between $PM_{2.5}$ exposure (3-month average) and HbA1c, a measure of blood glucose control, was observed. An animal toxicological study provided some evidence for $PM_{2.5}$ impairment of the insulin signaling pathway (Haberzettl et al., 2016). Limited animal toxicology studies provided some evidence for inflammation in the visceral adipose tissue (Xu et al., 2013). Although the controlled human exposure evidence is inconsistent possibly due to the transient nature of inflammation (Section 7.1.3.1), there is epidemiologic evidence of an increase in inflammatory markers in the liver, i.e., γ-GTP, ALT, and AST (Kim et al., 2015). In summary, evidence for a relationship between short-term $PM_{2.5}$ exposure and metabolic effects is based on a small number of epidemiologic and toxicological studies reporting effects on glucose and insulin homeostasis and other indicators of metabolic function such as inflammation in the visceral adipose tissue and liver. **Overall, the collective evidence is suggestive of, but not sufficient to infer, a causal relationship between short-term $PM_{2.5}$ exposure and metabolic effects.**

Table 7-6 Summary of evidence indicating that the evidence is suggestive of, but not sufficient to infer, a causal relationship between short-term $PM_{2.5}$ exposure and metabolic effects.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{2.5}$ Concentrations Associated with Effects[c]
Evidence of association from a limited number of high quality epidemiologic studies at relevant $PM_{2.5}$ concentrations.	Short term exposures were associated with increased fasting blood glucose, insulin, HOMA-IR and hospitalization for conditions related to diabetes.	†Peng et al. (2016) †Brook et al. (2013b)	1-day mean 10.9 5-day avg 11.5
No consideration of confounding by copollutants.	Epidemiologic studies did not present copollutant models.	Section 7.1.2.1	
Coherence across lines of evidence and related endpoints.	Small number of experimental studies report effects on glucose and insulin homeostasis providing evidence for direct effects on metabolism.	Section 7.1.2.2 Figure 7-2	
Limited biological plausibility.	Small number of studies demonstrating plausibility of pathways involving insulin resistance, systemic inflammation and peripheral inflammation.	Section 7.1.2.2 Section 7.1.3

[b]Describes the key evidence and references, supporting or contradicting, contributing most heavily to causal determination and, where applicable, to uncertainties or inconsistencies. References to earlier sections indicate where full body of evidence is described.

[c]Describes the $PM_{2.5}$ concentrations with which the evidence is substantiated.

7.2 Long-term $PM_{2.5}$ Exposure and Metabolic Effects

An animal toxicology study (Sun et al., 2009) that showed enhanced insulin resistance, visceral adiposity, and adipose inflammation in a diet-induced obesity mouse model was reviewed in the 2009 PM 1SA. In the present ISA, multiple epidemiologic and experimental studies of glucose and insulin homeostasis and diabetes, as well as other outcomes are available for review. Overall, there is evidence from some studies that long-term exposure to $PM_{2.5}$ can affect glucose and insulin homeostasis but prospective epidemiologic studies do not report consistent positive associations with the incidence of T2D.

The discussion of long-term $PM_{2.5}$ exposure and metabolic effects opens with a discussion of biological plausibility (Section 7.2.1) that provides background for the subsequent sections in which groups of related endpoints are presented in the context of relevant disease pathways. These outcome groupings are metabolic syndrome (Section 7.2.2), glucose and insulin homeostasis (Section 7.2.3), T2D

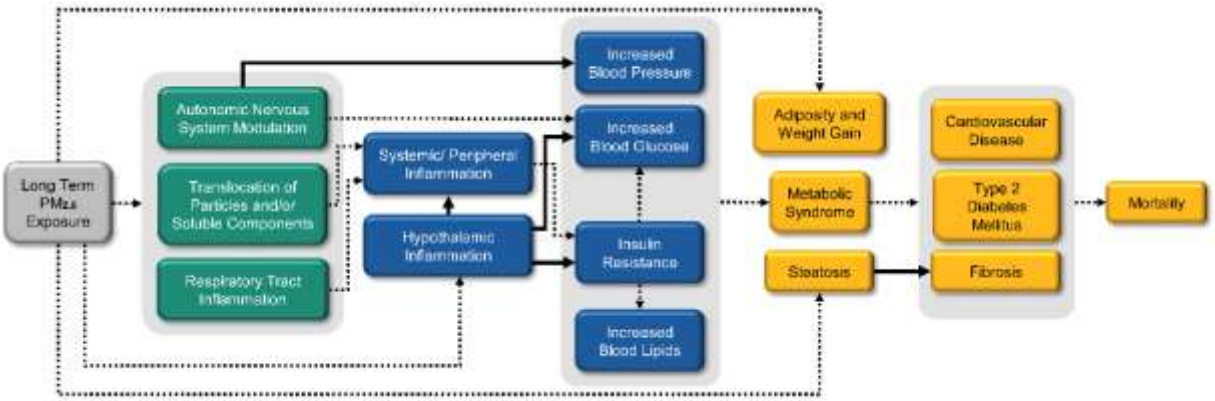
(Section 7.2.4), and other indicators of metabolic function (Section 7.2.5). Gestational diabetes and Type 1 diabetes are discussed in Section 7.2.6 and Section 7.2.7, respectively. Summary discussion for $PM_{2.5}$ components (Section 7.2.8), copollutant confounding (Section 7.2.9) and metabolic disease mortality (Section 7.2.10) follow. The collective body of evidence is integrated across and within scientific disciplines[69], and the rationale for the causality determination is outlined in Section 7.2.11.

7.2.1 Biological Plausibility

This section describes biological pathways that potentially underlie metabolic health effects resulting from long-term exposure to $PM_{2.5}$. Figure 7-3 graphically depicts the proposed pathways as a continuum of upstream events, connected by arrows, that may lead to downstream events observed in epidemiologic studies. This discussion of "how" exposure to $PM_{2.5}$ may lead to metabolic health effects contributes to an understanding of the biological plausibility of epidemiologic results evaluated later in Section 7.2.

The health sections below include numerous new long-term $PM_{2.5}$ exposure studies that further inform the potential pathways leading to metabolic effects. In the short-term $PM_{2.5}$ biological plausibility (Section 7.1.1) potential pathways were described that implicitly support proposed relationships between short term $PM_{2.5}$-mediated biological effects that collectively alter energy homeostasis to promote metabolic syndrome. New evidence gleaned from long-term $PM_{2.5}$ exposure studies expands the evidence pertaining to biological plausibility as well as our implicit understanding of the pathological continuum underlying metabolic disease development and progression. Specifically, the long-term exposure studies inform disease onset or longitudinal changes in measured endpoints that cannot be ascertained through the application of a short-term exposure study design. Furthermore, in some experimental studies, endpoints observed in short-term exposure studies are part of a long-term study and, therefore, do not include evidence gathered at animal sacrifice. Expansion of the pathways described in Section 7.1 are supported not only by the long-term exposure evidence described in this section, but also experimental and observational evidence described in the dosimetry, pulmonary, nervous system, and cardiovascular chapters (CHAPTER 4, CHAPTER 5, CHAPTER 6, and CHAPTER 8, respectively).

[69] As detailed in the Preface, risk estimates are for a 5 $\mu g/m^3$ increase in annual $PM_{2.5}$ concentrations unless otherwise noted.



The boxes above represent the effects for which there is experimental or epidemiologic evidence, and the dotted arrows indicate a proposed relationship between those effects. Shading around multiple boxes denotes relationships between groups of upstream and downstream effects. Progression of effects is depicted from left to right and color-coded (grey, exposure; green, initial event; blue, intermediate event; orange, apical event). Here, apical events generally reflect results of epidemiologic studies, which often observe effects at the population level. Epidemiologic evidence may also contribute to upstream boxes. When there are gaps in the evidence, there are complementary gaps in the figure and the accompanying text below.

Figure 7-3 Potential biological pathways for metabolic effects following long-term $PM_{2.5}$ exposure.

Inhalation of $PM_{2.5}$ may initiate pathways that include ANS activation, translocation of particles and/or soluble components, and respiratory tract inflammation that converge upon inflammation leading to insulin resistance (previously described in Section 7.1.1). The long-term exposure toxicological evidence from inhibitor studies in diabetic mouse models (Section 7.2.3.2) provide important evidence for connecting these initial pathways to metabolic syndrome risk factors and clinical outcomes. Aside from inflammatory mediator diffusion from the lung into the systemic circulation, inhibitor studies in a diabetic mouse model provide evidence that increased hypothalamic inflammation, mediated by the NFκβ signaling pathway, is sufficient to promote long term $PM_{2.5}$ mediated glucose intolerance, insulin resistance, increases in circulating inflammatory monocytes, and increases in inflammatory gene expression in peripheral tissues including liver, adipose, and heart (Zhao et al., 2015; Liu et al., 2014b) (CHAPTER 6 and CHAPTER 8). The convergence of these pathways on glucose and insulin disruption is notable since multiple studies, albeit from the same group of investigators evaluating $PM_{2.5}$ CAPs collected from the same Columbus, OH air shed, identified that long-term $PM_{2.5}$ exposure elicited insulin resistance and increased blood glucose/glucose intolerance in healthy mice (Section 7.2.3.2). Further molecular analysis of proteins involved in the NFκβ and insulin signaling pathways consistently showed that long-term $PM_{2.5}$ exposure decreased Akt phosphorylation in tissues including liver, adipose, heart, and skeletal muscle (Section 7.2.5.1), providing a potential connection between inflammatory mediator diffusion in the circulatory system leading to peripheral organ/tissue inflammation and insulin resistance. Zheng et al. (2013) indicated these effects were possibly mediated by activation of Toll-like receptor 4 (TLR4), c-Jun N-terminal kinase (JNK) and NFκβ, leading to suppression of the insulin-receptor substrate

1 (IRS-1) signaling and, consequently, decreased Akt phosphorylation leading to impaired insulin
2 signaling. These findings are consistent with the decreased Akt phosphorylation finding after short term
3 $PM_{2.5}$ exposure to CAPs collected from the Louisville, KY air shed (Haberzettl et al., 2016) and support a
4 continuum for $PM_{2.5}$ metabolic effects on insulin resistance.

5 In addition to the immune activation and NFκβ signaling pathways discussed above, evidence
6 from genetic knockout models also supports roles for TLR4 and NADPH oxidase pathways leading to
7 monocyte recruitment and inflammation. Mice with nonfunctional neutrophil NADPH oxidase activity,
8 which is required for superoxide anion production, were protected from $PM_{2.5}$-induced increases in
9 superoxide production (Kampfrath et al., 2011), insulin resistance, increase in abdominal mass and
10 visceral adiposity, and fibrosis in mice (Zheng et al., 2015; Xu et al., 2010). Kampfrath et al. (2011)
11 found that genetic knockout of *Tlr4* protected mice from $PM_{2.5}$-mediated increases in circulating
12 monocytes and prevented phosphorylation of the $p47^{phox}$ subunit that is required for NADPH oxidase
13 activity and superoxide production. Yet, while superoxide was attenuated in *Tlr4* deficient mice, it
14 remained induced in monocytes, aorta, and perivascular fat (Kampfrath et al., 2011). Mice with a
15 nonfunctional CC-chemokine receptor 2 (CCR2), with a phenotype of defective monocyte requirement
16 during immune responses, were protected from $PM_{2.5}$ and high fat diet induction of hepatic steatosis,
17 insulin resistance, and systemic and peripheral inflammation (Liu et al., 2014c). Although no association
18 was found in a cross-sectional study between long-term $PM_{2.5}$ exposure and steatosis (Li et al., 2016),
19 hepatic steatosis and fibrosis were found in mice exposed long-term to $PM_{2.5}$ (Section 7.2.5.2).

20 As described here, there are proposed pathways by which long-term exposure to $PM_{2.5}$ could lead
21 to metabolic health effects. One pathway involves ANS modulation, translocation of particulates and/or
22 soluble components, and respiratory tract inflammation that may lead to systemic and peripheral
23 inflammation that is linked to insulin resistance and metabolic syndrome comorbidities. While
24 experimental studies involving animals contribute most of the evidence of upstream effects,
25 epidemiologic studies found associations of long-term $PM_{2.5}$ exposure with metabolic syndrome
26 (Section 7.2.2), insulin resistance and glucose tolerance (Section 7.2.3), T2D (Section 7.2.4),
27 cardiovascular disease (Chapter 6), and metabolic disease mortality (Section 7.2.10). The pathways
28 leading to these outcomes are not without gaps (e.g., the pathways to hypothalamic inflammation,
29 steatosis, adiposity and weight gain); however, they provide coherence and biological plausibility for the
30 evidence streams supporting metabolic health effects and will be used to support the causal determination,
31 which is discussed later in the chapter (Section 7.2.11).

7.2.2 Metabolic Syndrome

32 The criteria for a diagnosis of metabolic syndrome, which are summarized in Table 7-1, include
33 changes in glucose and insulin homeostasis, obesity, increased blood pressure, and increased triglyceride
34 levels. Although most available studies focus on individual components of metabolic syndrome, most

commonly glucose and insulin homeostasis (Section 7.2.3), the association of long-term exposure to $PM_{2.5}$ with a diagnosis of metabolic syndrome was examined in an epidemiologic study (Table 7-6). In this study, older adult, male, participants of the Normative Aging Study (NAS) were followed between 1993 and 2011. Associations with the incidence of newly diagnosed metabolic syndrome [HR: 3.30 (95% CI: 1.34, 8.11)] and several of its components including FBG ≥100 mg/dL [HR: 2.49 (95% CI: 1.16, 5.19)], blood pressure ≥130/85 mmHg [HR 2.49 (95% CI: 0.86, 7.34)], increased triglycerides ≥150 mg/dL [HR: 1.93 (95% CI: 1.00, 3.71)] were reported (Wallwork et al., 2017). Wallwork et al. (2017) also examined the C-R relationship between long-term $PM_{2.5}$ exposure and the hazard for metabolic syndrome and its components (Figure 7-4). No major departures from linearity were apparent and HRs remained significant and strengthened in a sensitivity analysis restricted to 1-year average $PM_{2.5}$ concentrations <12 μg/m^3.

7.2.3 Glucose and Insulin Homeostasis

As discussed in the introduction to the metabolic effects chapter (Section 7.1), insulin regulates glucose homeostasis. There was one animal toxicology study (Sun et al., 2009) that showed enhanced insulin resistance in a diet-induced obesity mouse model in the 2009 PM 1SA. Several recent studies on this topic add to the overall evidence. Endpoints examined in these studies include FBG, HbA1c, and insulin resistance (e.g., the homeostatic model assessment of insulin-resistance [HOMA-IR]). Recent epidemiologic and experimental provide generally consistent evidence supporting the effect of long-term $PM_{2.5}$ exposure on glucose and insulin homeostasis.

7.2.3.1 Epidemiologic Studies

The epidemiologic studies of the association between long-term $PM_{2.5}$ exposure and glucose and insulin homeostasis are described in Table 7-6. Lucht et al. (2018b) conducted a longitudinal analysis of nondiabetic participants of the HNR reporting an association of 91-day average exposure to $PM_{2.5}$ with increased HbA1c. In this study $PM_{2.5}$ exposure was associated with 0.09% increase in HbA1c (95% CI: 0.05, 0.13) in the main model, which was adjusted for an array of covariates including BMI, physical activity, smoking, neighborhood-level unemployment.

Several cross-sectional epidemiologic studies of glucose and insulin homeostasis provide support for the findings from this longitudinal study. Chen et al. (2016) analyzed the effect of both short- (0−90-day lags) and long-term exposure to $PM_{2.5}$ on glucose homeostasis in Mexican American women with a history of gestational diabetes (GMD) and their family members (BetaGene study). Subjects with a FBG level <7 mmol/L were assessed using detailed measurements of insulin sensitivity and secretion from a frequently sampled intra-venous glucose tolerance test (FSIGT). Cumulative exposure to $PM_{2.5}$ (lags up to 60 days) and annual average $PM_{2.5}$ were associated with several measures of insulin resistance, higher fasting blood glucose and indicators of dyslipidemia in this study. Associations with $PM_{2.5}$ persisted after adjustment for NO_2.

Wolf et al. (2016) reported increases, although CIs were wide, in HOMA-IR [17.32% (95% CI: −2.32, 39.11)], glucose [2.86% (95% CI; 0.00, 5.89)], insulin [14.82% (95% CI: −3.57, 35.00)], as well as Leptin and CRP in association with long-term exposure to $PM_{2.5}$ in a cross-sectional analysis of a German cohort (KORA). HOMA IR was log-transformed in the analysis due to a deviation from linearity (Figure 7-5). In another study, Yitshak Sade et al. (2016) examined short-term (Section 7.1.2) and 3-month average exposures to serum glucose, HbA1c, and lipids, reporting an association between 3-month average $PM_{2.5}$ exposure and HbA1c, an indicator of diabetes control, among those with diabetes [2.09% (95% CI: 0.25, 3.99)]. Chuang et al. (2011) reported associations of 1-year average $PM_{2.5}$ concentration with blood lipid and glucose levels in a cross-sectional study in Taiwan. Liu et al. (2016) found cross-sectional positive associations of long-term $PM_{2.5}$ concentration with FBG [0.03 nmol/L

(95% CI: 0.02, 0.04)] and HbA1c (0.01% 95% CI: 0.01, 0.01) in a study of retired adults in China [Note: these results have been standardized to 5 µg/m^3 but were originally presented per IQR (41.1 µg/m^3) increase in $PM_{2.5}$ concentration.].

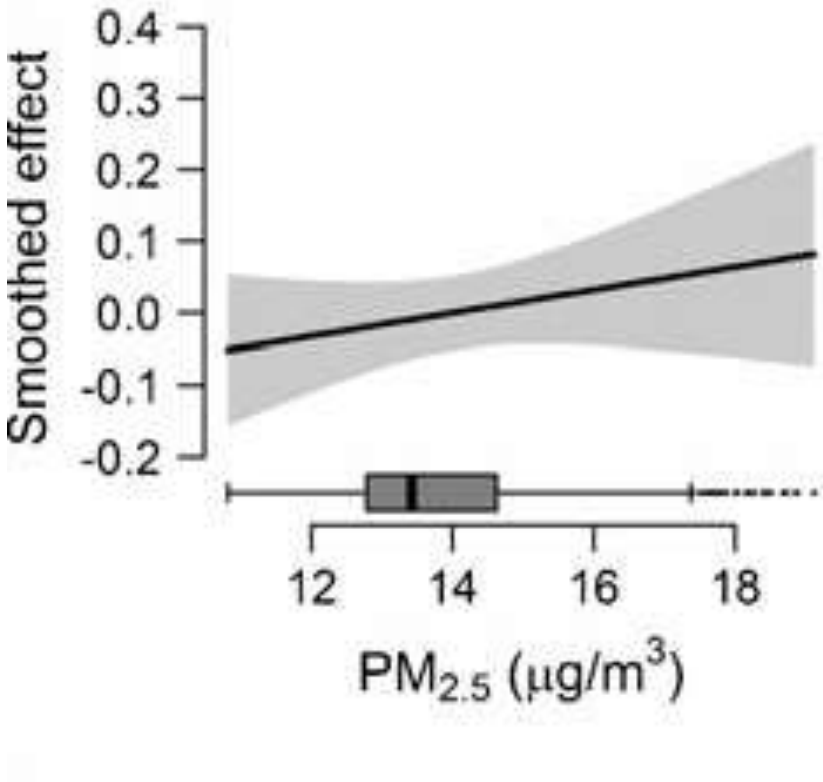
Figure 7-5 Concentration response function for $PM_{2.5}$ using restricted cubic spline with three degrees of freedom (adjusted for age, sex, body mass index (BMI), waist-hip ratio, smoking status, and month of blood draw).

Effects on glucose homeostasis in children are also observed in epidemiologic studies. Toledo-Corral et al. (2018) enrolled obese and overweight African-American and Latino children between 8 and 18 years of age to study the effect of long-term exposure to $PM_{2.5}$ on measures of glucose metabolism. $PM_{2.5}$ concentrations were associated with a metabolic profile that indicates an increased risk of developing T2D (i.e., fasting insulin, lower insulin sensitivity, higher acute insulin response to glucose and increased FBG) in this cross-sectional analysis. Thiering et al. (2013) reported an association between $PM_{2.5}$ concentration estimated at the residence using LUR and an increase in HOMA-IR at age 10, among participants in the GINIplus and LISAplus birth cohorts [27.7% (95% CI: −3.5, 66.2)]. In a subsequent analysis of a larger sample of children at age 15 years old (Thiering et al., 2016), a comparable increase in HOMA-IR was observed [16.59% (95% CI: −2.84, 39.32)]; however, the effect was attenuated in

copollutant models that adjusted for NO_2 [4.43% (−14.77, 27.50)]. The authors also examined the C-R relationship (Figure 7-6) reporting no statistical evidence that the relationship between long-term $PM_{2.5}$ exposure and HOMA-IR deviated from linearity.



Note: Box plots on the *x*-axis show the distribution of $PM_{2.5}$ concentration.

7.2.3.2 Toxicological Studies

The effects of long-term $PM_{2.5}$ on glucose homeostasis (e.g., glucose tolerance test, insulin tolerance test, fasting glucose and insulin, blood glucose and insulin levels, and the HOMA-IR) were demonstrated in several studies of experimental animals (Table 7-7). Increased ($p < 0.05$) blood glucose levels and/or glucose intolerance and increased HOMA-IR in wild-type animals eating a normal chow diet and exposed (long-term, ≥30 days) to $PM_{2.5}$ compared to controls, was shown in studies from two laboratories [Figure 7-7 (Liu et al., 2014c; Liu et al., 2014a; Zheng et al., 2013; Xu et al., 2011a; Xu et al., 2010)]. In contrast, Haberzettl et al. (2016) showed no increased in glucose levels in mice and Yan et al.

(2014) found no HOMA-IR effects in rats after $PM_{2.5}$ exposure. The molecular evidence consistently suggested that long-term $PM_{2.5}$ exposure disrupted the insulin signaling pathway by inhibition of IRS1 signaling leading to decreased ($p < 0.05$) peripheral Akt phosphorylation in the liver (Liu et al., 2014a; Zheng et al., 2013; Xu et al., 2011a) and aorta (Haberzettl et al., 2016) of mice (see Section 7.2.5.1).

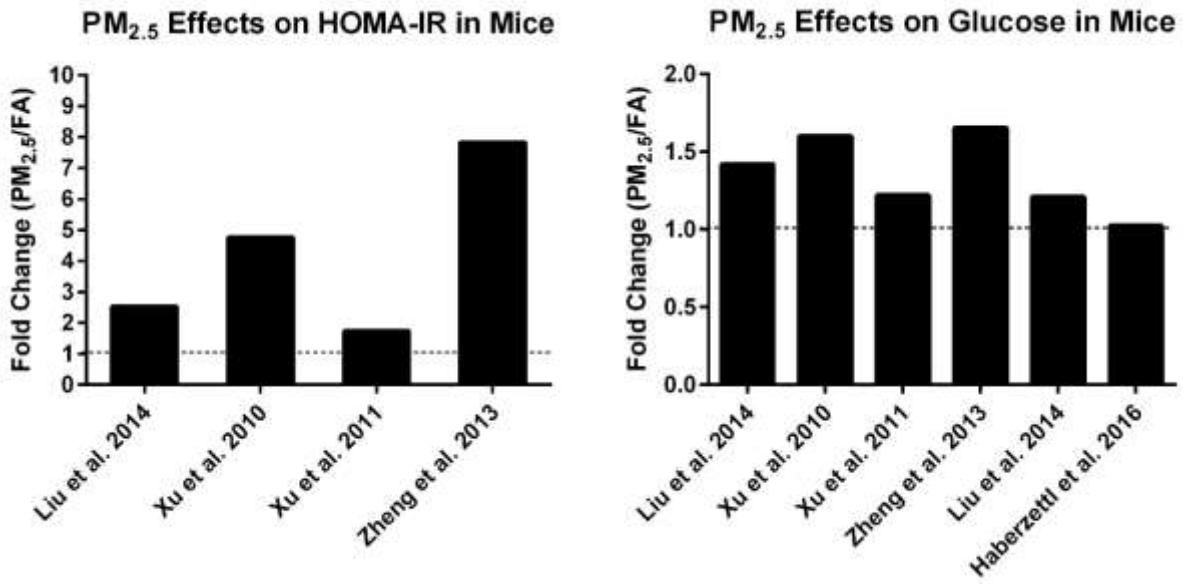

Figure 7-7 $PM_{2.5}$ effects on insulin resistance and glucose tolerance in mice exposed to 19.6−139 µg/m^3 $PM_{2.5}$ for 30 days to 17 weeks.

Stages of diabetes progression include prediabetes, which is characterized by impaired glucose tolerance and/or decreased insulin sensitivity, an initial phase (Phase 1) in which pancreatic beta cells become dysfunctional, and a second phase (Phase 2), which is characterized by fasting hyperglycemia and beta cell atrophy. In the end stage (Phase 3) of the disease, the pancreatic cells no longer release insulin.

†Studies published since the 2009 PM ISA.

1

There are several animal models available to evaluate diabetes progression including those that rely on diet to recapitulate prediabetes and diabetes-like phenotypes, KK-Ay mouse models of Phase 1 to 3 diabetes, and a streptozotocin-induced diabetic model, which selectively destroys the pancreatic islet β-cells resulting in a pathology like T1D in humans. Mouse models may present with varying degrees of obesity.

Recent studies of diabetes progression support the findings in animal toxicological studies of glucose homeostasis in wild-type animals fed normal chow (Table 7-8). In the diet-induced mouse models of diabetes Xu et al. (2010) and Liu et al. (2014c) found impaired ($p < 0.05$) glucose tolerance and/or insulin sensitivity independent of diet in mice exposed to $PM_{2.5}$ exposure for 10 and 17 weeks. Haberzettl et al. (2016) similarly fed animals a high fat diet, but found that 30-day exposure to $PM_{2.5}$ did not affect insulin resistance or glucose homeostasis. In contrast to the dietary models, the KK-Ay mouse model (for Phase 1−3 diabetes) developed hyperglycemia ($p < 0.05$) as soon as 5 weeks after $PM_{2.5}$ exposure, and the effects persisted 8-weeks after exposure, whereas insulin resistance (measured by HOMA-IR) was identified at 1, 3, and 8 weeks after CAPs exposure (Liu et al., 2014b). However, in a similar study Liu et al. (2014a) found glucose intolerance and insulin resistance 5 weeks after $PM_{2.5}$ exposure, but not 8 weeks after exposure. There was evidence from both models indicating that $PM_{2.5}$ caused inflammation (Section 7.2.5.1). Specifically, although $PM_{2.5}$ exposure and high fat diet did not interact to affect glucose tolerance or insulin resistance (discussed above), inflammation was worsened ($p < 0.05$) by high fat diets (Xu et al., 2010). In the KK-Ay mouse study Liu et al. (2014b) investigated the role of hypothalamic inflammation in T2DM. In two separate experiments Liu et al. (2014b) administered either a TNFα or IKKβ inhibitor into the intra-cerebroventricular region of KK-Ay mice. TNFα is an inflammatory cytokine and IKKβ binds cytosolic NF-κβ preventing NF-κβ translocation to the nucleus and regulation of inflammatory gene expression. TNFα inhibition had no effect on glucose tolerance or insulin sensitivity, however IKKβ inhibition ameliorated PM effects on GTT and ITT ($p < 0.05$). These results indicate a role for nervous system effects, specifically hypothalamic NF-κβ signaling, in regulating inflammation and energy homeostasis and are further discussed in the chapter on Nervous System Effects (Chapter 8).

7.2.3.3 Summary

A longitudinal study of older adults in the Boston-area that reported associations of long-term $PM_{2.5}$ with metabolic syndrome and several of its components and another longitudinal study reported an effect on HbA1c among those without diabetes. Multiple cross-sectional epidemiologic studies supported these findings but epidemiologic studies generally did not consider confounding by copollutants. Coherence with the epidemiologic findings was provided by findings from some animal toxicological studies that demonstrated increased blood glucose levels, glucose intolerance and increased HOMA-IR in wild-type animals eating a normal chow diet following long-term exposure to $PM_{2.5}$ compared to controls (Figure 7-7). Limited support for these findings was provided by studies of animal models of diabetes progression.

7.2.4 Type 2 Diabetes Mellitus

Type 2 Diabetes (T2D) Mellitus is an endocrine disorder characterized by high blood glucose levels (i.e., fasting blood glucose ≥126 mg per dL) and insulin resistance. There were no studies of long-term $PM_{2.5}$ exposure and diabetes reviewed in the 2009 PM ISA (U.S. EPA, 2009). Multiple recent studies examine the association of long-term exposure to $PM_{2.5}$ with diabetes in adult populations. Most of the epidemiologic studies are longitudinal in design and have been conducted in well-established cohorts in the U.S. (e.g., Multi-Ethnic Study of Atherosclerosis [MESA] Air, Black Women's Health Study [BWHS], Nurses' Health Study [NHS], and Health Professional Follow-up Study [HPFS]). The

collective epidemiologic and toxicological evidence described below provide a basis for long-term $PM_{2.5}$ exposures leading to impaired glucose and insulin homeostasis and diabetes. Although findings across epidemiologic studies were not consistent, some high quality, longitudinal studies reported positive associations between long-term exposure to $PM_{2.5}$ and the incidence of diabetes. In addition, there is toxicological evidence that found PM exacerbated glucose tolerance in mouse models of diabetes.

7.2.4.1 Epidemiologic Studies of Type 2 Diabetes Mellitus

Prospective studies do not consistently report positive associations between long-term $PM_{2.5}$ exposure and incident diabetes (Table 7-6, Table 7-9).

Studies used a variety of outcome ascertainment methods ranging from self-reported diabetes to confirmed FBG level. Although some studies did not explicitly distinguish between T1D and T2D, most studies focused on incident cases among adults, which are generally cases of T2D. Park et al. (2015) examined the association of long-term $PM_{2.5}$ exposure and diabetes in MESA Air participants (n = 5,135) who were free of the disease at their baseline exam. These investigators observed a positive but imprecise (i.e., wide confidence intervals) association with diabetes [HR: 1.11 (95% CI: 0.75, 1.61)]. Stratified analyses showed that the association between $PM_{2.5}$ and diabetes was present among women [HR: 1.22 (95% CI: 0.72, 2.03)] but not among men [HR: 1.00 (95% CI: 0.55, 1.77)]. Adjustment for covariates, including neighborhood-level SES and site, increased the magnitude of the effect estimates observed in this study. Unlike in the MESA cohort, sex-specific estimates for the association with incident diabetes were similar among female nurses and male health professionals in the study by Puett et al. (2011) where a positive but imprecise association was observed in the population overall [HR: 1.04 (95% CI: 0.95, 1.13)]. The association with $PM_{2.5}$ was unchanged after adjustment for neighborhood level SES (quantitative results not presented) but diminished in copollutant models adjusting for $PM_{10-2.5}$ (Puett et al., 2011).

In an analysis of Los Angeles residents in black women's health study (BWHS) who were followed from 1995 through 2005, Coogan et al. (2012) observed a positive association [HR: 1.28 (95% CI: 0.88, 1.85)] with a wide CI. In an extended analysis of the full BWHS cohort that included women residing in 56 metropolitan areas, followed from 2005 through 2011, Coogan et al. (2016) reported no association [HR: 0.98 (95% CI: 0.83, 1.16)], however. The preliminary analysis of Coogan et al. (2012) reported substantial attenuation in the association of $PM_{2.5}$ with diabetes after adjustment for NO_X (copollutant confounding was not evaluated in the 2016 study because a null association with $PM_{2.5}$ was observed). In a sensitivity analysis of Los Angeles residents followed through 2011 that allowed comparison to the previous findings, the HR was positive but attenuated and the CI was relatively wide (Coogan et al., 2016).

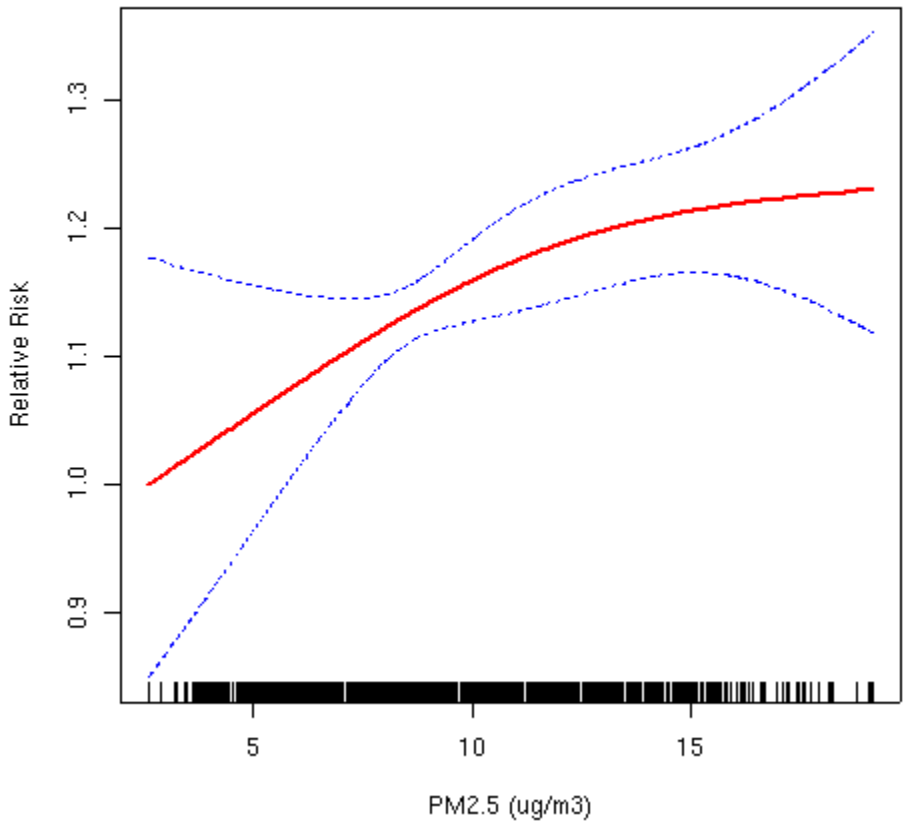
†Studies published since the 2009 PM ISA.

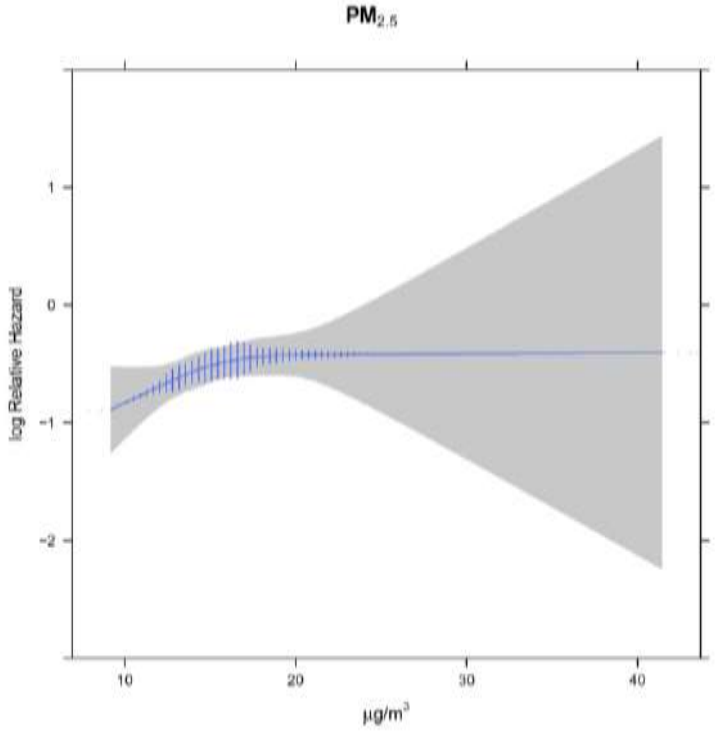
Several additional studies examining the effect of long-term $PM_{2.5}$ on the development of diabetes were conducted in Canada and Europe. Chen et al. (2013) combined several population-based surveys to establish a large cohort of men and women without diabetes living in Ontario, Canada (n = 62,012). This study found a positive association of long-term $PM_{2.5}$ exposures with incident diabetes [HR: 1.05 (95% CI: 1.01, 1.10)] after adjustment for covariates including individual and neighborhood indicators of SES and comorbidities. Chen et al. (2013) examined the shape of the concentration-response relationship using a natural cubic spline with two degrees of freedom and reported no statistical evidence of departure from linearity (Figure 7-8).



Source: Permission pending, Chen et al. (2013).

Figure 7-8 Concentration-response relationship between the concentration of $PM_{2.5}$ and incident diabetes among the cohort, depicted using a natural cubic spline function with two degrees of freedom. The hazard ratios were estimated by comparing to 2.6 µg/m^3.

In a study of Danish nurses, Hansen et al. (2016) reported relatively precise risk of diabetes in association with long-term exposure to $PM_{2.5}$ [HR: 1.18 (95% CI: 1.03, 1.38)]. In addition, the association with $PM_{2.5}$ persisted in the copollutant model adjusted for NO_2. An association of a similar magnitude but with a wider confidence interval was observed among participants in the HNR study [HR: 1.18 (95% CI: 0.78, 1.74)] (Weinmayr et al., 2015). Metrics derived to estimate $PM_{2.5}$ from traffic were also associated with incident diabetes in this study. The log relative hazard for the Danish Nurses Cohort is pictured in Figure 7-9 (Hansen et al., 2016). The curve is attenuated and the hazard estimate becomes less precise beginning above approximately 20 µg/m^3 but there was no statistical evidence of deviation from linearity.

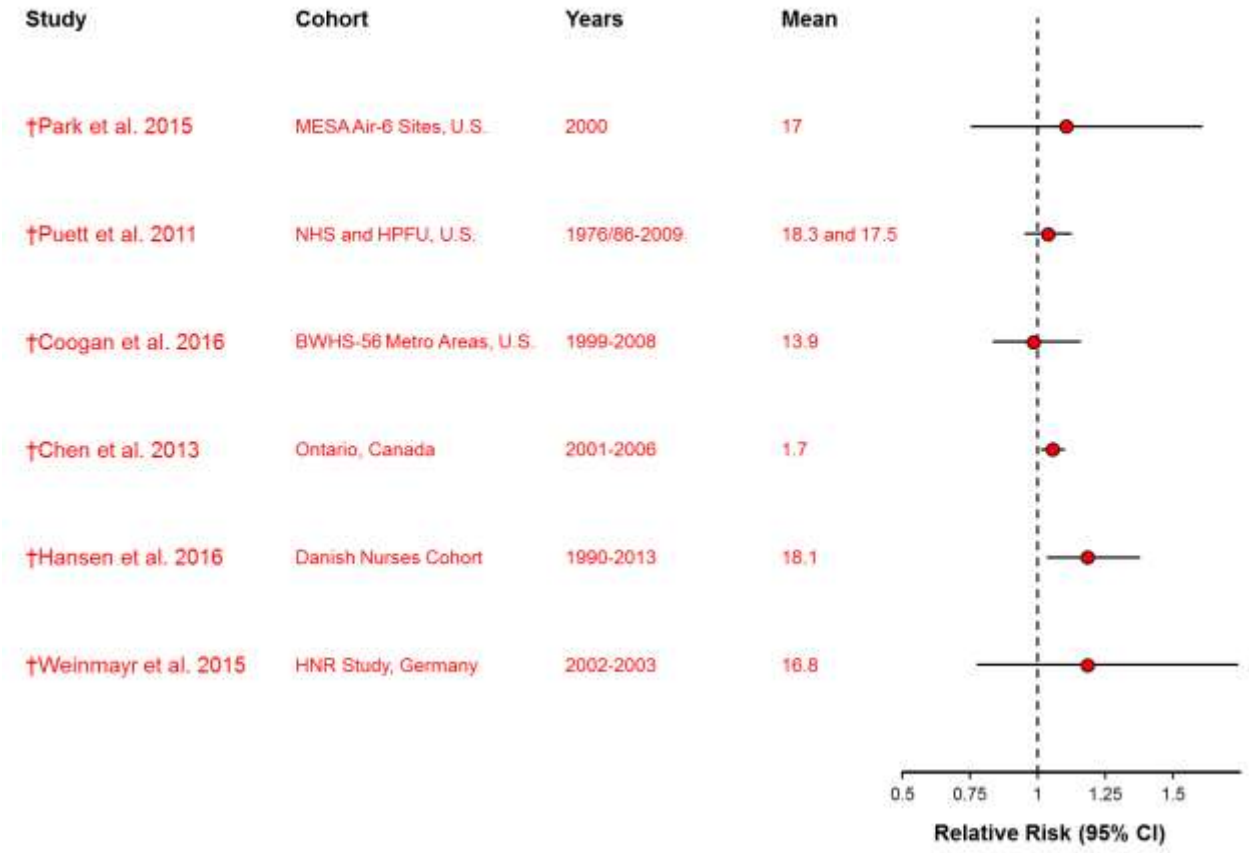


Source: Permission pending, Hansen et al. (2016).

Figure 7-9 Association (log relative hazard) between 5-year running average level at residence and incident diabetes in the Danish Nurses Study. Adjusted for age, calendar time, smoking, physical activity alcohol, fatty meat consumption, fruit and vegetable consumption, hypertension, myocardial infarction (MI), employment status, marital status and body mass index (BMI).

7.2.4.2 Summary

The risk of incident diabetes associated with long-term exposure $PM_{2.5}$ was increased in some, but not all, of the studies that were reviewed. With a few exceptions (Hansen et al., 2016; Chen et al., 2013), confidence intervals for the observed positive associations included the null. There were also differences regarding effect modification by sex (i.e., the effect size was larger in women enrolled in MESA but similar in women enrolled in NHS compared to men enrolled in HPFS). Note that Eze et al. (2015) reported a meta-analyzed pooled estimate for males [RR: 1.02 (95% CI: 0.96, 1.08)] and females [RR: 1.05 (95% CI: 1.01, 1.09)]. This pooled estimate, however, did not include the relatively recent MESA study or the extended analysis of the BWHS cohort, which reported no association. Based on a limited number of studies, associations with $PM_{2.5}$ were attenuated after adjustment for $PM_{10-2.5}$ with inconsistent findings in models adjusted NO_X or NO_2.



Circles represent point estimates; horizontal lines represent 95% confidence intervals for $PM_{2.5}$. Black text and circles represent evidence included in the 2009 PM ISA; red text and circles represent recent evidence not considered in previous ISAs or AQCDs. Mean concentrations in $\mu g/m^3$. Relative risks are standardized to a 5 $\mu g/m^3$ increase in $PM_{2.5}$ concentrations.

BWHS = Black Women's Health Study, CI = Confidence Interval, HPFU = Health Professionals Follow-up Study, HNR = Heinz Nixdorf Recall, MESA = Multi-Ethnic Study of Atherosclerosis, NHS = Nurses' Health Study.

†Studies published since the 2009 PM ISA.

Corresponding quantitative results are reported in Supplemental Table S7-1 (U.S. EPA, 2018).

Figure 7-10 Associations between long-term exposure to $PM_{2.5}$ and incident diabetes in longitudinal epidemiologic studies. Associations are presented per 5 $\mu g/m^3$ increase in pollutant concentration.

7.2.5 Other Indicators of Metabolic Function

7.2.5.1 Inflammation

Experimental, epidemiologic, and controlled human exposure evidence link inflammation to the development of metabolic disease and comorbidities (Chapter 6 and Section 7.1.1 and Section 7.2.1).

Furthermore, it is widely believed that inflammation plays a critical role in the development of T2D and atherosclerosis, further complicating heart disease. Metabolic tissues, such as liver and adipose tissue, are essentially cocultures of metabolic (hepatocytes and adipocytes) and immune cells (i.e., Kupffer cells and macrophages) (Boron and Boulpaep, 2017). Furthermore, metabolic and immune responses (i.e., toll-like receptor and NFκβ) are coordinately regulated by inflammatory and endocrine signaling between organs and cells in response to environmental stimuli such as nutrients and pathogens. Therefore, the discussion below integrates inflammatory evidence from the cardiovascular, respiratory, and nervous system health effects chapters below with a specific focus on peripheral inflammation (Table 7-10).

Table 7-10 Study specific details from animal toxicology studies of inflammation and other indicators of metabolic function.

Study	Species, Sex, Strain, Sex, Diet, Age	Exposure Details (Pollutant, Concentration, Duration, Route)	Endpoints Evaluated
Haberzettl et al. (2016)	Mouse, male, C57BL/6J, ND or HFD, 8–12 weeks, n = 4–8	Columbus, OH CAPs, $PM_{2.5}$; 30−100 μg/m^3 Group 1: exposed for 6 h/day for 9 or 30 days. Group 2: treated with daily dose of water, metformin (50 mg/kg dose 2 days before, 100 mg/kg dose 1 day before and 300 mg/kg at the time of), or 1 mg/kg rosiglitazone 2 mg/kg two days before 9 days CAP exposure in drinking water.	Body weight, fasting blood glucose and insulin, HOMA-IR, organ weights, blood lipids, liver clinical chemistry, insulin signaling pathway, circulating bone marrow derived stem cells.
Kampfrath et al. (2011)	Mouse, male, C57BL/6, $NOX2^{-/-}$ (C57BL/6 background) Balb/c (TLR4wt), Tlr4Lps-d (TLRd, BALB/cAnPt background), c-fmsYFP (FVB/N background)	CAPs $PM_{2.5}$; 6 h/day, 5 days/week for: TLR4wt, TLRd, NOX2wt, and $NOX2^{-/-}$ for 20 weeks; c-fmsYFP for 23 weeks.	PM increases monocyte adherence and infiltration in cremaster muscle and mesenteric adipose tissue.
Liu et al. (2014c)	Mouse, male, C57BL/6 and $Ccr2^{-/-}$ (inflammation model), ND or HFD, 18 weeks, WT-FA (n = 8), WT-PM (n = 9), CCR2-FA (n = 9), CCR2-PM (n = 8)	Columbus, OH CAPs $PM_{2.5}$; 116.9 μg/m^3; 6 h/day, 5 days/week for 17 weeks, whole body inhalation	Body weight, glucose tolerance test, HOMA-IR, inflammation, liver and plasma lipids, vasorelaxation, macrophage infiltration, intra-vital leukocyte-endothelial interactions in adipose and muscle.

Table 7-10 (Continued): Study specific details from animal toxicology studies of inflammation underlying metabolic disease.

Study	Species, Sex, Strain, Sex, Diet, Age	Exposure Details (Pollutant, Concentration, Duration, Route)	Endpoints Evaluated
Liu et al. (2014a)	Mouse, male, KK-Ay, 5 weeks old, n = 7−8/group	Columbus, OH CAPs $PM_{2.5}$; 102.9 ± 19.16 μg/m^3, 6 h/day, 5 days/week, 5 weeks or 8 weeks December 28, 2011–February 28, 2012, OASIS exposure system	IPGTT or ITT, blood glucose, adiponectin, and leptin, bone marrow, spleen, epididymal white adipose tissue, stromal vasculature cells were stained for inflammation (F4/80 + anti-CD11c + cells) and flow cytometry, aortic ring, O_2 consumption, CO_2 production, heat production, body weight, hepatic Akt, p38 and ERK phosphorylation
Liu et al. (2014b)	Mouse, KK-Ay (develop diabetes and overweightness), 5 or 7 weeks old, sex and genotype not reported, Exposure 1 (n = 7−8/group), Exposure 2 (n = 6/group), Exposure 3 (n = 8/group) IMD 0354 group n = 8, infliximab group n = 6	Columbus, OH CAPs $PM_{2.5}$ Exposure 1: 116.9 μg/m^3 for 6 h/day, 5 days/week, 5 weeks or 8 weeks Exposure 2: 139.5 μg/m^3 + infliximab (TNFα antibody) or artificial CSF for 6 h/day, 5 days/week, 5 weeks Exposure 3: 73.6 μg/m^3 + IMD-0354 (IKKB inhibitor) or DMSO for 6 h/day, 5 days/week, 4 weeks	Exposure 1: fasting blood glucose, HOMA-IR, hypothalamus TNFα, IL-6 and IKKB mRNA levels, oxidized PAPC Exposure 2: hypothalamic TNFα antagonism did not alter GTT, ITT, thermogenesis, body weight Exposure 3: IKKB inhibition IKK-NFkB pathway upregulation normalized PM effects on GTT and ITT, circulating monocytes (p = 0.0616), and visceral adipose monocytes ($p < 0.05$) compared to PM controls Body weight, food intake, glucose tolerance test, insulin levels, HOMA-IR, oxygen consumption, heat production, inflammation, inhibition of the cerebroventricular NFκβ pathway, insulin signaling pathway
Mendez et al. (2013)	Mouse, male, C57BL/6, normal diet (ND), 6 weeks, n = 4/group	Columbus, OH CAPs, $PM_{2.5}$; 94.4 μg/m^3; 6 h/day, 5 days/week for 10 mo, whole body inhalation	Inflammation, adipocyte size, ER stress markers
Wei et al. (2016)	Rat, pregnant females (12 weeks old) and male offspring, Sprague Dawley, ND or high fructose, gestation day 4–PND 3 or 8 weeks, filtered n = 8−10, unfiltered n = 6−10	Beijing, China air filtered for $PM_{2.5}$; 73.5 μg/m^3; continuous whole-body inhalation from gestation date 4 until PND 3 or 8 weeks	Body and organ weight, lung inflammation, LDL, TC, TG, malondialdehyde (MDA), GPL-1, chemoattractants, and anti-inflammatory cytokines

Table 7-10 (Continued): Study specific details from animal toxicology studies of inflammation underlying metabolic disease.

Study	Species, Sex, Strain, Sex, Diet, Age	Exposure Details (Pollutant, Concentration, Duration, Route)	Endpoints Evaluated
Xu et al. (2010)	Mouse, male, ND or high fat (HFD), wild-type or *p47*$^{phox-/-}$ ND, 3 weeks, n = 16/group	Columbus, OH CAPs, $PM_{2.5}$; diet study: 111.0 µg/m^3; 6 h/day, 5 days/week for 10 weeks, whole body inhalation	Glucose tolerance test, HOMA-IR, inflammatory markers and inflammation, adiposity, and vasomotor responses
Xu et al. (2011a)	Mouse, male, C57BL/6, ND, 4 weeks, n = 11 FA, n = 9 $PM_{2.5}$	Columbus, OH CAPs, $PM_{2.5}$; 94.4 µg/m^3; 6 h/day, 5 days/week for 10 mo, whole body inhalation	Body and adipose depot weights, glucose tolerance test, HOMA-IR, systemic inflammation, adipokines, mitochondrial size and number, gene expression, superoxide production/oxidative stress/Nrf2 signaling, insulin signaling pathway
Xu et al. (2011b)	Mouse, male, ApoE$^{-/-}$ (atherosclerosis), 4 weeks, n = 8/group	East Lansing, MI CAPs $PM_{2.5}$; 96.89 µg/m^3; 6 h/day, 5 days/week for 2 mo, whole body inhalation	Superoxide production, inflammatory response, WAT and BAT gene expression, mitochondrial number and size
Yan et al. (2014)	Rat, male, Sprague Dawley T1D (streptozotocin induced), 14 weeks, n = 8	Taipei Air Pollution Exposure System for Health Effects (TAPES) filtered for $PM_{2.5}$; 13.3 µg/m^3, 24 h/day, 7 days/week, for 16 weeks, whole body inhalation	Glucose/insulin/serum lipids, HOMA-IR, inflammatory and renal function blood biomarkers, urinary protein excretion, histopathology (heart, aorta, and kidney)
Zheng et al. (2013)	Mouse, male, C57BL/6, ND or high fat (HFD), 6 weeks, n = 4 FA, n = 5 CAPs exposed	Columbus, OH CAPs, $PM_{2.5}$; 74.6 µg/m^3; 6 h/day, 5 days/week for 3 or 10 weeks, whole body inhalation	Steatosis, steatohepatitis, glycogen storage, glucose tolerance test, fasting insulin and HOMA-IR, inflammatory pathway, liver and plasma lipids, gene expression, insulin signaling pathway
Zheng et al. (2015)	Mouse, male, C57BL/6, ND or high fat (HFD), 8 weeks; *p47*$^{phox-/-}$ (NADPH oxidase deficient, susceptible to infection and granulomatous inflammation), ND, 3 weeks, n = 8 per group	Columbus, OH CAPs, $PM_{2.5}$; 74.6 µg/m^3; 6 h/day, 5 days/week for 10 weeks, 111.0 µg/m^3; 6 h/day, 5 days/week for 9 mo, whole body inhalation	Liver steatosis, fibrosis and collagen production

1

There is evidence for systemic inflammation following long-term exposure to $PM_{2.5}$ (also see Section 6.2.12). Studies with $ApoE^{-/-}$ mice that are prone to develop atherosclerosis demonstrated worsened inflammation in white adipose tissue accompanied by mitochondrial alterations and oxidative stress in brown adipose tissue (Xu et al., 2011b). Long term $PM_{2.5}$ exposure led to systemic increases in proinflammatory cytokines in experimental models and was also associated with blood biomarkers of inflammation such as CRP (Section 6.2.12). In experimental models, long term $PM_{2.5}$ CAPs exposures in wild type rodents fed a normal diet demonstrated increased blood TNF-α (<0.05) (Zheng et al., 2013; Xu et al., 2011b; Xu et al., 2011a; Xu et al., 2010), TGF-β1 ($p < 0.05$) (Zheng et al., 2015), monocyte counts (Kampfrath et al., 2011), CD4+ and CD8+ T lymphocytes (Deiuliis et al., 2012), IL-6 ($p < 0.01$) (Yan et al., 2014), and malondialdehyde ($p < 0.001$) (Wei et al., 2016).

Increases in blood inflammation markers and immune cells were consistent with the histological observation of liver and adipose inflammation. Specifically, nonalcoholic steatohepatitis and fibrosis were noted in $PM_{2.5}$ CAPs exposed mice (Zheng et al., 2015; Zheng et al., 2013) and increased monocyte/macrophage infiltration in visceral (Xu et al., 2010), epididymal (Mendez et al., 2013; Xu et al., 2011b) adipose tissue. Further molecular analysis demonstrated a clear and consistent decrease in Akt phosphorylation in liver, skeletal, adipose, and heart tissues (Liu et al., 2014c; Liu et al., 2014a; Zheng et al., 2013; Xu et al., 2011a) possibly mediated by activation of TLR/Iκκβ/JNK pathways leading to repression of the PI3K/Akt pathways (also discussed above in Section 7.2.3).

Genetic models highlight a critical role for innate immunity in metabolic disease outcomes. Specifically, long-term $PM_{2.5}$ exposure had reduced or no effect on hepatic inflammation, hepatic steatosis and fibrosis, and adipose inflammation in mice with a mutation in *p47phox* (a critical subunit of NADPH oxidase) or CC-chemokine receptor Type 2 (CCR2, a receptor for CCL2 chemokines). Furthermore, $PM_{2.5}$-mediated effects on insulin resistance (discussed above) were improved ($p < 0.05$) in these genetic mouse models (Zheng et al., 2015; Liu et al., 2014c; Xu et al., 2010). Similarly, $PM_{2.5}$ exposure and HFD feeding worsened hepatic fibrosis and reactive oxygen species generation, whereas these effects were rescued in a $p47^{phox-/-}$ mouse (nonfunctional NADPH oxidase activity) (Zheng et al., 2015). These results indicate that $PM_{2.5}$ impacts on inflammation and glucose levels are mediated by the innate immune system and potentially modified by dietary fat.

In a mouse model genetically predisposed to diabetes and obesity, long-term $PM_{2.5}$ exposure resulted in hyperglycemia ($p < 0.05$), insulin resistance ($p < 0.05$), and systemic inflammation (Liu et al., 2014a).

In summary, these phenotypic observations demonstrate that long-term $PM_{2.5}$ CAPs exposure in rodents causes increased incidence of peripheral and systemic inflammation, extending from the lung to peripheral vasculature and distal adipose and hepatic organs that are exacerbated by diet and genetic predisposition. The implication is that systemic inflammation may impact liver and adipose function, and consequently disrupt insulin signaling leading to a shift in glucose and lipid homeostasis (Section 7.2.3).

7.2.5.2 Liver Function

Hepatic steatosis in the absence of alcohol consumption (i.e., nonalcoholic fatty liver disease [NAFLD]) is a progressive chronic disease. The main pathological feature of NAFLD is excessive lipid accumulation (>5% and typically triglycerides) within the cytosol of hepatocytes. NAFLD is often asymptomatic, but if left untreated may progress to steatohepatitis (inflamed fatty liver) and progress to permanent liver injury including fibrosis and cirrhosis (Angrish et al., 2016a). NFALD is often associated with metabolic syndrome risk factors, including obesity, T2D, and cardiovascular disease, and is therefore considered the hepatic manifestation of metabolic syndrome.

7.2.5.2.1 Epidemiologic Studies

There were no studies of long-term exposure to $PM_{2.5}$ and liver function reviewed in the 2009 PM ISA. The evidence remains limited (Table 7-11) Li et al. (2016) conducted a study of participants in the Framingham Offspring and Third Generation cohorts to determine the association between long-term $PM_{2.5}$ exposure and hepatic steatosis. No associations with liver-to-phantom ratio (LPR) [β = 0.00 (95% CI: 0.00, 0.01)] or hepatic steatosis [OR: 0.86 (95% CI: 0.66, 1.19)] was observed. In a study in Augsburg, Germany, Markevych et al. (2013) reported increase in several liver enzymes that may indicate reduced liver function. In this study increases in gamma-glutamyltransferase (GGT) [9.21% (95% CI: 0.18, 18.77)] but not aspartate transaminase (AST) [1.26% (95% CI: −2.89, 5.42)] or alanine transaminase (ALT) [−1.81% (−7.94, 4.69)] were observed.

Table 7-11 Epidemiologic studies of long-term exposure to $PM_{2.5}$ and indicators of liver function.

Study	Study Population	Exposure Assessment	Concentration µg/m^3	Outcome	Copollutants Examined
†Li et al. (2016) Cross-sectional $PM_{2.5}$: 2003 Outcome: 2002−2005	Framingham Offspring and Third Generation Study N = 2,513	Annual avg (2003), spatio-temporal model, 1 × 1 km resolution, satellite derived AOD, out of sample R^2 = 0.88	Mean 10.6 (IQR: 1.4)	LPR Hepatic Steatosis	Correlations (*r*): NR Copollutant model: NR

†Studies published since the 2009 PM ISA.

7.2.5.2.2 Toxicological Studies

There were no experimental studies of long-term exposure to $PM_{2.5}$ and liver function reviewed in the 2009 PM ISA. Several recent animal studies identified pathological fatty changes in the liver after exposure to $PM_{2.5}$ CAPs (Table 7-10). Specifically, histological phenotyping with H&E stain, Sirius-red, and Masson's trichrome staining identified hepatic steatosis, lobular and cellular inflammation, and perisinusoidal inflammation among mice exposed for 10 consecutive weeks to $PM_{2.5}$ CAPs (Zheng et al., 2013). Zheng also reported that $PM_{2.5}$ exposure reduced hepatic glycogen storage in the same animals. In a follow-up study Zheng et al. (2015) also found perisinusoidal fibrosis in mice exposed for 10 weeks or 9 months that was worsened by a high fat diet. However, there was no evidence of fibrosis in $p47^{phox-/-}$ mice (a mutation that inactivates NADPH oxidase (see Section 7.2.5.1) after 10 weeks of $PM_{2.5}$ CAPs exposure). Similarly, Liu et al. (2014c) identified steatosis marked by increased liver triglycerides ($p > 0.05$) and increased oil red O staining levels ($p > 0.05$) that were attenuated in $CCR2^{-/-}$ mice. Considered together, these results support that $PM_{2.5}$ exposure increases hepatic lipid levels and worsens progressive liver disease via innate immunity (see Section 7.2.5.1).

7.2.5.3 Endocrine Hormones

Body energy levels are maintained during feeding and fasting by many endocrine hormones secreted by organs and glands, e.g., the pancreas (insulin and glucagon), gastrointestinal tract (ghrelin), adipose tissue (adiponectin and leptin), neurons (i.e., epinephrine), and adrenal gland (glucocorticoids, i.e., cortisol). There are two recent studies reporting changes in adipose endocrine hormones. Xu et al. (2011a) identified decreased ($p < 0.05$) adiponectin and leptin blood levels in C57BL/6 mice exposed 6 hours/day, 5 days/week for 10 months compared to vehicle controls. Liu et al. (2014a) identified decreased plasma adiponectin and increased leptin levels ($p < 0.05$) in KK-Ay mice 5 weeks after $PM_{2.5}$ exposure compared to FA controls, whereas no differences were detected 8 weeks after exposure.

7.2.5.4 Adiposity and Weight Gain

Adiposity, particularly visceral adiposity, and weight gain are risk factors for metabolic syndrome, T2D and cardiovascular disease. Although most epidemiologic studies consider BMI as a potential confounder or modifier of the association between $PM_{2.5}$ and cardiovascular disease, there were no studies of the association of long-term exposure to $PM_{2.5}$ with adiposity or weight gain reviewed in the 2009 PM ISA.

7.2.5.4.1 Epidemiologic Studies

A limited number of epidemiologic studies of adiposity and weight gain (Table 7-12) are currently available for review. White et al. (2016) examined the associations of long-term exposure to $PM_{2.5}$ with weight gain among women in the BWHS. Overall, no evidence of an association between $PM_{2.5}$ was observed in this population.

Mao et al. (2017) reported increased risk of childhood overweight and obesity, comparing the highest to the lowest quartile of exposure, with exposure to $PM_{2.5}$ averaged over the first 2 years of life, as well as during each trimester of pregnancy. This study also indicated the highest risk among children of mothers who were overweight or obese prior to pregnancy and exposed to $PM_{2.5}$. There was a dose-response relationship between $PM_{2.5}$ and childhood obesity and overweight that was indicated after the median exposure (10.5−10.9 μg/m^3) for each of the exposure windows. Exposure during the second trimester showed a steeper C-R relationship.

Table 7-12 Epidemiologic studies of long-term exposure to $PM_{2.5}$, overweight and obesity.

Study	Study Population	Exposure Assessment	Concentration µg/m^3	Outcome	Copollutants Examined
†White et al. (2016) 56 Metro areas, U.S. Prospective cohort $PM_{2.5}$: 1998−2008 Outcome: 1995−2011	BWHS N = 38,374 Follow-up 16 yr	Multiyear avg, LUR with BME (C-V R^2 = 0.79) for residential histories	Mean: 13.9	Weight change	Correlations (*r*): NR Copollutant model: NR

BME = Bayesian Maximum Entropy; BMC = Boston Medical Center; HOMA-IR = Homeostatic Model Assessment of Insulin; Resistance; LUR = Land Use Regression; NR = not reported.

†Studies published since the 2009 PM ISA.

7.2.5.4.2 Toxicological Studies

Long-term $PM_{2.5}$ exposures had little to no effect on animal body weight. Long-term $PM_{2.5}$ exposure affected abdominal fat mass (measured by MRI) in one study ($p < 0.05$), although there was no interaction between high fat feeding and $PM_{2.5}$ on abdominal fat mass (Xu et al., 2010). Liu et al. (2014a) identified a trend ($p = 0.0578$) toward increased epididymal white adipose tissue 5 weeks after exposure, but found no difference between $PM_{2.5}$ and filtered air 8 weeks after exposure. Studies are detailed in Table 7-10.

7.2.5.5 Blood Lipids

7.2.5.5.1 Epidemiologic Studies

The previous PM ISA did not include any relevant epidemiologic studies describing associations between long-term exposure to $PM_{2.5}$ and blood lipid levels. The available literature includes ecological studies or studies conducted at relatively high concentration (>20) (Calderón-Garcidueñas et al., 2013; Chuang et al., 2011). In addition, Wallwork et al. (2017) examined blood lipids in the context of all the components of metabolic syndrome and observed increased triglycerides among older adult males in the NAS in association with annual average $PM_{2.5}$ concentration. Yitshak Sade et al. (2016) examined blood lipids, in addition to HbA1c and FBG, and reported associations of 3-month average $PM_{2.5}$ exposure with HDL and LDL in a retrospective study in Israel noting larger effect sizes among those with diabetes.

7.2.5.5.2 Toxicological Studies

In mice, long-term $PM_{2.5}$ CAPs exposures resulted in increased ($p < 0.05$) liver (Liu et al., 2014c), (116 μg/m^3 for 17 weeks), and blood (Zheng et al., 2013), (74 μg/m^3 for 9 months), triglycerides and blood cholesterol (Zheng et al., 2013) levels. It is important to note, however that rodent cholesterol dietary intake and plasma clearance is markedly higher than humans meaning that rodents, on average, have much lower plasma LDL levels (7 mg/dl) than humans (120 mg/dl). Study characteristics are detailed in Table 7-10.

7.2.5.6 Blood Pressure and Hypertension

Small increases in SBP, PP, and MAP were found in association with $PM_{2.5}$ in MESA and Sister Study but not in all the available studies (Section 6.3.7). A limited number of animal toxicological studies

demonstrate a relationship between long-term exposure to $PM_{2.5}$ and consistent increases in BP (Section 6.2.7.2). These results are in coherence with epidemiologic studies reporting positive associations between long-term exposure to $PM_{2.5}$ and hypertension (Section 6.2.18).

7.2.6 Gestational Diabetes

Several studies of gestational diabetes were conducted. Generally, the results of the studies were inconsistent, though several reported positive associations with gestational diabetes or impaired glucose tolerance with $PM_{2.5}$ exposures during the second trimester. While the evidence base for gestational diabetes is growing, it is still limited to a relatively small number of studies which report generally inconsistent results (see Section 9.2.1 on Reproductive and Developmental Effects for more details).

7.2.7 Type 1 Diabetes

Type 1 diabetes (T1D) mellitus, which typically affects children and young adults, is a chronic condition that results when the pancreas fails to produce the insulin needed for glucose homeostasis. There were no studies of T1D reviewed in the 2009 PM ISA.

7.2.7.1 Epidemiologic Studies

The evidence relating to the effect of long-term exposure to $PM_{2.5}$ on T1D is limited to a study examining the age of onset as opposed to development of the disease (Table 7-12). Beyerlein et al. (2015) analyzed data from the Bavaria, Germany registry of incident diabetes in children. $PM_{2.5}$ was associated with reduced age of onset of diabetes [10th percentile age of diagnosis −1.4 years (95% CI: −1.97, 0.77) per 2 SD increase] after adjustment for level of urbanization. Manifestation of T1D was not associated with PM_{10} in a larger study designed to replicate these findings (Rosenbauer et al., 2016). Ambient pollution concentrations were modelled at a lower spatial resolution in the Rosenbauer et al. (2016) study. In addition, Beyerlein et al. (2015) adjusted for individual-level SES (i.e., parental education) while Rosenbauer et al. (2016) adjusted for community-level SES (i.e., German Index of Multiple Deprivation).

Table 7-13 Epidemiologic studies of long-term exposure to $PM_{2.5}$ and age of onset for Type 1 diabetes.

Study	Study Population	Exposure Assessment	Concentration µg/m^3	Outcome	Copollutants Examined
†Beyerlein et al. (2015) Cross-sectional Bavaria, Germany 2009−2013	Registry mean age = 9.3 yr N = 617	Annual avg (2001) Kriging interpolation and LUR (1 × 1 km grid), at residential address	NR	Age of onset T1D (islet antibody test)	Correlations (*r*): NR Copollutant models; NR

†Studies published since the 2009 PM ISA.

7.2.7.2 Toxicological Studies

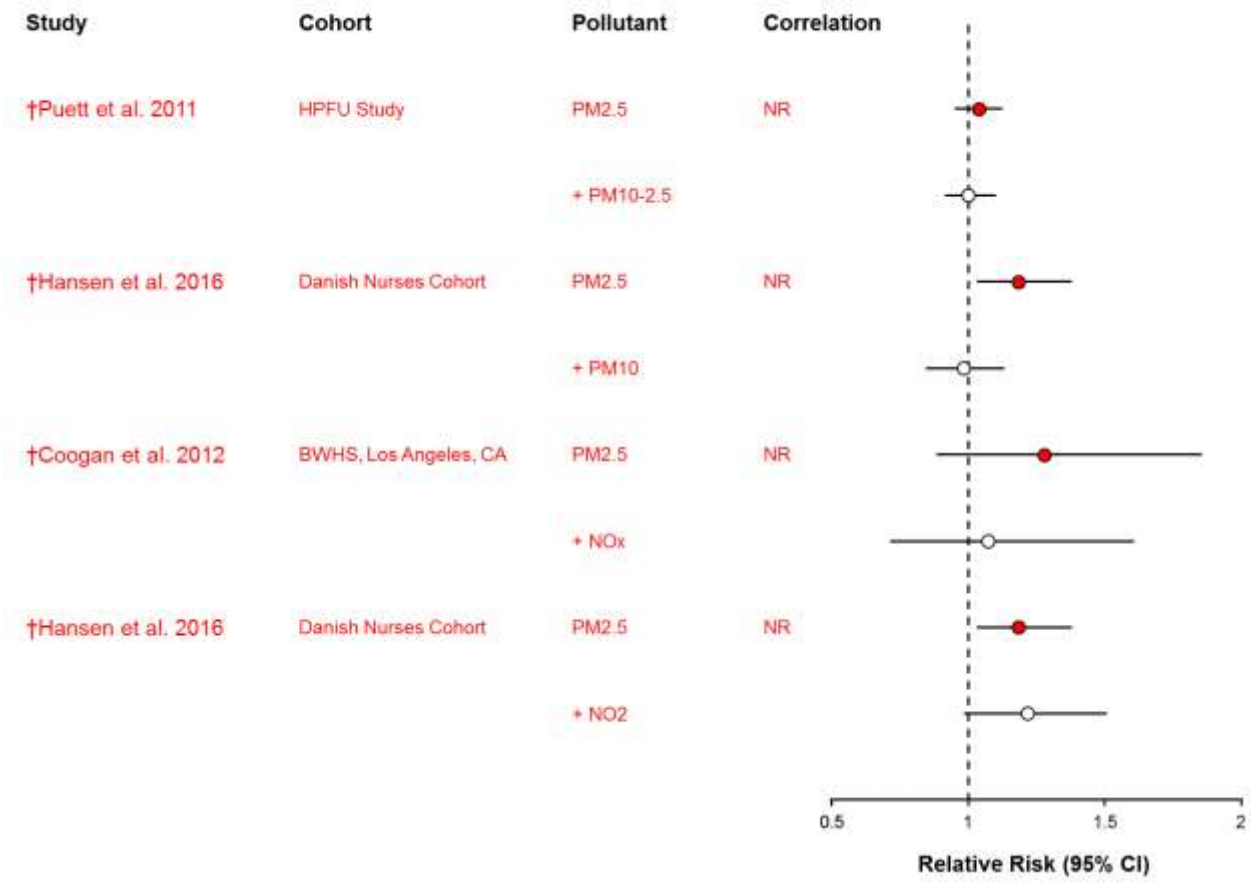
In a Type 1 diabetic rat model, $PM_{2.5}$ exposure had no effect on glucose homeostasis, insulin sensitivity, or blood lipid chemistry, however glycated hemoglobin (HbA1c, a marker of elevated glucose) was increased ($p < 0.05$) (Yan et al., 2014).

7.2.8 Associations between $PM_{2.5}$ Components and Sources and Metabolic Effects

There were no studies of the association of long-term $PM_{2.5}$ components or sources with metabolic effects reviewed in the 2009 PM ISA. The literature on this topic remains limited. Weinmayr et al. (2015) developed metrics to distinguish exposure to total $PM_{2.5}$ from $PM_{2.5}$ from traffic using data from the HNR Study in Germany. In this longitudinal analysis of T2D (mean follow-up 5.1 years), the authors reported similar hazards when standardized to an IQR increase [HR: 1.08 (95% CI: 0.89, 1.29) total $PM_{2.5}$ vs. HR: 1.1 (95% CI: 0.99, 1.23) traffic $PM_{2.5}$].

7.2.9 Copollutant Confounding

A limited number of studies are available that report results from copollutant models. Overall, estimates were not robust to adjustment for NO_2, NO_X or $PM_{10-2.5}$. Puett et al. (2011) reported that the weak association of long-term exposure to $PM_{2.5}$ with incident diabetes [HR: 1.04 (95% CI: 0.95, 1.13)] was null after adjustment for $PM_{10-2.5}$ [HR: 1.00 (95% CI: 0.91, 1.11)]. Note that the results for Coogan et al. (2012) included in the figure are for an interim analysis of women from Los Angeles, CA not the full cohort. No association between $PM_{2.5}$ and diabetes was observed in the later analysis of the entire cohort that included additional years of follow-up. The larger HR reported by Hansen et al. (2016) of 1.18 (95% CI: 1.03,1.38) among Danish nurses was null after adjustment for PM_{10} [HR: 0.98 (95% CI: 0.84, 1.13)] but persisted after adjustment for NO_2 [HR: 1.22 (95% CI: 0.98, 1.51)]. The decrease in HOMA-IR reported by Thiering et al. (2016) among children was also diminished after adjustment for NO_2 in a copollutant model (not presented in Figure 7-11). In this study, the 14.6% (95% CI −2.5, 34.6) increase in HOMA-IR was reduced 4.3% (95% CI: −14.8, 27.5) in the copollutant model.



Circles represent point estimates; horizontal lines represent 95% confidence intervals for $PM_{2.5}$. Black text and circles represent evidence included in the 2009 PM ISA; red text and circles represent recent evidence not considered in previous ISAs or AQCDs. Mean concentrations in $\mu g/m^3$. Hazard Ratios are standardized to a 5 $\mu g/m^3$ increase in $PM_{2.5}$ concentrations.

BWHS = Black Women's Health Study, CI = Confidence Interval, HPFU = Health Professionals Follow-up Study, NO_2 = nitrogen dioxide, NO_X = Oxides of Nitrogen, NR = Not Reported.

†Studies published since the 2009 PM ISA.

Corresponding quantitative results are reported in Supplemental Table S7-2 (U.S. EPA, 2018).

Figure 7-11 Copollutant model results for studies of long-term exposure to $PM_{2.5}$ and incident diabetes. Associations are presented per 5 $\mu g/m^3$ increase in pollutant concentration.

7.2.10 Metabolic Disease Mortality

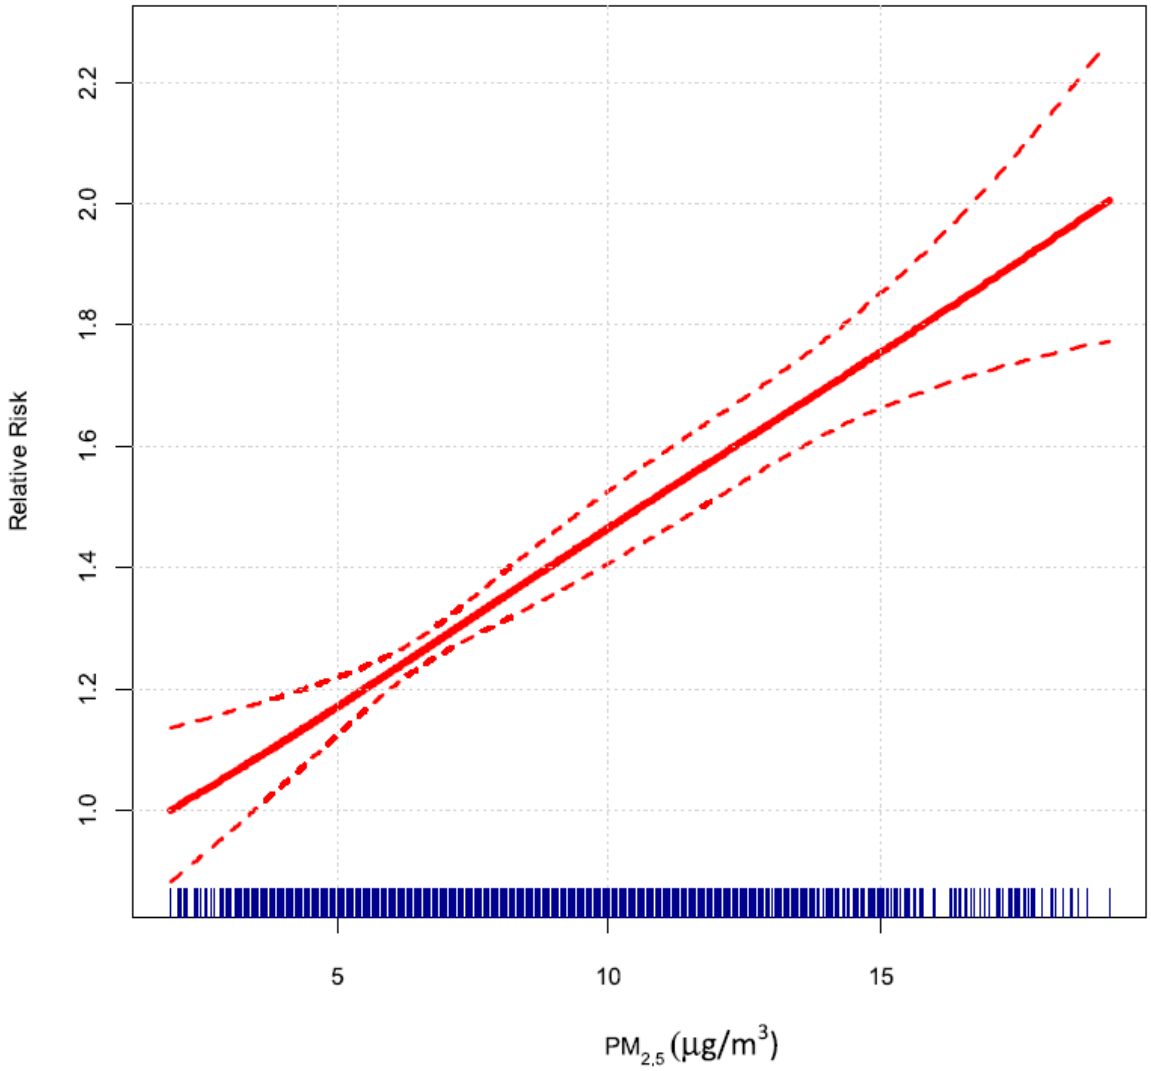
Studies that examine the association between long-term $PM_{2.5}$ exposure and cause-specific mortality outcomes, such as diabetes or other metabolic disease mortality, provide additional evidence for $PM_{2.5}$-related metabolic effects, specifically whether there is evidence of an overall continuum of effects. Evidence from studies of long-term $PM_{2.5}$ exposure and mortality are presented in detail in Section 11.2; no studies investigating metabolic disease mortality related to long-term $PM_{2.5}$ exposure were identified in

the 2009 PM ISA (U.S. EPA, 2009). Recent analyses from two well-established cohorts (the ACS and CanCHEC cohorts) have included this outcome and are summarized here to inform the effect of long-term $PM_{2.5}$ exposure on metabolic disease effects (Figure 7-12).

Pope et al. (2014), Turner et al. (2016) and Jerrett et al. (2016) all used the extended follow-up period of the ACS (1982−2004) to examine the associations between long-term $PM_{2.5}$ exposure and mortality due to diabetes. Pope et al. (2014) and Turner et al. (2016) assigned exposure using an LUR-BME model and observed positive associations with deaths due to diabetes. Jerrett et al. (2016) assigned $PM_{2.5}$ exposure using six different methods and observed positive associations with diabetes mortality for each one, though the precision of the association varied across exposure assessment methods. The most precise estimate was observed for the monitor-LUR hybrid model (HR: 1.09; 95% CI: 1.03, 1.17), and was similar in magnitude to the associations observed by Pope et al. (2014) and Turner et al. (2016).

A recent series of studies conducted in Canada linked census data with data from the Canadian Mortality Database to create the Canadian Census Health Environment Cohort (CanCHEC) and evaluated the relationship between long-term $PM_{2.5}$ exposure and metabolic disease mortality. These studies either examined deaths due to diabetes or the combination of circulatory disease and diabetes in their evaluation of metabolic disease. The authors observed positive associations between diabetes mortality and long-term $PM_{2.5}$ exposure, with similar estimates for satellite-derived estimates and ground monitor estimates (Crouse et al., 2016; Crouse et al., 2015; Brook et al., 2013a). The hazard ratios remained positive, but were less consistent in magnitude for circulatory disease and diabetes deaths combined (Weichenthal et al., 2016; Crouse et al., 2015). Pinault et al. (2016) linked a subset of participants from the CanCHEC cohort to the Canadian Community Health Survey, which allowed them to include an expanded set of individual-level covariates in their analyses. Among the nearly 300,000 participants included in the study, the authors observed positive associations with combined circulatory and diabetes mortality similar in magnitude to those observed for diabetes mortality in the larger cohort (Crouse et al., 2016; Crouse et al., 2015).

An important consideration in characterizing the association between long-term $PM_{2.5}$ exposure and mortality is whether the concentration-response relationship is linear across the full concentration range that is encountered, or if there are concentration ranges where there are departures from linearity. Brook et al. (2013a) conducted an analysis of the CanCHEC cohort to inform the shape of the C-R relationship for the association between long-term exposure to $PM_{2.5}$ and diabetes mortality, observing a linear, no-threshold relationship across the full range of concentrations measured during the study (Figure 7-12). C-R relationships for metabolic morbidity outcomes are described in Supplemental Table S7-4 (U.S. EPA, 2018).



Note: The association shown represents the results from the standard Cox survival model with a natural spline of $PM_{2.5}$ with two degrees of freedom. Tick marks on the *x*-axis represent the position of $PM_{2.5}$ concentration measured in µg/m^3. Dashed lines represent 95%confidence intervals (CIs).

7.2.11 Summary and Causality Determination

There were no causal conclusions for metabolic effects in the 2009 PM ISA (U.S. EPA, 2009). The literature pertaining to the effect of long-term exposure to $PM_{2.5}$ and metabolic effects has expanded substantially since the 2009 PM ISA, with multiple epidemiologic and experimental studies currently available for review. Positive associations between long-term exposure to $PM_{2.5}$ and diabetes-related mortality were observed in well-established cohorts in the U.S. and Canada. The mortality findings are supported by epidemiologic and experimental studies reporting effects on glucose and insulin homeostasis, as well as other indicators of metabolic function (e.g., peripheral inflammation and liver function). Findings from epidemiologic studies of metabolic disease were not entirely consistent and consideration of copollutant confounding was limited; however, some well-conducted studies reported positive associations of long-term exposure to $PM_{2.5}$ with metabolic syndrome and its components (e.g., increased blood glucose, insulin resistance, and dyslipidemia) and the incidence of diabetes. The evidence characterizing the relationship between long-term exposure to $PM_{2.5}$ and metabolic effects is detailed below (Table 7-14), using the framework for causal determination described in the Preamble to the ISAs (U.S. EPA, 2015).

Several recent epidemiologic analyses of the ACS cohort found positive associations between long-term $PM_{2.5}$ exposure, which was estimated using a variety of exposure assessment methods, and mortality due to diabetes (Jerrett et al., 2016; Turner et al., 2016; Pope et al., 2014). Positive associations were also identified between long-term $PM_{2.5}$ exposure and diabetes in series of analyses from the large Canadian cohort, CanCHEC (Crouse et al., 2016; Crouse et al., 2015; Brook et al., 2013a). When the CanCHEC cohort was combined with Canadian Community Health Survey Pinault et al. (2016) observed positive associations with combined circulatory disease and diabetes mortality. Additionally, Brook et al. (2013a) observed a linear, no-threshold relationship across the full range of concentrations measured in this cohort.

Well-conducted studies from Canada and Denmark reported positive associations between long-term $PM_{2.5}$ exposure and the incidence of T2D (Hansen et al., 2016; Chen et al., 2013). A relationship between long-term $PM_{2.5}$ exposure and incident diabetes was not supported by analyses of data from well-established U.S. cohorts including MESA, NHS, HPFU, and BWHS, however (Coogan et al., 2016; Park et al., 2015; Puett et al., 2011). A longitudinal analysis of older adult male participants in the NAS (Wallwork et al., 2017), reported associations of long-term $PM_{2.5}$ with metabolic syndrome and several components including increased FBG and dyslipidemia. Another longitudinal epidemiologic study provided additional support, reporting an increase in blood glucose level in association with 28-day average $PM_{2.5}$ exposure (Lucht et al., 2018a). Several cross-sectional analyses also showed associations with measures of glucose and insulin homeostasis (Section 7.2.3.1). The limited number of epidemiologic studies that considered confounding by copollutants did not consistently report that the effect of $PM_{2.5}$ remained after adjustment for NO_2, NO_X or PM_{10}.

Experimental animal studies address some of the uncertainty in the epidemiologic evidence related to the independent effect of $PM_{2.5}$ exposure by providing evidence of direct effects on metabolic function. The animal toxicological studies provided evidence that long-term $PM_{2.5}$ exposure resulted in impaired insulin signaling, glucose tolerance, and insulin resistance (Section 7.2.3). In addition, these pathophysiological changes were often accompanied by increased inflammatory markers in the blood and peripheral inflammation in adipose, liver and heart tissues (Section 7.2.5). Most of the animal toxicology studies evaluating effects on glucose and insulin derived $PM_{2.5}$ CAPs from the same Columbus, OH air shed and were performed by the same group of investigators. Importantly, long-term $PM_{2.5}$ exposure effects were evaluated in animals fed a normal diet and animals models of metabolic syndrome-like phenotypes and provided evidence that long-term $PM_{2.5}$ exposure could lead to development or worsening of metabolic syndrome or its risk factors.

Epidemiologic studies report positive associations between long-term $PM_{2.5}$ exposure and diabetes-related mortality. Although results were not consistent across cohorts, some epidemiologic studies report positive associations with incident diabetes, metabolic syndrome, glucose and insulin homeostasis. Consideration of copollutant confounding was limited. Some support was provided by experimental studies demonstrating increased blood glucose, insulin resistance, and inflammation and visceral adiposity but the experimental evidence was not entirely consistent. **Overall, the collective evidence is suggestive of, but is not sufficient to infer, a causal relationship between long-term $PM_{2.5}$ exposure and metabolic effects.**

Table 7-14 Summary of evidence that is suggestive of, but not sufficient to infer, a causal relationship between long-term $PM_{2.5}$ exposure and metabolic effects.

7.3 Short-term $PM_{10-2.5}$ Exposure and Metabolic Effects

There were no epidemiologic or experimental studies of short-term exposure to $PM_{10-2.5}$ and metabolic effects such as diabetes or glucose and insulin homeostasis reviewed in the 2009 PM ISA nor have recent studies become available. **The evidence is inadequate to infer the presence or absence of a causal relationship between short-term $PM_{10-2.5}$ exposure and metabolic effects.**

7.4 Long-Term $PM_{10-2.5}$ Exposure and Metabolic Effects

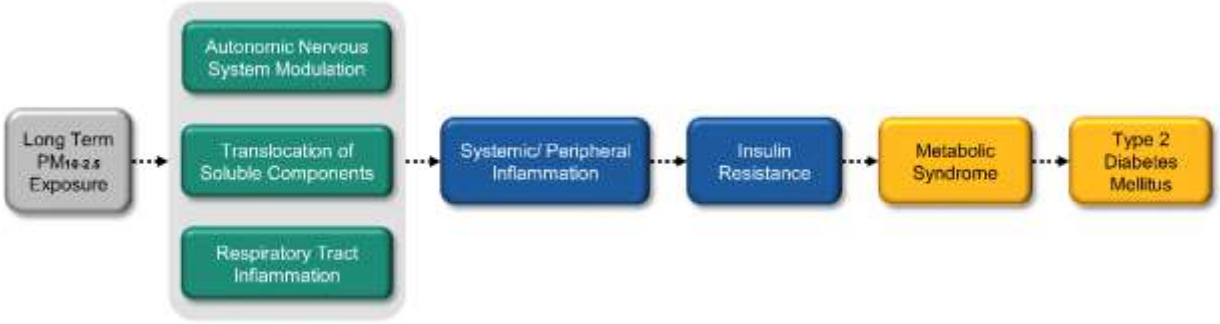
There were no studies of $PM_{10-2.5}$ and metabolic effects reviewed in the 2009 PM ISA. The discussion of the limited number of recent studies long-term $PM_{2.5}$ exposure and metabolic effects opens with a discussion of biological plausibility (Section 8.1.1) that provides background for the subsequent section in which the evidence related to T2D is presented. The collective body of evidence is integrated across and within scientific disciplines[70], and the rationale for the causality determination is outlined in Section 7.4.3.

7.4.1 Biological Plausibility

This section describes biological pathways that potentially underlie metabolic effects resulting from long-term exposure to $PM_{10-2.5}$. Figure 7-13 graphically depicts the potential pathways as a continuum of upstream events, connected by arrows, that may lead to downstream events observed in epidemiologic studies. This discussion of "how" exposure to $PM_{10-2.5}$ may lead to metabolic health effects contributes to an understanding of the biological plausibility of epidemiologic results evaluated later in Section 7.4.

Soluble components of $PM_{10-2.5}$ may translocate into the systemic circulation and contribute to inflammatory or other processes in extrapulmonary compartments. The extent to which translocation into the systemic circulation occurs is currently uncertain (Chapter 4). Furthermore, the PM administered dose depends on deposition, which is a function of particle size, intake, and physical chemistry as well as modifying factors such as lifestages and species. It is possible that deposition of $PM_{10-2.5}$ may initiate pathways that include ANS modulation, translocation of soluble components, and respiratory tract inflammation that converge upon inflammation leading to insulin resistance. Therefore, implicit relationships between long-term $PM_{10-2.5}$ exposure and observed health effects that include diabetes can be drawn even though the evidence is limited. For example, Wolf et al. (2016) reported positive increases in CRP (a nonspecific marker of inflammation produced by the liver) supporting a pathway toward systemic and peripheral inflammation. Wolf et al. (2016) also reported a positive association with HOMA-IR, a measure of insulin resistance. These events and endpoints are on the pathway leading to T2D, an outcome that was positively associated with long-term exposure to $PM_{10-2.5}$ by Puett et al. (2011).

[70] As detailed in the Preface, risk estimates are for a 5 $\mu g/m^3$ increase in annual $PM_{10-2.5}$ concentrations unless otherwise noted.



The boxes above represent the effects for which there is experimental or epidemiologic evidence, and the dotted arrows indicate a proposed relationship between those effects. Shading around multiple boxes denotes relationships between groups of upstream and downstream effects. Progression of effects is depicted from left to right and color-coded (grey, exposure; green, initial event; blue, intermediate event; orange, apical event). Here, apical events generally reflect results of epidemiologic studies, which often observe effects at the population level. Epidemiologic evidence may also contribute to upstream boxes. When there are gaps in the evidence, there are complementary gaps in the figure and the accompanying text below.

Figure 7-13 Potential biological pathways for metabolic effects following long-term $PM_{10-2.5}$ exposure.

As described here, there are proposed pathways by which long-term exposure to $PM_{10-2.5}$ could lead to metabolic health effects. One pathway involves ANS modulation, translocation of soluble components, and respiratory tract inflammation that may lead to systemic and peripheral inflammation that is linked to insulin resistance and metabolic syndrome comorbidities. Together, these proposed pathways provide limited biological plausibility for epidemiologic results of metabolic health effects, highlight areas where further scientific understanding is needed, and will be used to support a causal determination, which is discussed later in the chapter (Section 7.4.3).

7.4.2 Type 2 Diabetes

Puett et al. (2011) observed a small increased hazard in association with long-term exposure to $PM_{10-2.5}$ [HR: 1.05 (95% CI: 0.98,1.13)] that remained after adjustment for $PM_{2.5}$ in the NHS. Cross-sectional studies provided supporting evidence that long-term $PM_{10-2.5}$ exposure is associated with IGM, diabetes, HOMA-IR, leptin and CRP (Wolf et al., 2016; Teichert et al., 2013). Overall, the number of epidemiologic studies (Table 7-14) is limited but findings are compatible with an effect of $PM_{10-2.5}$.

7.4.3 Summary and Causal Determination

There were no studies of $PM_{10-2.5}$ and metabolic effects in the 2009 PM ISA. A high quality epidemiologic study reporting an association between long-term $PM_{10-2.5}$ exposure and incident diabetes is now available (Puett et al., 2011). In addition, effects on glucose (Teichert et al., 2013) or insulin (Wolf et al., 2016) were observed in cross-sectional studies of glucose and insulin homeostasis conducted in European cohorts. Limited biological plausibility is derived from the potential for deposition of $PM_{10-2.5}$ to modulate the ANS, the immune system or disrupt glucose, lipid, and insulin homeostasis. The evidence relevant to the causal determination for long-term exposures to $PM_{10-2.5}$ is evaluated using the framework described in Table II of the Preamble to the ISAs (U.S. EPA, 2015). The key evidence, as it relates to the causal framework, is summarized in Table 7-15. **Overall, the evidence is suggestive of, but not sufficient to infer, a causal relationship between short-term $PM_{10-2.5}$ exposure and metabolic effects.**

Table 7-16 Summary of evidence that is suggestive of, but not sufficient to infer, a causal relationship between long-term $PM_{10-2.5}$ exposure and metabolic effects.

Rationale for Causal Determination[a]	Key Evidence[b]	Key References[b]	$PM_{10-2.5}$ Concentrations Associated with Effects[c]
Evidence at least one high quality epidemiologic study but studies limited in number, overall.	Positive association with incident T2D reported in NHS; Effects on glucose and insulin homeostasis observed in cross-sectional analyses of European cohorts.	Puett et al. (2011) Teichert et al. (2013) Wolf et al. (2016)	Mean concentrations across studies 6.2−34.0 μg/m^3
Uncertainty regarding epidemiologic evidence from copollutant models to support and independent $PM_{10-2.5}$ association	$PM_{10-2.5}$ association persisted after adjustment for $PM_{2.5}$ but evidence lacking, overall.	Puett et al. (2011)	
Uncertainty regarding exposure measurement error	$PM_{10-2.5}$ concentrations estimated using difference of monthly modelled concentrations of PM_{10} and $PM_{2.5}$ which has noted limitations.	Section 2.4.2	
	Potentially uncharacterized spatial variation adds additional uncertainty.	Section 2.5 and Section 3.3.1.1	
Limited biological plausibility	Some evidence that $PM_{10-2.5}$ may modulate the ANS following deposition, the immune system or disrupt glucose, lipid, and insulin homeostasis.	Section 7.4.1	

$PM_{2.5}$ = particulate matter with a nominal aerodynamic diameter less than or equal to 2.5 μm; $PM_{10-2.5}$ = particulate matter with a nominal aerodynamic diameter less than or equal to 10 μm and greater than a nominal diameter of 2.5 μm.

[b]Describes the key evidence and references contributing most heavily to causal determination and, where applicable, to uncertainties or inconsistencies. References to earlier sections indicate where the full body of evidence is described.

[c]Describes the $PM_{10-2.5}$ concentrations with which the evidence is substantiated.

7.5 Short-Term UFP Exposure and Metabolic Effects

There are no experimental studies examining the effects short-term UFP exposure on metabolic function. A recent longitudinal analysis of the data from the HNR study found an association of 28-day

average accumulation mode UFP (NC) exposure with increased blood glucose [0.64 mg/dL (95% CI: 0.07, 1.21) per IQR increase] and increased HbA1c [0.03% (0.01, 0.05) per IQR increase] (Lucht et al., 2018a). Uncharacterized temporal and spatial variability in the exposure concentration is an uncertainty for this study because a 28-day average exposure was estimated for 1 km^2 grid cells, not the participants' residence (Section 3.4.5.1.1). **Overall, the evidence is inadequate to infer the presence or absence of a causal relationship between short-term UFP exposure and metabolic effects.**

7.6 Long-Term UFP Exposure and Metabolic Effects

There were no studies of the effect of long-term UFP exposure and metabolic effects reviewed in the 2009 PM ISA. In a recent longitudinal epidemiologic study, Lucht et al. (2018a) reported an increase in FBG (0.67 mg/dL 0.10 1.24) and HbA1c [0.09% (0.07, 0.11) per IQR increase] in association with 91-day average exposure to accumulation mode UFP (NC). Uncharacterized spatial and temporal variability is an uncertainty in this study because UFP exposure was assigned to a 1 km^2 grid cell, not at the level of the participants' residence (Section 3.4.5.2). In addition, a toxicological study (Li et al., 2013) evaluated the effects of long-term UFP in mice (Table 7-16). This study investigated the effects of long-term UFP exposure in an *Ldlr*$^{-/-}$ mouse model fed a high fat diet in the presence or absence of an apolipoprotein A-I mimetic peptide (D-4F). This genetic mouse model has a mutation in the low-density lipoprotein receptor and are prone to very high blood cholesterol levels when fed a high fat diet. While the investigators identified UFP effects such as increased triglyceride, decreased HDL, reduced HDL antioxidant index, increased oxidized lipid metabolites (HETEs and HODEs), increased serum amyloid A (SAA) and TNFα, and increased area in atherosclerotic plaque lesions (all $p < 0.05$) that were improved by D-4F (a mimetic peptide of apolipoprotein A-I made of D-amino acids) administration, the authors did not include wild-type controls. Furthermore, there are inherent differences in cholesterol metabolism between mouse and human that render the mouse somewhat resistant to the development of atherosclerotic plaques. Specifically, mice lack cholesterol ester transfer protein that shuttles cholesterol from HDL to LDL for reverse cholesterol transport; therefore, mice carry most of their cholesterol on HDL particles rather than, like human, on LDL particles (Getz and Reardon, 2012). The available studies continue to be limited. **Overall, the evidence is inadequate to infer the presence or absence of a causal relationship between long-term UFP exposure and metabolic effects.**

Table 7-17 Study specific details from animal toxicology studies of metabolic homeostasis.

Study	Study Population	Exposure Details	Endpoints Examined
Li et al. (2013)	*Ldlr*$^{-/-}$ mouse on C57Bl/6 background, male, 90 days old	Whole body inhalation of UFP collected in urban regions of Los Angeles, CA. Animals were exposed to 360 μg/m^3 for 10 weeks ± poA1 mimetic peptide	Plasma HDL, HDL oxidation index, paraoxonase activity. Plasma, 9-HODE and 12-HETE, SAA and TNF-α. In the aorta, Sudan IV staining for fatty streaks, both in en face and aortic leaflet preparations

CHAPTER 8 NERVOUS SYSTEM EFFECTS

Summary of Causality Determinations for Short- and Long-Term Particulate Matter (PM) Exposure and Nervous System Effects

This chapter characterizes the scientific evidence that supports causality determinations for short- and long-term PM exposure and nervous system effects. The types of studies evaluated within this chapter are consistent with the overall scope of the ISA as detailed in the Preface (see Section P 3.1). In assessing the overall evidence, strengths and limitations of individual studies were evaluated based on scientific considerations detailed in the Appendix. More details on the causal framework used to reach these conclusions are included in the Preamble to the ISA (U.S. EPA, 2015).

Size Fraction	Causality Determination
Short-term Exposure	
$PM_{2.5}$	Suggestive of, but not sufficient to infer
$PM_{10-2.5}$	Inadequate
UFP	Suggestive of, but not sufficient to infer
Long-term Exposure	
$PM_{2.5}$	Likely to be causal
$PM_{10-2.5}$	Suggestive of, but not sufficient to infer
UFP	Likely to be causal

8.1 Short-term $PM_{2.5}$ Exposure and Nervous System Effects

The evidence in the 2009 ISA for PM was characterized as "inadequate" to determine if a causal relationship between short-term $PM_{2.5}$ exposure and nervous system effects exists (U.S. EPA, 2009). A small number of experimental animal studies relevant to the assessment were available for review. Exposure to $PM_{2.5}$ CAPs resulted in pro-inflammatory responses in the brain (Campbell et al., 2005) and modulation of norepinephrine and corticosterone levels, which are indicative of sympathetic nervous system (SNS) and hypothalamic-pituitary-adrenal (HPA) stress axis activation (Sirivelu et al., 2006). Studies found that exposure to $PM_{2.5}$ CAPs could affect the autonomic nervous system (ANS) by activating sensory nerves in the respiratory tract, leading to cardiac oxidative stress and changes in cardiac function (Ghelfi et al., 2008; Rhoden et al., 2005). In addition, multiple studies reported that short-term exposure to $PM_{2.5}$ is associated with changes in heart rate variability (HRV), which reflect an imbalance between the sympathetic and parasympathetic arms of the ANS (Section 6.1.1). Findings from

recent experimental studies are generally consistent with previous studies, adding to the evidence that short-term exposure to $PM_{2.5}$ can lead to brain inflammation and activation of the SNS. The small number of epidemiologic studies published since the 2009 PM ISA do not consistently report positive associations between short-term exposure to $PM_{2.5}$ and hospitalizations for nervous system diseases, depression, or reduced cognitive function.

The discussion of short-term $PM_{2.5}$ exposure and nervous system effects opens with a discussion of biological plausibility (Section 8.1.1) that provides background for the subsequent sections in which groups of related endpoints are presented in the context of relevant disease pathways. These outcome groupings are activation of the SNS and HPA stress Axis (Section 8.1.2), brain inflammation and oxidative stress (Section 8.1.3), and diseases of the nervous system and depression (Section 8.1.4). Evidence pertaining to $PM_{2.5}$ components is summarized in Section 8.1.5. Finally, the collective body of evidence is integrated[71] across and within scientific disciplines, and the rationale for the causality determination is outlined in Section 8.1.6.

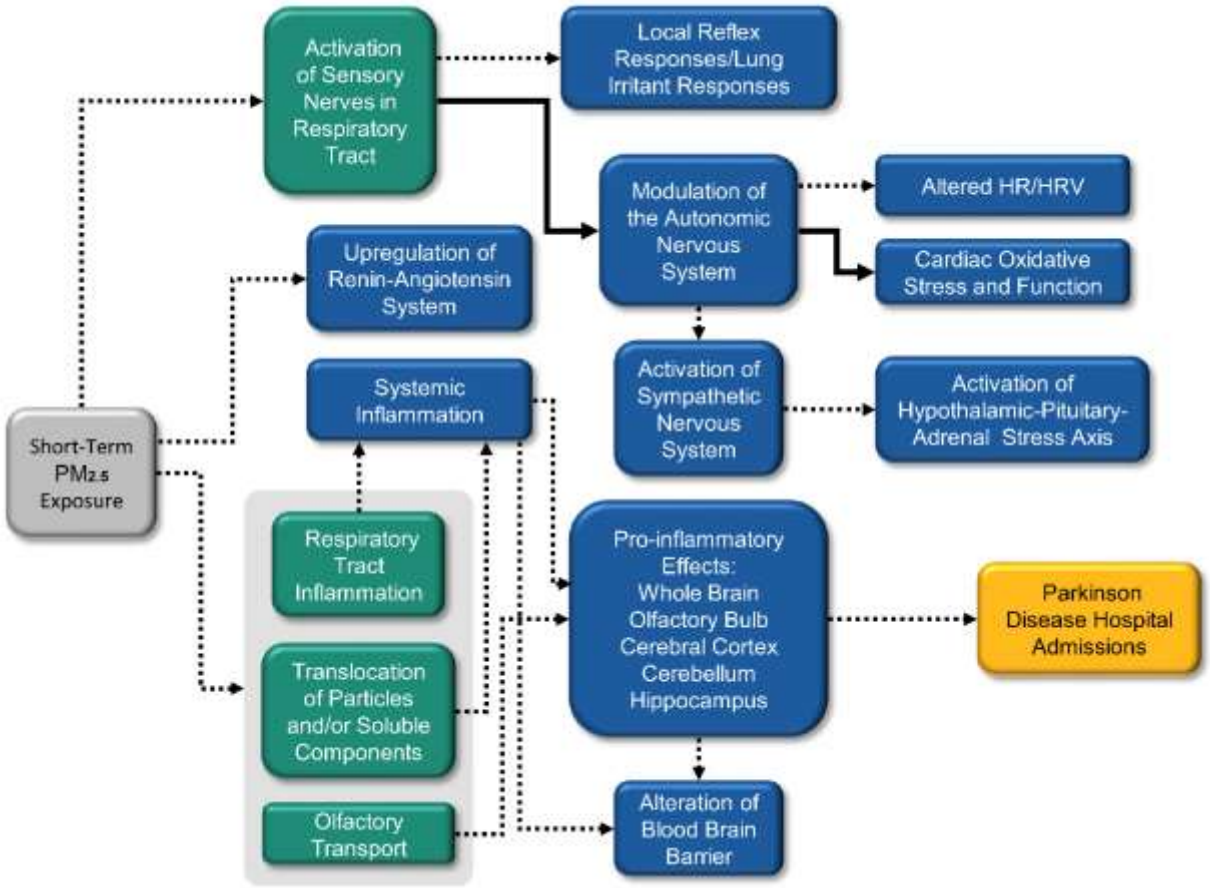
8.1.1 Biological Plausibility

This section describes biological pathways that potentially underlie the development of nervous system effects resulting from short-term exposure to $PM_{2.5}$. Figure 8-1 graphically depicts the proposed pathways as a continuum of upstream events, connected by arrows, that may lead to downstream events observed in epidemiologic studies. This discussion of "how" short-term exposure to $PM_{2.5}$ may lead to nervous system effects contributes to an understanding of the biological plausibility of epidemiologic results evaluated later in Section 8.1.

Once $PM_{2.5}$ deposits in the respiratory tract, it may be retained, cleared, or solubilized (see Chapter 4). $PM_{2.5}$ and its soluble components may interact with cells in the respiratory tract, such as epithelial cells, inflammatory cells, and sensory nerve cells. One way in which this may occur is through reduction-oxidative (redox) reactions. As discussed in Section 2.3.3, PM may generate reactive oxygen species (ROS) and this capacity is termed "oxidative potential". Furthermore, cells in the respiratory tract may respond to the presence of PM by generating ROS. Further discussion of these redox reactions, which may contribute to oxidative stress, is found in Section 5.1.1 of the 2009 PM ISA (U.S. EPA, 2009). In addition, poorly soluble particles may translocate to the interstitial space beneath the respiratory epithelium and accumulate in the lymph nodes (see CHAPTER 4). Immune system responses due to the presence of particles in the interstitial space may contribute to health effects. Inflammatory mediators may diffuse from the respiratory tract into the systemic circulation and lead to inflammation in extrapulmonary compartments (Section 6.1.1). Soluble components of $PM_{2.5,}$ and poorly soluble particles

[71] As detailed in the Preface, risk estimates are for a 10 $\mu g/m^3$ increase in 24-hour avg $PM_{2.5}$ concentrations unless otherwise noted.

that are part of the $PM_{2.5}$ fraction and smaller than approximately 200 nm, may translocate into the systemic circulation and contribute to inflammatory or other processes in extrapulmonary compartments. A fraction of $PM_{2.5}$ may deposit on the olfactory epithelium. Soluble components of $PM_{2.5,}$ and poorly soluble particles that are part of the $PM_{2.5}$ fraction and smaller than approximately 200 nm, may also be transported via the olfactory nerve to the olfactory bulb of the brain. The extent to which translocation into the systemic circulation or transport to the olfactory bulb occurs is currently uncertain. For further discussion of translocation and olfactory transport, see Chapter 4.



Note: The boxes above represent the effects for which there is experimental or epidemiologic evidence, and the dotted arrows indicate a proposed relationship between those effects. Solid arrows denote direct evidence of the relationship as provided, for example, by an inhibitor of the pathway or a genetic knock-out model used in an experimental study. Progression of effects is depicted from left to right and color-coded (gray, exposure; green, initial event; blue, intermediate event; orange, apical event). Here, apical events generally reflect results of epidemiologic studies, which often observe effects at the population level. Epidemiologic evidence may also contribute to upstream boxes. When there are gaps in the evidence, there are complementary gaps in the figure and the accompanying text below.

Figure 8-1 Potential biological pathways for nervous system effects following short-term $PM_{2.5}$ exposure.

Evidence that short-term exposure to $PM_{2.5}$ may affect the nervous system generally informs two different pathways (Figure 8-1). The first pathway begins with the activation of sensory nerves in the respiratory tract that can trigger local reflex responses and transmit signals to regions of the central nervous system that regulate autonomic outflow. Altered autonomic tone may result in downstream systemic effects. The second pathway begins with pulmonary inflammation and may lead to systemic inflammation and to inflammation in the brain. Inflammation may lead to a worsening of neurodegenerative disease. Evidence for these pathways is described below.

Activation of Sensory Nerves and Modulation of the Autonomic Nervous System (ANS)

With regard to the first pathway, activation of sensory nerves in the respiratory tract leads to modulation of the sympathetic and parasympathetic branches of the ANS. The ANS influences all the internal organs, including the heart. Lung irritant responses, discussed in Chapter 5 (Section 5.1.1, Section 5.1.7, and Section 5.1.8), are local reflex responses triggered by $PM_{2.5}$ exposure-induced activation of sensory nerves. Altered autonomic outflow can manifest as changes in heart rate and heart rate variability, as discussed in Section 6.1.1. Furthermore, an animal toxicological study demonstrated that specific receptors on the sensory nerves, the transient receptor potential (TRP) cation channels, were involved in mediating autonomic responses in the heart (Ghelfi et al., 2008). Treatment with a receptor antagonist blocked cardiac oxidative stress and changes in electrophysiologic parameters resulting from short-term exposure to $PM_{2.5}$. Inhibitors of the parasympathetic nervous system and SNS also blocked cardiac oxidative stress in this model (Rhoden et al., 2005). The solid lines depicted in Figure 8-1, which connect activation of sensory nerves to modulation of the ANS and to cardiac oxidative stress/function, indicate that activation of TRP receptors on sensory nerves in the respiratory tract mediated changes in the heart via the ANS.

The SNS may be especially impacted by $PM_{2.5}$ exposure. Animal toxicological studies demonstrated that short-term $PM_{2.5}$ exposure results in increased norepinephrine in specific hypothalamic regions (Balasubramanian et al., 2013; Sirivelu et al., 2006) and in peripheral tissues (Chiarella et al., 2014). Increases in norepinephrine, both in the brain and peripheral organs, are hallmarks of increased SNS activity. Further, a neuroendocrine response, activation of the HPA stress axis, may be initiated in the hypothalamus via norepinephrine and corticotropin releasing hormone (CRH), resulting in increased levels of circulating glucocorticoids. Sirivelu et al. (2006) and Balasubramanian et al. (2013) found increased CRH levels in the hypothalamus, as well as increased serum glucocorticoids. Thus, short-term exposure to $PM_{2.5}$ may lead to activation of the SNS and to activation of the HPA stress axis.

Furthermore, studies suggest connections between modulation of the ANS resulting from short-term $PM_{2.5}$ exposure and other effects. A study in mice found that exposure to $PM_{2.5}$ increased SNS activity, as indicated by increased norepinephrine levels in the lung and in brown adipose tissue (Chiarella et al., 2014). Inhalation of $PM_{2.5}$ increased BALF cytokine levels, an effect which was enhanced by β2

adrenergic receptor agonists, which mimic the actions of norepinephrine. Using knock-out mice lacking the β2 adrenergic receptor specifically in alveolar macrophage, it was demonstrated that inhalation of $PM_{2.5}$ enhanced cytokine release from alveolar macrophages. This involvement of the SNS in inflammatory responses resulting from $PM_{2.5}$ exposure is depicted by the solid line that connects ANS responses and respiratory tract inflammation in Figure 5-1. This is likely to represent a positive feed-back mechanism by which the ANS may enhance inflammation. Another study found upregulation of the renin-angiotensin (RAS) system in the lung and heart (Aztatzi-Aguilar et al., 2015), as depicted in Figure 5-1. The SNS and RAS are known to interact in a positive feedback fashion (Section 8.2.1), with important ramifications for the cardiovascular system. However, it is not known whether SNS activation or some other mechanism mediated the changes in the RAS observed in the respiratory tract (Aztatzi-Aguilar et al., 2015). Ghelfi et al. (2010) found that short-term exposure to $PM_{2.5}$ increased levels of circulating angiotensin II, which is an important component of the RAS.

Inflammation

With regard to the second pathway, deposition of $PM_{2.5}$ in the respiratory tract may lead to pulmonary inflammation (see Section 5.1.1) and to systemic inflammation (see Section 6.1.1). Brain inflammation may be due to peripheral immune activation (Fonken et al., 2011) or to systemic circulation of $PM_{2.5}$, alone or engulfed by macrophages, that results in particle uptake in the brain (Ljubimova et al., 2013). Inflammation in the brain may alternatively occur following olfactory transport of poorly soluble particles or their soluble components or to a neuroendocrine stress response resulting from activation of the HPA stress axis (Kodavanti, 2016).

Several animal toxicological studies demonstrated pro-inflammatory effects following short-term $PM_{2.5}$ exposure (Campbell et al., 2005), (Bos et al., 2012), (Tyler et al., 2016). Inflammation was observed in the olfactory bulb, cerebral cortex, cerebellum, and hippocampus. Two of these studies demonstrated brain inflammation in the absence of pulmonary or systemic inflammation (Tyler et al., 2016; Bos et al., 2012), pointing to a direct effect of $PM_{2.5}$ on the brain. Evidence for perturbation of the blood brain barrier is provided by a controlled human exposure study (Liu et al., 2017). Circulating inflammatory mediators and soluble components of $PM_{2.5,}$ as well as brain inflammation, may play a role in altering the blood brain barrier. Inflammation may lead to a worsening of neurodegenerative disease and provide support for epidemiologic evidence of hospitalization for Parkinson disease (Zanobetti et al., 2014).

Summary of Biological Plausibility

As described here, there are two proposed pathways by which short-term exposure to $PM_{2.5}$ may lead to nervous system effects. Experimental studies in animals and humans contribute all the evidence of upstream events. The first pathway begins with activation of sensory nerves in the respiratory tract and may potentially lead to modulation of the ANS resulting in increased activity of the SNS and stimulation

of the HPA stress axis. Upregulation of the RAS may also contribute to SNS activation. Thus, the ANS may mediate systemic responses due to exposure to $PM_{2.5}$. The second proposed pathway begins with pulmonary/systemic inflammation or olfactory transport of $PM_{2.5}$ leading to brain inflammation. This pathway provides biological plausibility for epidemiologic results of increased hospital admissions for Parkinson disease. These pathways will be used to inform a causality determination, which is discussed later in the chapter (Section 8.1.6).

8.1.2 Activation of the Sympathetic Nervous System and the Hypothalamic-Pituitary-Adrenal (HPA)Stress Axis

As discussed in the biological plausibility section above, sensory nerves in the respiratory tract can transmit signals to regions of the central nervous system that regulate autonomic outflow. The ANS regulates many different functions in the body (e.g., heart rate). Further, a neuroendocrine response, activation of the HPA stress axis, may be initiated in the hypothalamus via norepinephrine and CRH, resulting in increased levels of circulating glucocorticoids.

8.1.2.1 Controlled Human Exposure Study

A controlled human exposure study examined the effects of a 130 minute exposure to $PM_{2.5}$ CAPs in Toronto on urinary and blood biomarkers associated with neural effects (Liu et al., 2017). No association was observed with SNS or HPA stress axis-related biomarkers (Table 8-1).

Table 8-1 Study-specific details from a controlled human exposure study of short-term $PM_{2.5}$ exposure and activation of the sympathetic nervous system (SNS) and hypothalamic-pituitary-adrenal (HPA) stress axis.

Study/Study Population	Pollutant	Exposure Details	Endpoints Examined
Liu et al. (2017) Species: Human Health status: Healthy nonsmokers Sex: 29 females, 26 males Age: 18−60 yr Study design: Single-blind randomized cross-over trial	CAPs from Toronto, ON Particle sizes: 0.15−2.5 µm Control: HEPA filtered ambient air or HEPA-filtered medical air (ultrafine study)	Route: Face mask inhalation Dose/concentration: 238.4 ± 62.0 µg/m^3 Duration of exposure: 130 min Time to analysis: 1 and 21 h	Urinary and blood markers of neural effects

CAPs = concentrated ambient particles, h=hours, HEPA = high efficiency particulate air, yr=years.

8.1.2.2 Animal Toxicological Studies

An animal toxicological study included in the 2009 ISA PM (U.S. EPA, 2009) found that $PM_{2.5}$ CAPs exposure resulted in modulation of norepinephrine in the paraventricular nucleus of the hypothalamus and in the olfactory bulb of nonallergic rats, while rats that were sensitized and challenged with ovalbumin exhibited increases in dopamine in the medial preoptic area (Sirivelu et al., 2006). Increased norepinephrine levels in the hypothalamus indicate activation of the SNS and this study also found an increase in serum corticosterone in non-allergic $PM_{2.5}$ CAPs-exposed rats, suggesting an activation of the HPA stress axis subsequent to changes in these neurotransmitters. Recent studies provide additional support demonstrating an effect of $PM_{2.5}$ on the SNS and HPA stress axis (Table 8-2).

Balasubramanian et al. (2013) found that inhalation of $PM_{2.5}$ CAPs altered levels of neurotransmitters and CRH in specific brain regions of lean and obese rats. Lean Brown Norway rats exposed to $PM_{2.5}$ CAPs in Grand Rapids, MI had increased levels of norepinephrine in the paraventricular nucleus of the hypothalamus 1 day ($p < 0.05$), but not 3 days, after exposure. A similar pattern was observed for 5-hydroxy-indole acetic acid ($p < 0.05$), the main metabolite of serotonin, while dopamine levels were unchanged. An increase in CRH in the median eminence of the hypothalamus was found after 1 day ($p < 0.05$), but not 3 days, of $PM_{2.5}$ CAPs exposure. Corpulent JCR/LA rats exposed for 4 days to CAPs in Detroit, MI had increased norepinephrine and 5-hydroxy-indole acetic acid in the paraventricular nucleus ($p < 0.05$), while the amount of CRH in the median eminence was unchanged. Increased norepinephrine levels in the paraventricular nucleus of the hypothalamus indicate activation of the SNS, while increased CRH levels in the median eminence of the hypothalamus indicate activation of the HPA stress axis. Linkage between the SNS and the HPA stress axis occurs when norepinephrine in the paraventricular nucleus stimulates CRH neurons resulting in the release of CRH from the median eminence. Subsequently, circulating CRH stimulates adrenocorticotropin secretion from the pituitary and adrenocorticotropin acts on the adrenal gland resulting in the secretion of glucocorticoids such as corticosterone. Thus, activation of the SNS may lead to increased glucocorticoid levels. In the current study, an increase in norepinephrine was accompanied by an increase in CRH only in the lean rats exposed for 1 day to $PM_{2.5}$ CAPs.

Findings of Balasubramanian et al. (2013) build on the results of (Sirivelu et al., 2006) that found increases in norepinephrine levels in the paraventricular nucleus of the hypothalamus and in serum corticosterone levels following a 1-day exposure to CAPs. Together, these studies indicate that $PM_{2.5}$ exposure may increase the activity of the SNS and the HPA stress axis via effects on the hypothalamus. In Balasubramanian et al. (2013), increases in neurotransmitter levels were observed in obese animals, but they were not increased in the lean animals, following a multi-day exposure to $PM_{2.5}$. This raises the possibility that an adaptive response dampened the SNS and HPA stress axis in the lean, but not in the obese, animals.

Evidence for SNS activation following short-term exposure to $PM_{2.5}$ is also provided by (Chiarella et al., 2014). In this study, C57BL/6 mice were exposed to $PM_{2.5}$ CAPs in Chicago, IL for

several days. Norepinephrine levels in both lung and brown adipose tissue were increased above controls ($p < 0.05$), indicating activation of the SNS. Norepinephrine was found to enhance the amount of IL−6 in BALF, a pro-inflammatory effect, in the lung (see Section 5.1.7).

Table 8-2 Study-specific details from animal toxicological studies of short-term $PM_{2.5}$ exposure and activation of the sympathetic nervous system (SNS) and hypothalamic-pituitary-adrenal (HPA) stress axis.

Study/Study Population	Pollutant	Exposure Details	Endpoints Examined
Balasubramanian et al. (2013) Species: rat Strain: Brown Norway (lean) JCR/LA (corpulent) Sex: male Age/Weight: JCR/LA-4 and 8 mo	CAPs from urban Grand Rapids, MI or urban Detroit, MI Particle Sizes: $PM_{2.5}$ HEPA-filtered clean air	Route: Whole body inhalation Dose/Concentration: 1 day: mean 519 µg/m^3 $PM_{2.5}$ CAPs Grand Rapids 3 day: mean 595 µg/m^3 $PM_{2.5}$ CAPs 4 day: mean 291 µg/m^3 $PM_{2.5}$ CAPs Grand Rapids Duration of exposure: 1, 3, or 4 days Time to analysis: 24 h after the last exposure	Brain tissue—neurotransmitter and corticotrophin releasing hormone levels in the hypothalamus
Chiarella et al. (2014) Species: Mouse Sex: Male Strain: C57BL/6 WT and Adrb2 knockouts Age/Weight: 8−12 week	CAPs from Chicago, IL Particle size: $PM_{2.5}$ Control: filtered ambient air	Route: Whole body inhalation Dose/Concentration: 109.1 ± 6.1 µg/m^3 Duration: 8 h/day for 3 days	BALF and lung tissue—IL−6, norepinephrine Brown adipose tissue • norepinephrine Liver tissue • prothrombin and TF mRNA Thrombotic potential

Adrb2 = adrenergic beta 2, BALF = bronchoalveolar lavage fluid, CAPs = concentrated ambient particles, h=hour(s), HEPA=high efficiency particulate air, IL−6 = interleukin−6; TF = tissue factor; WT = wild type.

8.1.3 Brain Inflammation and Oxidative Stress

Chronic brain inflammation is thought to underlie conditions such as neurodegenerative disease. Although repeated exposure may lead to similar downstream health consequences, the effect of acute inflammation is less clear.

8.1.3.1 Controlled Human Exposure Study

A controlled human exposure study examined the effects of a 130 minute exposure to $PM_{2.5}$ CAPs in Toronto, ON on urinary and blood biomarkers associated with neural effects (Liu et al., 2017). An association was observed between exposure to $PM_{2.5}$ CAPs and blood ubiquitin C-terminal hydrolase L1, a biomarker related to blood brain barrier integrity, measured 21 hours post-exposure ($p < 0.1$). Impaired blood brain barrier integrity is associated with brain inflammation (Table 8-3).

Table 8-3 Study-specific details from a controlled human exposure study of short-term $PM_{2.5}$ exposure and brain inflammation and oxidative stress.

Study/Study Population	Pollutant	Exposure Details	Endpoints Examined
Liu et al. (2017) Species: Human Health status: Healthy nonsmokers Sex: 29 females, 26 males Age: 18−60 yr Study design: Single-blind randomized cross-over trial	CAPs from Toronto, ON Particle sizes: 0.15−2.5 µm Control: HEPA filtered ambient air or HEPA-filtered medical air (ultrafine study)	Route: Face mask inhalation Dose/concentration: 238.4 ± 62.0 µg/m^3 Duration of exposure: 130 min Time to analysis: 1 and 21 h	Urinary and blood markers of neural effects

CAPs = concentrated ambient particles, h=hour(s), HEPA = high efficiency particulate absorber, min=minute.

8.1.3.2 Animal Toxicological Studies

An animal toxicological study included in the 2009 PM ISA (U.S. EPA, 2009) provided evidence that short-term exposure to $PM_{2.5}$ can lead to brain inflammation. In this study, Campbell et al. (2005) found that $PM_{2.5}$ CAPs exposure enhanced pro-inflammatory responses including cytokine levels and NFκB activation in the brain of animals that had been sensitized and challenged with ovalbumin. Recent studies of short-term exposure to $PM_{2.5}$ add to the evidence base reporting findings that are consistent with brain inflammation (Table 8-4).

Several recent studies examined the effects of traffic-related $PM_{2.5}$ on gene expression in the brain. In one of these, 2 groups of C57BL/6 mice were placed in a highway tunnel (Antwerp, Belgium) for 5 days in cages with and without a highly efficient particle filter (Bos et al., 2012). Other groups of animals were housed in a building near the tunnel in a cage with a less efficient particle filter and in a cage in the animal facility. Bronchoalveolar lavage was performed and demonstrated the presence of carbon particles in alveolar macrophages only in the animals exposed to unfiltered tunnel air. No evidence

of pulmonary (i.e., bronchoalveolar lavage fluid (BALF) cell counts, histology) or systemic inflammation (i.e., coagulation parameters in blood) was found. Alterations in gene expression were observed in the hippocampus and olfactory bulb of animals exposed to unfiltered tunnel air compared with controls. In the hippocampus, this included upregulation of COX2, NOS2, and NOS3 compared to the group exposed to filtered tunnel air and upregulation of COX2, NOS2, and NFE2L2 compared to the group exposed to the building air ($p < 0.05$). In the olfactory bulb, this included downregulation of IL−2α, COX2, NFE2L2, and BDNF compared to the group exposed to filtered tunnel air and downregulation of IL−2α, COX2, and IL−6 compared to the group exposed to the building air ($p < 0.05$). Some differences in gene expression were noted between responses in the control group exposed to filtered tunnel air and the control group exposed to building air, indicating that upregulation of COX2 in hippocampus and downregulation of IL−6 in olfactory bulb may have been due to confounders such as noise stress.

A second study also found evidence of brain inflammation following short-term exposure to $PM_{2.5}$. Tyler et al. (2016) exposed C67BL/6 and ApoE knockout mice to resuspended diesel exhaust particles (DEP) for 6-hours and found decreased mRNA levels for IL−6 and TGF-β in hippocampus of C67BL/6 mice ($p < 0.05$) and increased mRNA levels for IL−6, TGF-β, and TNFα in hippocampus of ApoE knockout mice ($p < 0.05$). In contrast, no inflammatory effects were seen in BALF (see Section 5.1.7.3). Another study examined changes in global gene expression in the brain, as well as expression of Arc and Rac genes and their protein products, in Fischer 344 rats exposed to CAPs in Riverside, CA for 2 weeks (Ljubimova et al., 2013). Exposure to CAPs did not induce any changes in gene or protein expression.

Table 8-4 Study-specific details from animal toxicological studies of short-term $PM_{2.5}$ exposure and brain inflammation and oxidative stress.

Study/Study Population	Pollutant	Exposure Details	Endpoints Examined
Bos et al. (2012) Species: Mouse Sex: Male Strain: C57BL/6 Age/Weight: 10−12 weeks	Ambient PM– Tunnel in Antwerp, Brussels Particle size: $PM_{2.5}$ Controls: 1) HEPA-filtered tunnel air 2) Ambient air in building near roadside	Route: Whole body inhalation Dose/Concentration: Mean 55.1 µg/m³ $PM_{2.5}$ Duration: 5 days Time to analysis: immediately after exposure	Gene expression of inflammatory-related proteins in hippocampus and olfactory bulb BALF cell counts Blood coagulation parameters Lung histology
Ljubimova et al. (2013) Species: Rat Sex: Male Strain: Fisher 344 Age/Weight: 3−7 weeks	CAPs from Riverside, CA (summer) Particle size: 0.18−2.5 µm Control: Filtered air	Route: Whole body inhalation Dose/Concentration: 149 ± 24 µg/m³ Particle number: 67 ± 6 particles/cm³ 10−3 Duration: 5 h/day, 4 days/week for 0.5 mo	Brain tissue—Immunohistochemistry Gene expression—mRNA
Tyler et al. (2016) Species: Mouse Strain: C67BL/6 and ApoE knockout Age/Weight: 6−8 weeks	DEP, resuspended Particle Size: 1.5−3.0 µm ± 1.3−1.6 µm Control: filtered air	Route: Whole body inhalation Dose/Concentration: 315.3 ± 50.7 µg/m³ Duration: 6 h Time to analysis: overnight	Hippocampal tissue: cytokine mRNA expression

8.1.4 Diseases of the Nervous System and Depression

A small number of epidemiologic studies of short-term exposure to $PM_{2.5}$ and nervous system outcomes were conducted since the 2009 PM ISA (U.S. EPA, 2009) was published (Table 8-5). A large U.S. study of Medicare enrollees reported an association with Parkinson Disease [RR: 1.03 (95%CI: 1.01, 1.05)] but not dementia or Alzheimer's disease (Zanobetti et al., 2014). Although only the primary ICD code was used to identify Parkinson disease hospitalizations, the specific reason for the admission is not clear and could reflect a range of complications experienced by Parkinson disease patients. No association of short-term $PM_{2.5}$ exposure with dementia related hospital admissions was reported in a smaller study in Madrid, Spain (quantitative results not presented) (Linares et al., 2017).

Studies of short-term exposure to $PM_{2.5}$ and depression also add to the still limited evidence base. No overall increase in hospital admissions for depressive symptoms was observed in a Canadian study (Szyszkowicz, 2007), although associations were detected in some subgroups (i.e., among females during the cold season [RR: 1.12 (95%CI: 1.03, 1. 21)]). Wang et al. (2014) reported a decrease in depressive

symptoms among older adults enrolled in the Maintenance of Balance, Independent Living, Intellect and Zest in the Elderly of Boston (MOBILIZE) study [OR: 0.31 (95%CI: 0.10, 0.94)] in association with $PM_{2.5}$ exposure averaged over 14 days preceding the assessment.

Finally, a study of neuropsychological function in children was conducted at home and at school. In this study, short-term exposure (lagged 0−48 hours), was associated with some of the tests of administered, including those for processing speed (Saenen et al., 2016).

8.1.5 Components and Sources of $PM_{2.5}$

There are few studies examining components or sources of $PM_{2.5}$ in relation to nervous system effects (Table 8-6). Decreased scores on some of the neurobehavioral tests (e.g., pattern comparison) with increasing 24 hour black carbon (BC) exposure (lagged 0−2 days) were observed in the study by Saenen et al. (2016). Saenen et al. (2016) observed associations with processing speed were observed in association with short-term $PM_{2.5}$ exposure in this study. Wang et al. (2014) did not find evidence indicating that BC exposure is associated with depressive symptoms among older adults in the Boston MOBILIZE study [OR: 1.0 (95%CI: 0.75, 1.33)]. The results of the studies included in this section that pertain to exposure to $PM_{2.5}$ are found in Section 8.1.4.

8.1.6 Summary and Causality Determination

The evidence reviewed in the 2009 PM ISA was characterized as "inadequate to infer" a causal relationship between short-term exposure and nervous system effects. Recent studies strengthen the evidence that short-term exposure to $PM_{2.5}$ can affect the nervous system.

Effects on the ANS and downstream consequences on the heart were observed in toxicological studies (Section 8.1.1). In addition, changes in hypothalamic neurotransmitters, including norepinephrine, and CRH were found in a study of mice exposed to $PM_{2.5}$ CAPs (Balasubramanian et al., 2013), and add to evidence described in the 2009 PM ISA of increased norepinephrine in the hypothalamus and olfactory bulb and increased serum corticosterone (Sirivelu et al., 2006). Such evidence that $PM_{2.5}$ exposure leads to changes in norepinephrine indicates that the hypothalamus plays an important role in mediating effects such as activation of the SNS and the HPA stress axis. Preliminary evidence shows a dampening of these responses after repeated exposures in lean, but not obese animals. Findings that short-term exposure to $PM_{2.5}$ results in altered expression of proinflammatory and antioxidant genes in hippocampus and olfactory bulb regions, in the absence of pulmonary or systemic inflammation, point to a direct effect of $PM_{2.5}$ on the brain (Tyler et al., 2016; Bos et al., 2012). They build on evidence, described in the 2009 PM ISA, of increased cytokines and NFκB activation in the cortex following short-term $PM_{2.5}$ CAPs exposure (Campbell et al., 2005). The evidence from epidemiologic studies that focus on specific diseases of the nervous system, however, remains limited. The evidence for the relationship between short-term exposure to $PM_{2.5}$ and effects on the nervous system is summarized in Table 8-7, using the framework for causality determination described in the Preamble to the ISAs (U.S. EPA, 2015). With regard to the epidemiologic studies relating to short-term exposure to $PM_{2.5}$ and diseases of the nervous system or depression, the evidence is limited to a small number of analyses. Positive associations were not observed in studies of hospital admissions for depression, dementia, or Alzheimer's disease. A small increase in hospital admissions for Parkinson disease was reported in a large national study of Medicare recipients indicating that short-term exposure to $PM_{2.5}$ may exacerbate a range of symptoms experienced by Parkinson disease patients (Zanobetti et al., 2014). Finally, a study of school children reported associations with some tests of neuropsychological function. There was no consideration of confounding by copollutant exposures in these epidemiologic studies and studies of components were limited in number.

The strongest evidence to indicate an effect of short-term exposure to $PM_{2.5}$ on the nervous system is provided by experimental animal studies that show effects on the brain. Toxicological studies demonstrate changes in neurotransmitters in the hypothalamus that are linked to SNS and HPA stress axis activation, as well as upregulation of inflammation-related genes, changes in cytokine levels, and NFkB activation that are indicative of brain inflammation. In addition, an association of short-term $PM_{2.5}$ exposure with hospital admissions for PD was observed indicating the potential for exacerbation of the

disease. **Overall, the collective evidence is suggestive of, but not sufficient to infer, a causal relationship between short-term exposure to $PM_{2.5}$ and nervous system effects.**

8.2 Long-term $PM_{2.5}$ Exposure and Nervous System Effects

The 2009 PM ISA described the limited available studies of the effects of long-term exposures to $PM_{2.5}$ on the nervous system (U.S. EPA, 2009). A study in mongrel dogs from two areas of Mexico with contrasting air pollution levels ($PM_{2.5}$ annual average concentration 21.5 μg/m^3 versus <15 μg/m^3) reported inflammation and stress protein responses in the brain, but had limitations stemming from its ecological design (Calderón-Garcidueñas et al., 2003). Another study found Parkinson disease-like brain histopathology following long-term exposure to $PM_{2.5}$ CAPs in ApoE knockout mice (Veronesi et al., 2005). There were no epidemiologic studies of long-term exposure to $PM_{2.5}$ although an analysis of NHANES III respondents reported an association between annual average PM_{10} concentration and cognitive function, which was approximately null after adjustment for race or ethnicity and SES (Chen and Schwartz, 2009). Recent studies add to the information, specifically strengthening the lines of evidence indicating that long-term exposure to $PM_{2.5}$ can lead to effects on the brain associated with neurodegeneration (i.e., neuroinflammation and reductions in brain volume), as well as cognitive effects in older adults.

The discussion of long-term $PM_{2.5}$ exposure and nervous system effects opens with a discussion of biological plausibility (Section 8.1.1) that provides background for the subsequent sections in which groups of related endpoints are presented in the context of relevant disease pathways. These outcome groupings are activation of the SNS and HPA stress Axis (Section 8.1.2), brain inflammation and oxidative stress (Section 8.1.3), morphologic changes in the brain (Section 8.2.4), cognitive and behavioral effect (Section 8.2.5), neurodegenerative diseases (Section 8.2.6) and neurodevelopmental effects (Section 8.2.7). Evidence pertaining to $PM_{2.5}$ components is summarized in Section 8.2.8. Finally, the collective body of evidence is integrated[72] across and within scientific disciplines, and the rationale for the causality determination is outlined in Section 8.1.6.

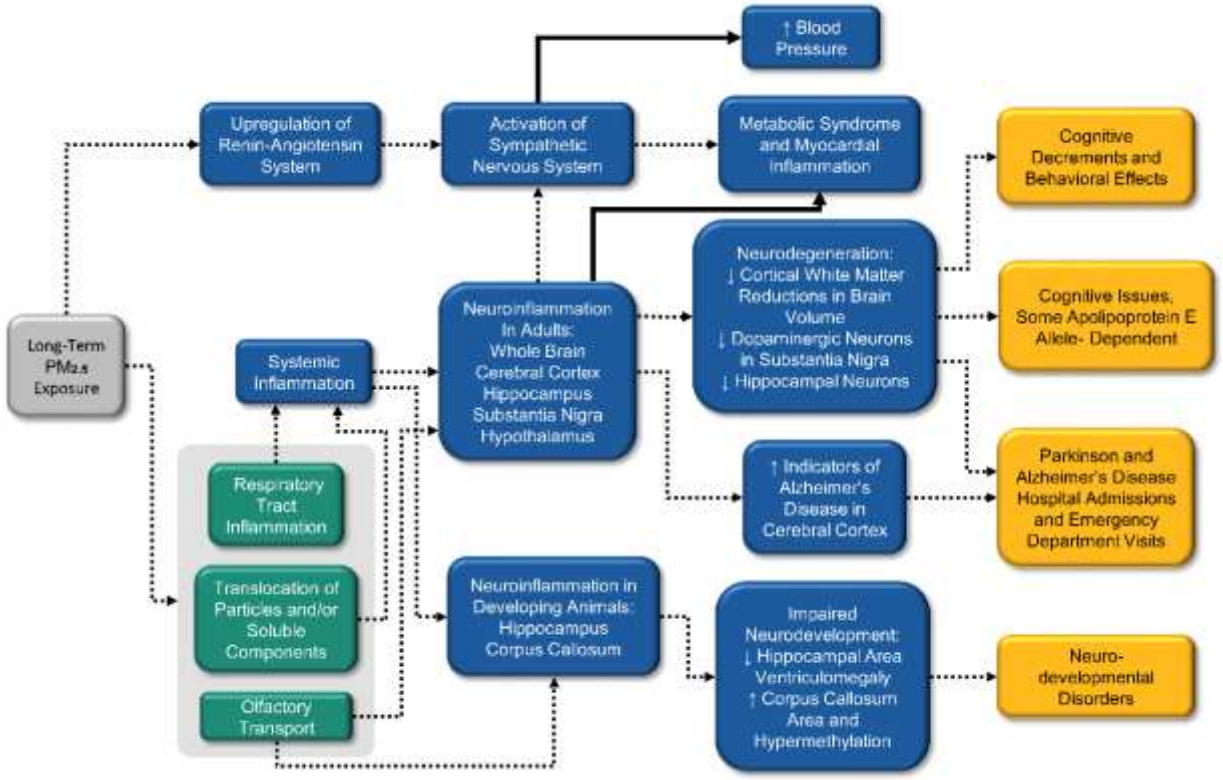
8.2.1 Biological Plausibility

This section describes biological pathways that potentially underlie the development of nervous system effects resulting from long-term exposure to $PM_{2.5}$. Figure 8-2 graphically depicts the proposed pathways as a continuum of upstream events, connected by arrows, that may lead to downstream events observed in epidemiologic studies. This discussion of "how" long-term exposure to $PM_{2.5}$ may lead to nervous system effects contributes to an understanding of the biological plausibility of epidemiologic results evaluated later in Section 8.2.

Once $PM_{2.5}$ deposits in the respiratory tract, it may be retained, cleared, or solubilized (see Chapter 4). $PM_{2.5}$ and its soluble components may interact with cells in the respiratory tract, such as epithelial cells, inflammatory cells, and sensory nerve cells. One way in which this may occur is through reduction-oxidative (redox) reactions. As discussed in Section 2.3.3, PM may generate reactive oxygen species (ROS) and this capacity is termed "oxidative potential". Furthermore, cells in the respiratory tract may respond to the presence of PM by generating ROS. Further discussion of these redox reactions, which may contribute to oxidative stress, is found in Section 5.1.1 of the 2009 PM ISA (U.S. EPA, 2009). In addition, poorly soluble particles may translocate to the interstitial space beneath the respiratory epithelium and accumulate in the lymph nodes (see Chapter 4). Immune system responses due to the presence of particles in the interstitial space may contribute to health effects. Inflammatory mediators may diffuse from the respiratory tract into the systemic circulation and lead to inflammation in extrapulmonary compartments (Section 6.2.1). Soluble components of $PM_{2.5,}$ and poorly soluble particles that are part of the $PM_{2.5}$ fraction and smaller than approximately 200 nm, may translocate into the systemic circulation and contribute to inflammatory or other processes in extrapulmonary compartments. A fraction of $PM_{2.5}$ may deposit on the olfactory epithelium. Soluble components of $PM_{2.5,}$ and poorly soluble particles that are part of the $PM_{2.5}$ fraction and smaller than approximately 200 nm, may also be transported via the olfactory nerve to the olfactory bulb of the brain. The extent to which translocation

[72] As detailed in the Preface, risk estimates are for a 5 µg/m3 increase in annual PM2.5 concentrations unless otherwise noted.

into the systemic circulation or transport to the olfactory bulb occurs is currently uncertain. For further discussion of translocation and olfactory transport, see Chapter 4.



Note: The boxes above represent the effects for which there is experimental or epidemiologic evidence, and the dotted arrows indicate a proposed relationship between those effects. Solid arrows denote direct evidence of the relationship as provided, for example, by an inhibitor of the pathway or a genetic knock-out model used in an experimental study. Progression of effects is depicted from left to right and color-coded (gray, exposure; green, initial event; blue, intermediate event; orange, apical event). Here, apical events generally reflect results of epidemiologic studies, which often observe effects at the population level. Epidemiologic evidence may also contribute to upstream boxes. When there are gaps in the evidence, there are complementary gaps in the figure and the accompanying text below.

Figure 8-2 Potential biological pathways for nervous system effects following long-term $PM_{2.5}$ exposure.

Evidence that long-term exposure to $PM_{2.5}$ may affect the nervous system generally informs two different pathways (Figure 8-2). The first pathway involves activation of the SNS, possibly by upregulation of the RAS. This pathway may lead to downstream systemic effects. The second pathway begins with pulmonary inflammation, leading to systemic inflammation and resulting in neuroinflammation. Neurodegenerative and neurodevelopmental disorders may be downstream effects of neuroinflammation. Evidence for both pathways is described below.

Upregulation of the Renin-Angiotensin (RAS) and Activation of the Sympathetic Nervous System (SNS)

With regard to the first pathway, activation of the SNS resulting from long-term $PM_{2.5}$ exposure may occur secondarily to RAS upregulation. Unlike the case of short-term exposure to $PM_{2.5}$, there is a lack of evidence that long-term $PM_{2.5}$ exposure results in activation of sensory nerves in the respiratory tract. However, animal toxicological studies support a role for the RAS. Aztatzi-Aguilar et al. (2016); Aztatzi-Aguilar et al. (2015) demonstrated that long-term exposure to $PM_{2.5}$ upregulates components of the RAS in the heart, lung, and kidneys (Section 5.2.8 and Section 6.2.7.2). Interaction between SNS and the RAS has important ramifications for cardiovascular health and disease. Angiotensin II enhances the release of norepinephrine from sympathetic nerve endings via the angiotensin 1 receptor (Brasch et al., 1993). SNS activation, in turn, stimulates secretion of the angiotensin II precursor protein, renin, from the kidney, thus providing positive feedback for the pathway (Gordon et al., 1967). Evidence that increased SNS activity leads to hypertension following long-term $PM_{2.5}$ CAPs exposure was provided by Ying et al. (2014). In this study, acute inhibition of the SNS resulted in decreased blood pressure. The solid line depicted in Figure 8-2 that connects activation of the SNS and increased blood pressure indicates that the SNS mediates the increase blood pressure observed following long-term exposure to $PM_{2.5}$.

Inflammation

With regard to the second pathway, deposition of $PM_{2.5}$ in the respiratory tract may lead to pulmonary inflammation (see Section 5.2.1) and to systemic inflammation (see Section 6.2.1), which in turn may lead to neuroinflammation. This could be due to peripheral immune activation (Fonken et al., 2011) or to systemic circulation of $PM_{2.5}$, alone or engulfed by macrophages, that results in particle uptake in the brain (Ljubimova et al., 2013). Neuroinflammation may alternatively occur following olfactory transport of poorly soluble particles or their soluble components or to a neuroendocrine stress response resulting from activation of the HPA stress axis (Kodavanti, 2016).

Several animal toxicological studies in adult rodents demonstrated neuroinflammation in the cerebral cortex, hippocampus, substantia nigra, and hypothalamus following $PM_{2.5}$ exposure (Tyler et al., 2016; Hogan et al., 2015; Ying et al., 2015; Liu et al., 2014; Ying et al., 2014; Fonken et al., 2011; Veronesi et al., 2005). One study found hippocampal inflammation in the absence of pulmonary inflammation (Tyler et al., 2016). Another found that inflammation in the hypothalamus, but not in the lung, was reversed following cessation of exposure (Ying et al., 2015). Evidence for a link between hypothalamic inflammation and peripheral effects was provided by animal toxicological studies using an inhibitor of inflammation (Zhao et al., 2015; Liu et al., 2014). The solid line depicted in Figure 8-2, which connects neuroinflammation with metabolic syndrome and with myocardial inflammation, indicates that hypothalamic inflammation mediates these peripheral effects following long-term exposure to $PM_{2.5}$. Hypothalamic inflammation may possibly activate the SNS (Ying et al., 2014).

In animal toxicological studies, neuroinflammation and astrocyte activation (an index of injury) were observed in specific brain regions following long-term exposure to $PM_{2.5}$. These responses were accompanied by neurodegeneration in those regions, which included the hippocampus (Hogan et al., 2015; Fonken et al., 2011) and the substantia nigra (Veronesi et al., 2005). Hippocampal changes occurred in conjunction with impaired learning and memory and with behavioral issues. Lesions in the substantia nigra are hallmarks of Parkinson disease. In addition, an animal toxicological study found increased markers of Alzheimer's disease in the cerebral cortex (Bhatt et al., 2015). Epidemiologic studies observed associations between exposure to $PM_{2.5}$ and decreases in cortical white and gray matter and in cerebral brain volume (Casanova et al., 2016; Chen et al., 2015; Wilker et al., 2015). Epidemiologic studies also provide evidence of cognitive impairment and Alzheimer's and Parkinson disease in association with exposure to $PM_{2.5}$ (Section 8.2.6).

Neuroinflammation may potentially lead to neurodevelopmental disorders in developing animals. In an animal toxicological study, prenatal exposure to $PM_{2.5}$ resulted in neuroinflammation in the hippocampus and corpus callosum (Klocke et al., 2017). These changes were sex-specific, occurring only in males. Morphologic changes, which were not sex-specific, were found in these same brain regions and were accompanied by enlarged lateral ventricles (i.e., ventriculomegaly). This study suggests a link between exposure to $PM_{2.5}$ and neurodevelopmental disorders; however, there was no evidence of cognitive or behavioral effects.

Summary of Biological Plausibility

As described here, there are two proposed pathways by which long-term exposure to $PM_{2.5}$ may lead to nervous system effects. The first pathway begins with upregulation of the RAS, which in turn may activate the SNS. Altered autonomic tone may result in a wide range of systemic responses. As proof of this concept, animal toxicological evidence supports a direct link between the SNS and increased blood pressure following long-term $PM_{2.5}$ exposure. The second proposed pathway begins with pulmonary/systemic inflammation or olfactory transport of $PM_{2.5}$ and leads to neuroinflammation. Animal toxicological evidence supports a direct link between neuroinflammation and peripheral effects associated with metabolic syndrome and myocardial inflammation. In addition, neuroinflammation may lead to neurodegeneration and the development of Alzheimer's disease, as well as to impaired learning and memory and to behavioral issues. While experimental studies in animals contribute most of the evidence of upstream events, epidemiologic studies report associations between long-term exposure to $PM_{2.5}$ and reduced brain volume and cognitive impairment in adults. Neuroinflammation and neurodegeneration provide biological plausibility for epidemiologic results of increased hospital admissions or emergency department visits for Alzheimer's and Parkinson disease. In developing animals, neuroinflammation may potentially lead to neurodevelopmental disorders. These pathways will be used to inform a causality determination, which is discussed later in the chapter (Section 8.2.9).

8.2.2 Activation of the Sympathetic Nervous System and the Hypothalamic-Pituitary-Adrenal (HPA)Stress Axis

Activation of the SNS by long-term $PM_{2.5}$ exposure was investigated in animal toxicological studies (Table 8-8). Ying et al. (2014) evaluated the contribution of SNS to sustained increases in blood pressure, which have previously been observed in animals chronically exposed to $PM_{2.5}$. While studies have identified several mechanisms underlying this response, sympathetic activation had not been tested. C57BL/6J mice were exposed for 6 months to $PM_{2.5}$ CAPs in Columbus, OH. Exposure to $PM_{2.5}$ CAPs increased mean arterial blood pressure ($p < 0.05$), but did not affect heart rate or locomotor activity. Exposure to $PM_{2.5}$ CAPs also resulted in vascular dysfunction, which was measured ex vivo in terms of contractile response to phenylephrine and relaxation response to acetylcholine in mesenteric arteries (a type of resistance vessel) ($p < 0.05$). Two measures of sympathetic tone, low-frequency blood pressure variability and urinary norepinephrine excretion, were also increased in $PM_{2.5}$ CAPs-exposed mice ($p < 0.05$). Pharmacologic agents were used to test the role of the ANS in mediating responses to CAPs. Propranolol decreased heart rate in $PM_{2.5}$ CAPs exposed mice ($p < 0.05$), but not in controls. However, propranolol did not alter blood pressure in either group. Atropine had no effect on heart rate or blood pressure in either group. Acute inhibition of the central SNS with guanfacine resulted in a large decrease in blood pressure in both controls and $PM_{2.5}$ CAPs-exposed mice. This decrease was greater in $PM_{2.5}$ CAPs-exposed mice than in controls ($p < 0.05$). $PM_{2.5}$ CAPs exposure also increased the hypertensive response to air-jet stress ($p < 0.05$). Since sympathetic tone is modulated by hypothalamic inflammation in response to several pathophysiological signals, markers of hypothalamic inflammation were examined in $PM_{2.5}$ CAPs-exposed animals. Results, described in Section 8.2.3, provide evidence that $PM_{2.5}$ CAPs exposure mediates hypothalamic inflammation that may be linked to activation of the SNS and to an increase in sympathetic tone. Results of this study also indicate that increased sympathetic tone contributes to hypertension in response to $PM_{2.5}$ CAPs exposure.

Fonken et al. (2011) examined stress-related responses in C57BL/6J mice exposed for 10 months to $PM_{2.5}$ CAPs in Columbus, OH. No differences were found in serum corticosterone concentrations between control and $PM_{2.5}$-exposed mice, despite evidence of inflammation and morphological changes in the brain as described in Section 8.2.3 and Section 8.2.4.

In addition, the RAS may contribute to SNS activity. Long-term exposure to $PM_{2.5}$ CAPs resulted in upregulation of components of the RAS such as angiotensin I receptor and angiotensin converting enzyme in the heart, lung, and kidneys (Aztatzi-Aguilar et al., 2016; Aztatzi-Aguilar et al., 2015) (see Section 5.2.8, Section 6.2.7.2). Activity of the angiotensin converting enzyme results in angiotensin II formation from angiotensin I. Angiotensin II enhances the release of norepinephrine from sympathetic nerve endings via the angiotensin 1 receptor (Brasch et al., 1993). Sympathetic nerve activation, in turn, stimulates secretion of the angiotensin II precursor protein, renin, from the kidney, thus providing positive feedback for the pathway (Gordon et al., 1967).

Table 8-8 Study-specific details from animal toxicological studies of long-term exposure and activation of the sympathetic nervous system (SNS) and hypothalamic-pituitary-adrenal (HPA) stress axis.

CAPs = concentrated ambient particles; HEPA = high efficiency particulate absorber.

8.2.3 Brain Inflammation and Oxidative Stress

Recent experimental animal studies showing that long-term exposure to $PM_{2.5}$ CAPs can result in brain inflammation (Table 8-9) and oxidative stress add to the sparse evidence presented in the 2009 PM ISA. Several studies demonstrated that $PM_{2.5}$ CAPs exposure induced neuroinflammation and astrocyte activation in specific brain regions, as described below. Findings from these studies as they relate to neurodegeneration (Section 8.2.6), cognitive impairment, and behavioral effects (Section 8.2.5) are discussed in more detail in sections that follow.

Hippocampal inflammation was examined in several recent studies. Fonken et al. (2011) investigated the effects of a 10-month exposure to $PM_{2.5}$ CAPs from Columbus, OH on neuroinflammation and oxidative stress in the hippocampus of C57BL/6 mice. $PM_{2.5}$ CAPs exposure increased gene expression of proinflammatory cytokines TNFα and IL−1β ($p < 0.05$), but not of IL−6 and HMGB1. Upregulation of HO−1, a marker of oxidative stress ($p < 0.05$), was also seen, while the

microglial marker MAC1 was unchanged. Another study by the same group of investigators evaluated neuroinflammation in the hippocampus of $PM_{2.5}$ CAPs-exposed C3H/HeNHsd mice (Hogan et al., 2015). This mouse model is a nocturnal species with intact melatonin production. CAPs exposures for 4 weeks in Columbus, OH during a 14:10 light/dark cycle resulted in upregulation of IL−6 ($p < 0.05$), but not TNF or IL−1β. Tyler et al. (2016) exposed C67BL/6 and ApoE knockout mice to resuspended DEP for 30 days. In the hippocampus, there were increases in levels of mRNA for TGF-β in C67BL/6 mice ($p < 0.05$), but no changes in cytokine gene expression in ApoE knockout mice ($p < 0.05$). No inflammatory effects were seen in BALF although particle uptake into bronchial macrophages was increased in ApoE knockout, but not in C57BL/6 mice (see Section 5.2.9).

Ying et al. (2014) found evidence of hypothalamic inflammation in C57BL/6J mice exposed for 6 months to $PM_{2.5}$ CAPs from Columbus, OH. Increased hypothalamic gene expression of E-selectin, TNFα and ICAM−1 ($p < 0.05$) were observed. In addition, phosphorylation of IKK was increased in the arcuate nucleus but not in the paraventricular nucleus of the hypothalamus, while the number of c-fos positive cells was increased in both ($p < 0.05$). These results indicate activation of the NFκB pathway and upregulation of pro-inflammatory genes as a result of exposure to $PM_{2.5}$ CAPs. Hypothalamic inflammation was also demonstrated in Liu et al. (2014), in a genetically susceptible model of Type II diabetes, the KKay mouse, following exposure to $PM_{2.5}$ CAPs from Columbus, OH for 5−8 weeks. Increased gene expression of IL−6, TNFα, and IKKβ was observed ($p < 0.05$). In addition, the amount of oxidized phospholipid Ox-PAPC, which can activate TLR pathways, was increased in brain tissue. TLR pathways are involved in activation of the innate immune system. Subsequently, mice were treated with an inhibitor of IKKβ, which blocks NFκB activation, by inter-cerebroventricular infusion during a 4-week exposure to $PM_{2.5}$ CAPs. Central IKKβ inhibition dampened the effects of CAPs exposure on hypothalamic inflammation, including IL−6 and IKKβ gene expression and activation of microglia and astrocytes, as indicated by IBA−1 and GFAP immunostaining, respectively ($p < 0.05$). Exposure to $PM_{2.5}$ CAPs enhanced hyperglycemia, insulin resistance, and peripheral inflammation (see Section 7.2.3.2) that was dampened by IKKβ inhibition. Liu et al. (2014) provides evidence that the central nervous system, possibly via hypothalamic inflammation, contributes to the diabetic phenotype in CAPs-exposed susceptible mice. Treatment with this same inhibitor of IKKβ by intra-cerebroventricular infusion blocked myocardial inflammation in a separate study of long-term $PM_{2.5}$ CAPs exposure in KKay mice (Zhao et al., 2015). Evidence of hypothalamic inflammation was also found in spontaneously hypertensive (SH) rats exposed to CAPs from Columbus, OH for 15 weeks (Ying et al., 2015). Expression of TNFα mRNA in the hypothalamus was increased ($p < 0.05$) and returned to baseline 5 weeks following the end of exposure.

Bhatt et al. (2015) investigated the effects of $PM_{2.5}$ CAPs exposure on brain inflammation and markers of Alzheimer's disease in C57BL/6 mice. Exposure to $PM_{2.5}$ CAPs from Columbus, OH for 9 months, but not 3 months, resulted in increases in several indices of inflammation and early Alzheimer's disease-related pathology in the temporal cortex. This included a subset of cytokines, COX−1 and COX−2, PSD−95, and amyloidβ 1−40 ($p < 0.05$). A decrease in amyloid precursor protein

(APP) levels was observed, along with an increase in the beta-site APP cleaving enzyme (BACE) ($p < 0.05$). No changes in tau, synaptophysin, markers of oxidative stress, DNA methylation or activation of astrocytes (GFAP), glia (1BA−1), or endothelial cells (VCAM−1) were found.

However, changes in gene expression were not found in every study involving $PM_{2.5}$ CAPs. Ljubimova et al. (2013) examined changes in global gene expression in the brain, as well as expression of Arc and Rac genes and their protein products, in Fischer 344 rats exposed to $PM_{2.5}$ CAPs in Riverside, CA for 10 months. Exposure did not induce changes in gene or protein expression in this study.

In summary, inflammation was observed in the hippocampus, hypothalamus, and temporal cortex of several different mice strains exposed for 1−10 months to $PM_{2.5}$ CAPs. Hippocampal inflammation, in the absence of pulmonary inflammation, was also found in mice exposed to traffic-related $PM_{2.5}$. In a mouse model of diabetes, $PM_{2.5}$ CAPs-exposure induced hypothalamic inflammation that was linked to a worsening of the diabetic phenotype and to myocardial inflammation. Hypothalamic inflammation was found to be reversible with cessation of exposure in SH rats. In the temporal cortex, brain inflammation was observed in conjunction with markers of Alzheimer's disease following $PM_{2.5}$ CAPs exposure. Oxidative stress was also seen in the hippocampus and hypothalamus.

8.2.4 Morphologic Changes in the Brain

There were no epidemiologic studies relating long-term exposure to $PM_{2.5}$ to changes in brain morphology evaluated in the 2009 PM ISA. However, an animal toxicological study found Parkinson disease-like brain histopathology following long-term exposure to $PM_{2.5}$ CAPs in ApoE knockout mice (Veronesi et al., 2005). Dopaminergic neurons were decreased in substantia nigra, which is part of the midbrain, and GFAP immunoreactivity, an indicator of astrocyte activation, was increased in the nucleus compacta, which is part of the substantia nigra.

Recent analyses from two established cohorts (Casanova et al., 2016; Chen et al., 2015; Wilker et al., 2015), using magnetic resonance imaging (MRI) to identify attributes or changes in brain structure that may stem from neurodegenerative processes or cerebrovascular dysfunction, report $PM_{2.5}$ associated reductions in brain volume (Table 8-10). Morphologic changes in the brain were also demonstrated in experimental animal studies (Table 8-11). These changes were accompanied by inflammation (Section 8.2.3).

Epidemiologic Studies

The effect of long-term exposure to $PM_{2.5}$ on brain morphology, using MRI scans, was studied in older women (age 65−80) who were free of dementia at baseline when they were enrolled in the Women's Health Initiative Memory Study (WHIMS) (Chen et al., 2015). Information on a wide array of covariates including individual characteristics such as hormone replacement therapy, BMI, lifestyle, depression, cardiovascular risk factors and SES was collected for WHIMS. A pattern of lower white matter (WM) volume of the frontal, parietal and temporal areas of the brain in fully adjusted models with increasing cumulative $PM_{2.5}$ exposures was observed [−8.30 cm^3 (95% CI: −4.70, −11.89) decrease in total WM]. Details on the quantitative relationship between $PM_{2.5}$ and gray matter (GM) were not reported because they did not reach statistical significance. This research was extended through the analyses conducted by Casanova et al. (2016) using finely grained voxel-wise methods, which are better able to detect patterns that extend across multiple brain regions. Increased 3-year average $PM_{2.5}$ concentrations was associated with smaller subcortical WM and smaller cortical GM volumes in the multi-variable models used in this study. The exposure metrics (3 year average and cumulative average) used in WHIMS analysis were highly correlated (r = 0.93).

In a cross-sectional analysis of the Framingham Heart Offspring Study, Wilker et al. (2015) examined the association of long-term $PM_{2.5}$ exposure with total cerebral brain volume, hippocampal volume, WM hyperintensity volume, and preclinical brain infarcts among older men and women (≥60 years old) who were free of dementia and stroke. Wilker et al. (2015) reported that total cerebral brain volume was smaller with increasing $PM_{2.5}$ exposure after adjustment for covariates [−0.80 cm^3 (95% CI: −0.13, −1.48) total cerebral brain volume]. After further adjustment for risk factors for cardiovascular disease, this association persisted but lost precision. An increased risk of covert brain infarcts was also observed [OR: 2.58 (95%CI: 1.27, 5.24)].

Animal Toxicological Studies

Fonken et al. (2011) investigated morphologic changes in the hippocampus of C57BL/6 mice exposed for 10 months to $PM_{2.5}$ CAPs from Columbus, OH. $PM_{2.5}$ CAPs exposure resulted in structural changes in the hippocampus. Apical spine density in the CA1 region of the hippocampus was decreased ($p < 0.05$). Basilar spine density in the CA1 region and spine density in the CA3 and dentate gyrus (DG) regions were unchanged. Apical dendritic length and cell complexity were also decreased by $PM_{2.5}$ CAPs exposure ($p < 0.05$), although cell body area was unchanged. Another study by the same group of investigators found altered brain morphology in C3H/HeNHsd mice exposed for 4 weeks to $PM_{2.5}$ CAPs during a 14:10 light/dark cycle (Hogan et al., 2015). This mouse model is a nocturnal species with intact melatonin production. $PM_{2.5}$ CAPs exposures resulted in decreased apical and basilar spine densities, apical dendritic length, and cell body area in the CA1 region of the hippocampus ($p < 0.05$).

8.2.5 Cognitive and Behavioral Effects

8.2.5.1 Animal Toxicological Studies

Fonken et al. (2011) investigated affective and cognitive processes in C57BL/6 mice exposed for 10 months to $PM_{2.5}$ CAPs in Columbus, OH (Table 8-12). Behavioral testing showed that $PM_{2.5}$ CAPs exposure had a number of effects – impaired spatial learning and spatial memory, as measured in the Barnes maze ($p < 0.05$); increased behavioral despair and a more rapid onset of behavioral despair as measured in the Porsolt forced swim test ($p < 0.05$); and increased anxiety-like behavior in one of two tasks (time spent in the center of an open field, $p < 0.05$). Neuroinflammation and morphologic changes, described in Section 8-26 and Section 8-30, may be related to changes in cognition and affective processes. Another study by the same group of investigators examined affective and cognitive processes in C3H/HeNHsd mice exposed for 4 weeks to $PM_{2.5}$ CAPs during a 14:10 light/dark cycle (Hogan et al., 2015). This mouse model is a nocturnal species with intact melatonin production. Behavioral testing demonstrated an effect of CAPs exposure on locomotion and anxiety-like responses (time spent in the center of an open field, $p < 0.05$), but no effects on depressive responses.

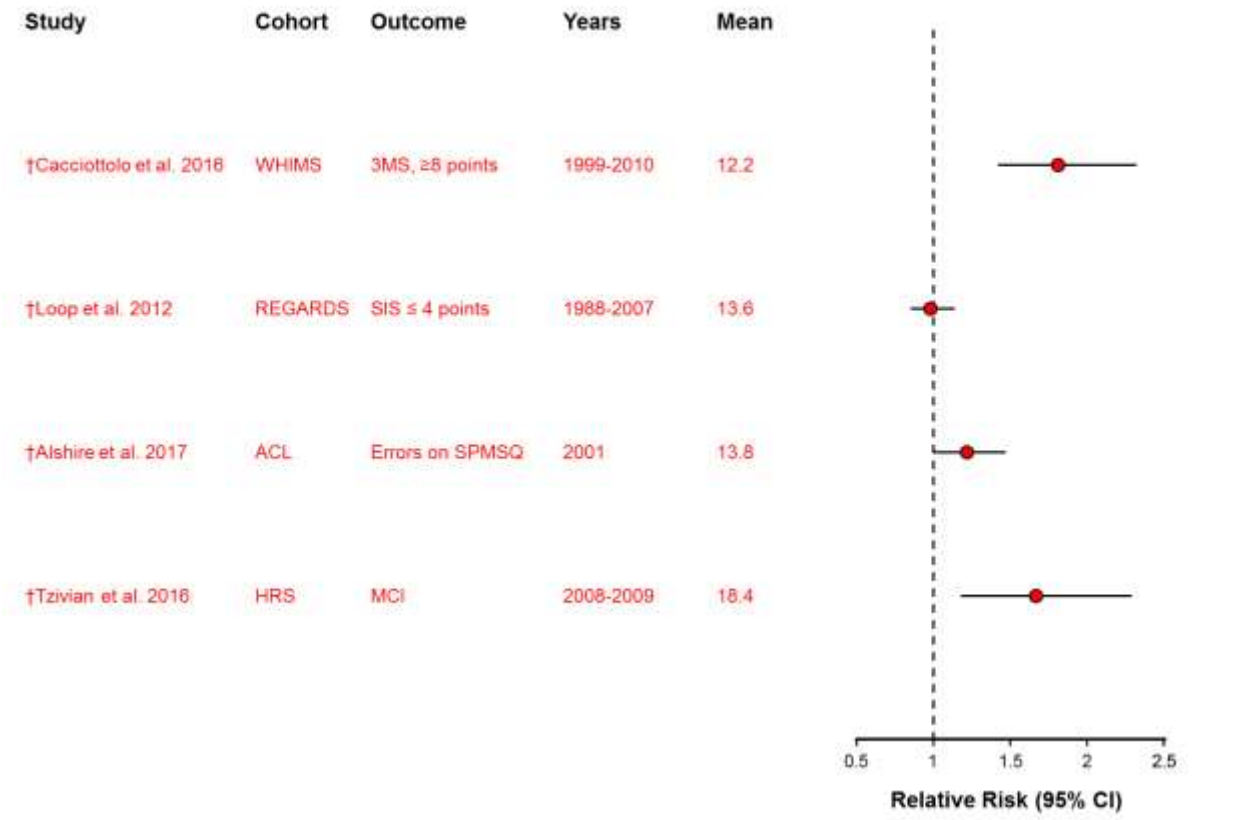
8.2.5.2 Epidemiologic Studies

Although there were no studies of long-term exposure to $PM_{2.5}$ evaluated in the 2009 PM ISA (U.S. EPA, 2009), Chen and Schwartz (2009) reported a cross-sectional association of annual average exposure to PM_{10} with cognitive function using data from NHANES III. Multiple additional studies reporting associations with dichotomous measures of cognitive function or effects on continuous measures of global or domain specific subtests of cognitive function add to the evidence in the current review. Overall, these studies were heterogeneous in their methods and design, and their findings were not entirely consistent. Several high-quality studies reported associations with long-term exposure to $PM_{2.5}$, however.

Studies that modeled cognitive decline as a dichotomous outcome are presented in Figure 8-3. Cacciottolo et al. (2017) examined the effect of long-term $PM_{2.5}$ exposure on accelerated global cognitive decline among WHIMS participants using a cutpoint of ≥8 points on the Modified Mini-Mental State (3MS). The authors report an increased risk of accelerated global cognitive decline in adjusted models [HR: 1.81 (95%CI: 1.42, 2.32) comparing 3-year moving average concentration >12 to ≤12 µg/m^3] in the women, with a larger HR among carriers of the APOE allele Ɛ4/4. Cacciottolo et al. (2017) considered potential confounders including age, geographic region, education income, employment, lifestyle factors, and clinical characteristics (i.e., hormone treatment, depression, BMI, hypercholesterolemia, hypertension, diabetes, history of CVD) in their analysis. In a study of the effect of $PM_{2.5}$ on pre-clinical cognitive impairment, Loop et al. (2013) analyzed data from a large U.S. cohort designed to study stroke (REGARDS). Authors conducted a cross-sectional analysis of incident cognitive impairment using logistic regression and adjusting for length of follow-up. $PM_{2.5}$ exposure was not associated with

cognitive impairment, defined as a score of ≤4 on a telephone administered Six-Item Screener (SIS), after full adjustment for potential confounders including demographic factors and incident stroke. Ailshire et al. (2017) analyzed U.S. national scale data from the Americans Changing Lives (ACL) survey reporting and increased error rate on the Short Portable Mental Status Questionnaire (SPMSQ) in association with $PM_{2.5}$ exposure that was worse in areas of high neighborhood stress. Tzivian et al. (2016) reported a positive association between long-term $PM_{2.5}$ exposure and prevalence of mild cognitive impairment (MCI) in the HRS study [OR: 1.67 (95%CI: 1.18, 2.29)] that remained after adjustment for noise. MCI was defined to identify cases with subjective cognitive complaints and objective impairment that did not reach the criteria for dementia.



Circles represent beta coefficients; horizontal lines represent 95% confidence intervals. Red text and circles represent recent evidence not considered in previous ISAs or AQCDs. Concentrations are in μg/m^3. Results are standardized to a 5 μg/m^3 increase in $PM_{2.5}$ concentrations. Corresponding quantitative results are reported in Supplemental Table S8-1 (U.S. EPA, 2018).

3MS = Modified Mini-Mental State; ACL = Americans Changing Lives; HRS = Health and Retirement Survey; REGARDS = Reasons for Geographic and Racial Differences in Stroke; SIS = Six-Item Screener; SPMSQ = Short Portable Mental Status Questionnaire; WHIMS = Women's Health Initiative Memory Study.

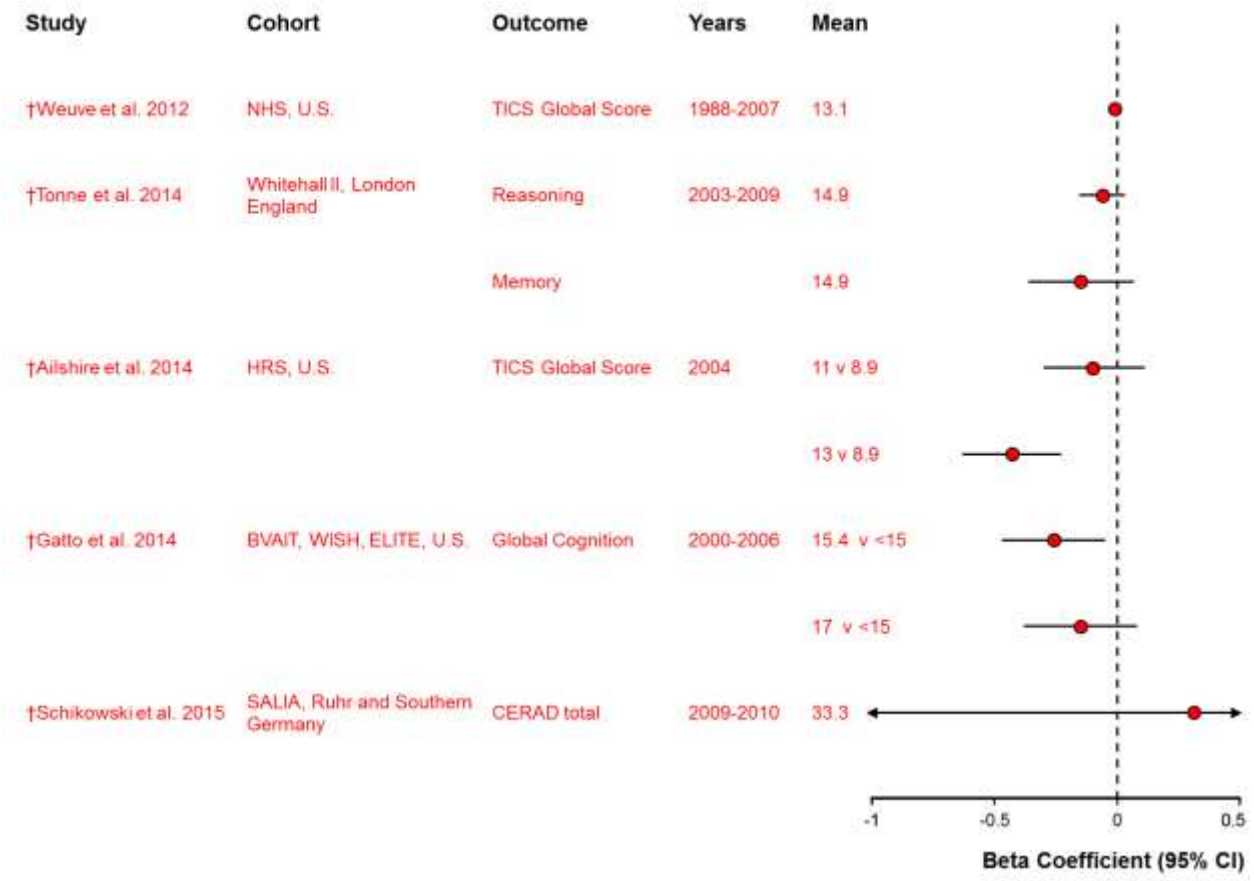
†Studies published since the 2009 PM ISA.

Figure 8-3 Associations between long-term exposure to $PM_{2.5}$ and cognitive effects. Associations are presented per 5 μg/m^3 increase in pollutant concentration (unless otherwise noted).

Small changes on cognitive test scores were observed in some but not all studies that evaluated these changes using continuous variables (Table 8-13, Figure 8-4). Weuve et al. (2012) measured the change in cognitive function of women enrolled in the Nurses' Health Study (NHS) with no history of stroke, using the validated Telephone Interview for Cognitive Status (TICS) instrument. Investigators used month-long average $PM_{2.5}$ concentrations to compute metrics indicating $PM_{2.5}$ exposures for several highly correlated time periods prior to the cognitive function assessment. Results for the longest duration

multi-year exposure metric are included in Figure 8-4. $PM_{2.5}$ was associated with a small decrease in global cognitive test score during the 2-year period between successive outcome measurements ($\beta = -0.01$ (95%CI: −0.02, 0.00) that is approximately equivalent to a decrease expected with 1 year of aging. This association persisted after adjustment for potential confounders including SES and cardiovascular conditions (i.e., high blood pressure, CHD, CHF, coronary artery bypass graft, TIA, and carotid endarterectomy). Tonne et al. (2014) used a set of tests designed to measure reasoning, memory, semantic fluency, and phonemic fluency to examine the association with long-term exposure to $PM_{2.5}$. Only associations with 5-year average concentrations are presented in Figure 8-4 because results were generally similar across exposure metrics. Authors reported 5-year declines on several cognitive tests [e.g., Reasoning: −0.06 (95% CI: −0.15, 0.03) and Memory: −0.15 (95% CI: −0.36, 0.07)].

Several cross-sectional analyses were also conducted. Ailshire and Crimmins (2014) used the TICS instrument to assess the cross-sectional association of annual average $PM_{2.5}$ concentration with cognitive effects reporting associations comparing the upper and third quartiles of exposure to the reference category (8.9 μg/m^3). The component of the TICS score reflecting episodic memory, rather than mental status, appeared to drive the observed association. In a cross-sectional analysis of several clinical trial participants enrolled through the University of Southern California, Gatto et al. (2014) found small decreases in global cognition, as well as decreases in several domain-specific tests that comprised a global cognition score. In the SALIA cohort, Schikowski et al. (2015) examined the association of $PM_{2.5}$ exposure with several domain-specific tests of the Consortium to Establish a Registry for Alzheimer's Disease (CERAD) battery, which includes the Mini Mental State Examination (MMSE). Although no association of $PM_{2.5}$ with global cognition was observed, associations with a figure copying subtest measuring constructional praxis was reported (ten subtests were administered).



Note: Ailshire and Crimmins (2014) and Gatto et al. (2014) specify exposure categories and compare the categories to a reference group (8.9 µg/m$_3$). Circles represent beta coefficients; horizontal lines represent 95% confidence intervals. Red text and circles represent recent evidence not considered in previous ISAs or AQCDs. Concentrations are in µg/m^3. Results are standardized to a 5 µg/m^3 increase in $PM_{2.5}$ concentrations. Corresponding quantitative results are reported in Supplemental Table S8-2 (U.S. EPA, 2018).

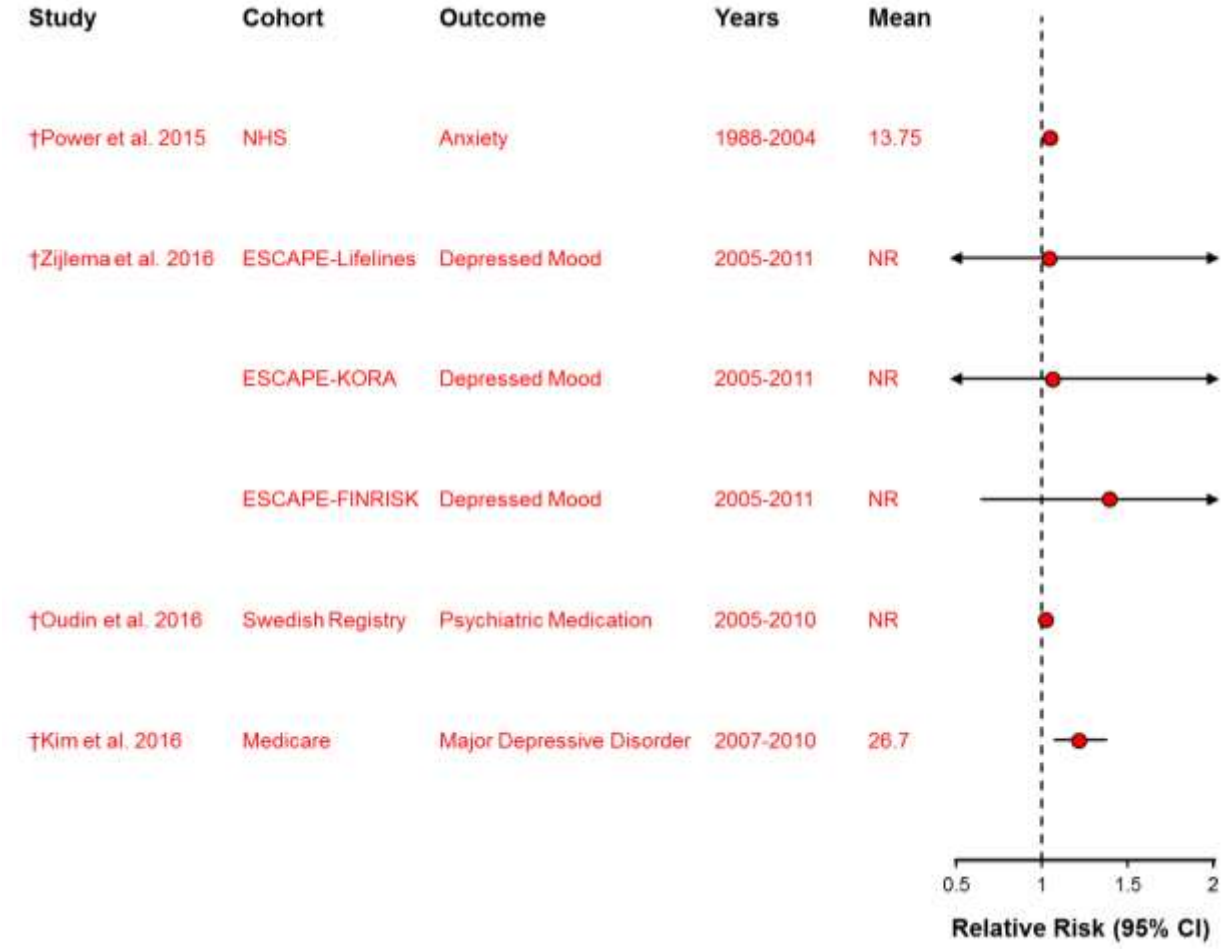
1

Anxiety and Depression

There were no analyses of the association of long-term exposure to $PM_{2.5}$ with anxiety or depression evaluated in the 2009 PM ISA. Several studies are currently available that examine associations with depressive, anxiety, or use of psychiatric medication (Figure 8-5, Table 8-14). Overall, these studies do not report consistently positive associations and the magnitude of the association varies substantially by study. Within the European ESCAPE project, statistical evidence of heterogeneity across cohorts was observed, precluding meta-analysis of cohort-specific results.

Power et al. (2015) analyzed data from the NHS to determine the association between several exposure metrics averaged from 1 month to multiple years (1988−2004) and anxiety among older women. Authors observed positive associations between prevalent anxiety and multi-year average concentration [OR: 1.04 (95% CI: 1.00, 1.09)]. The associations with shorter averaging times were also present [e.g., 1.06 (95% CI: 1.03, 1.09) per 5 μg/m^3 increase in 1-mo avg concentration], and models that adjusted for averaging time indicated the strongest associations were with shorter averaging times. In a cross-sectional analysis of ESCAPE, Zijlema et al. (2015) observed heterogenous results across cohorts with a large imprecise positive association among FINRISK participants [OR: 1.39 (95% CI: 0.64, 3.05)] and associations that were close to the null in other cohorts. In a longitudinal analysis of use of psychiatric medication reported in the national registry of Sweden, (Oudin et al., 2016) reported a small positive association between use of psychiatric medication and PM_{10} [1.02 (95% CI: 1.00, 1.04)], noting that the association was similar to the association with $PM_{2.5}$. A relatively large association with major depressive disorder was reported by Kim et al. (2016) in an analysis of the National Health Insurance Database (NHID) of Korea [HR: 1.21 (95% CI: 1.07, 1.38)], where the annual average $PM_{2.5}$ concentration was 26.7 μg/m^3.



Circles represent point estimates; horizontal lines represent 95% confidence intervals for $PM_{2.5}$. Black text and circles represent evidence included in the 2009 PM ISA; red text and circles represent recent evidence not considered in previous ISAs or AQCDs. Mean concentrations in $\mu g/m^3$. Hazard Ratios are standardized to a 5 $\mu g/m^3$ increase in $PM_{2.5}$ concentrations. Corresponding quantitative results are reported in Supplemental Table S8-3 (U.S. EPA, 2018).

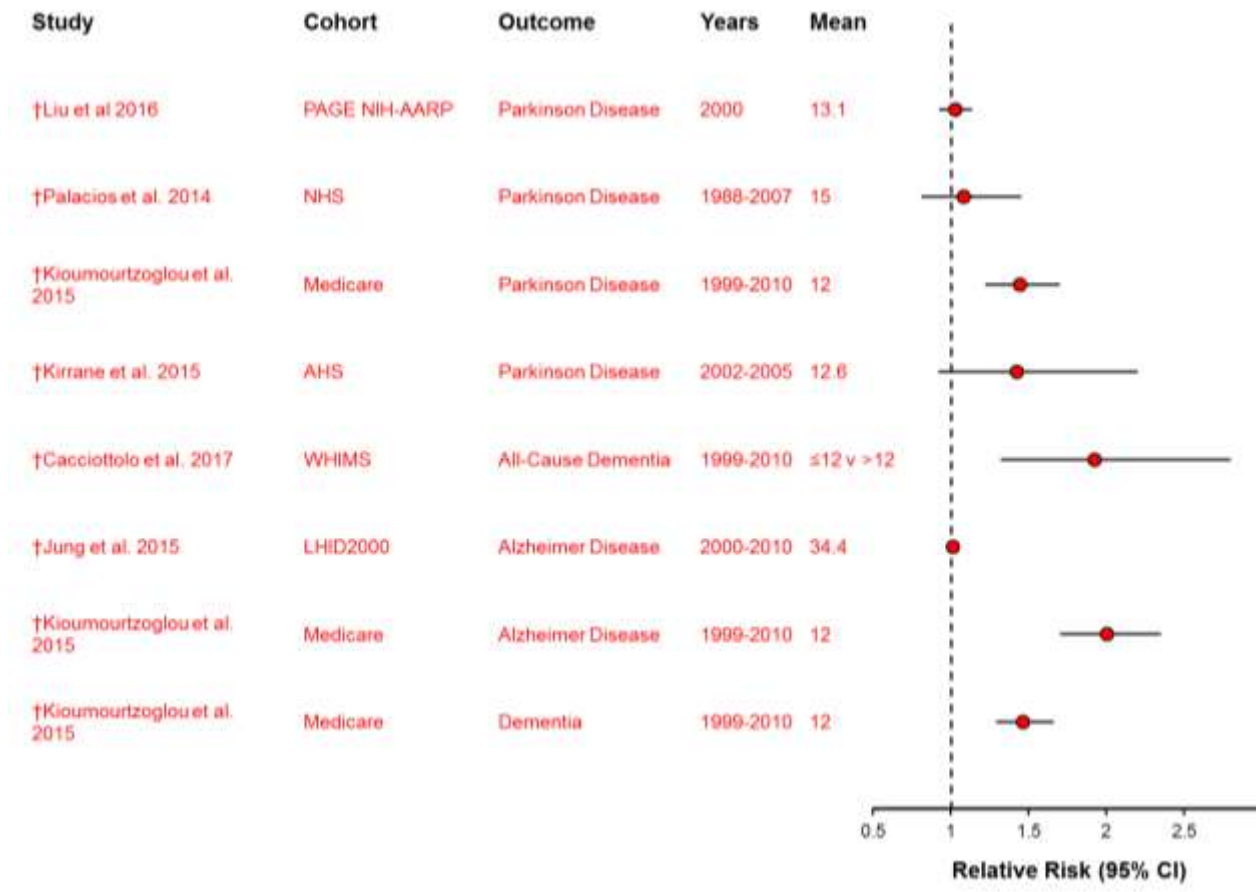
8.2.6 Neurodegenerative Diseases

There were no epidemiologic studies of the effect of long-term exposure to $PM_{2.5}$ and neurodegenerative disease evaluated in the previous ISA (U.S. EPA, 2009). A limited number of studies of Parkinson disease, Alzheimer's disease, and dementia are currently available for review (Figure 8-6, Table 8-15). Animal toxicological evidence of neurodegenerative diseases following long-term $PM_{2.5}$ exposure includes the demonstration of Parkinson disease-like brain histopathology (Veronesi et al., 2005), which is discussed in the 2009 PM ISA and in Section 8.2.4, and the demonstration of early markers of Alzheimer's disease (Bhatt et al., 2015), which is discussed in Section 8.2.3.

The set of studies of Parkinson disease includes a case control analysis from the Parkinson Genes and Environment study, National Institutes of Health, American Association of Retired People (PAGE NIH-AARP) study (Liu et al., 2016) and a prospective analysis from the NHS (Palacios et al., 2014). These studies are well-conducted in that self-reported outcomes were validated and individual-level data on an array of covariates including sex, smoking, and caffeine use was considered in the analyses. Although slightly increased, the relative risks reported in both studies were small relative to their wide confidence intervals, providing little evidence of an association [HR: 1.03 (95% CI 0.92, 1.13) in the PAGE NIH-AARP study and HR: 1.08 (95% CI: 0.81, 1.45) in the NHS study]. Kioumourtzoglou et al. (2015) reported large positive associations between long-term exposure to $PM_{2.5}$ and first hospital admission for Parkinson disease (ascertained using primary or secondary diagnosis code) indicating higher risk of Parkinson-related complications that require hospitalization among older adults receiving Medicare benefits in 50 Northeastern U.S. cities [HR: 1.44 (95% CI 1.22, 1.70)]. Although age and sex were controlled in the analysis, individual level data on smoking or dietary covariates was not available, nor was the outcome validated in this study. The other study of $PM_{2.5}$ exposure and Parkinson disease analyzed data from rural populations in North Carolina and Iowa reporting an imprecise, positive association between 4-year average $PM_{2.5}$ concentration and Parkinson disease (OR 1.34 95% CI: 0.93, 1.93) among farmers in North Carolina while no association was observed in among farmers in Iowa where exposures were much lower [OR: 0.91 (95% CI: 0.75, 1.11) per IQR (0.7 $\mu g/m^3$) increase] (Kirrane et al., 2015). Self-reported doctor-diagnosed Parkinson disease was validated for a subset of participants in this study.

Studies of Alzheimer's disease and dementia are also plotted on Figure 8-6. Some studies report positive associations with long-term $PM_{2.5}$ exposure, but findings are not consistent overall. In the analysis of the WHIMS cohort described previously, Cacciottolo et al. (2017) found an increased risk of all-cause dementia comparing 3-year moving average exposure to $PM_{2.5}$ of <12 $\mu g/m^3$ to ≥ 12 $\mu g/m^3$ [HR: 1.92 (95%CI: 1.32, 2.8)]. In a study in China where concentrations are relatively high, Jung et al. (2014) found little evidence of an association between annual average $PM_{2.5}$ exposure at baseline and Alzheimer's disease, although an increase in $PM_{2.5}$ during follow-up was associated with the disease. Similar to their

results for Parkinson disease Kioumourtzoglou et al. (2015) reported large associations of hospital admissions for Alzheimer's disease and dementia with $PM_{2.5}$ among Medicare recipients [HR: 2.0 (95%CI: 1.7, 2.35) and HR: 1.46 (95%CI: 1.29, 1.66), respectively].



Circles represent point estimates; horizontal lines represent 95% confidence intervals for $PM_{2.5}$. Black text and circles represent evidence included in the 2009 PM ISA; red text and circles represent recent evidence not considered in previous ISAs or AQCDs. Mean concentrations in $\mu g/m^3$. Hazard Ratios are standardized to a 5 $\mu g/m^3$ increase in $PM_{2.5}$ concentrations. Corresponding quantitative results are reported in Supplemental Table S8-4 (U.S. EPA, 2018).

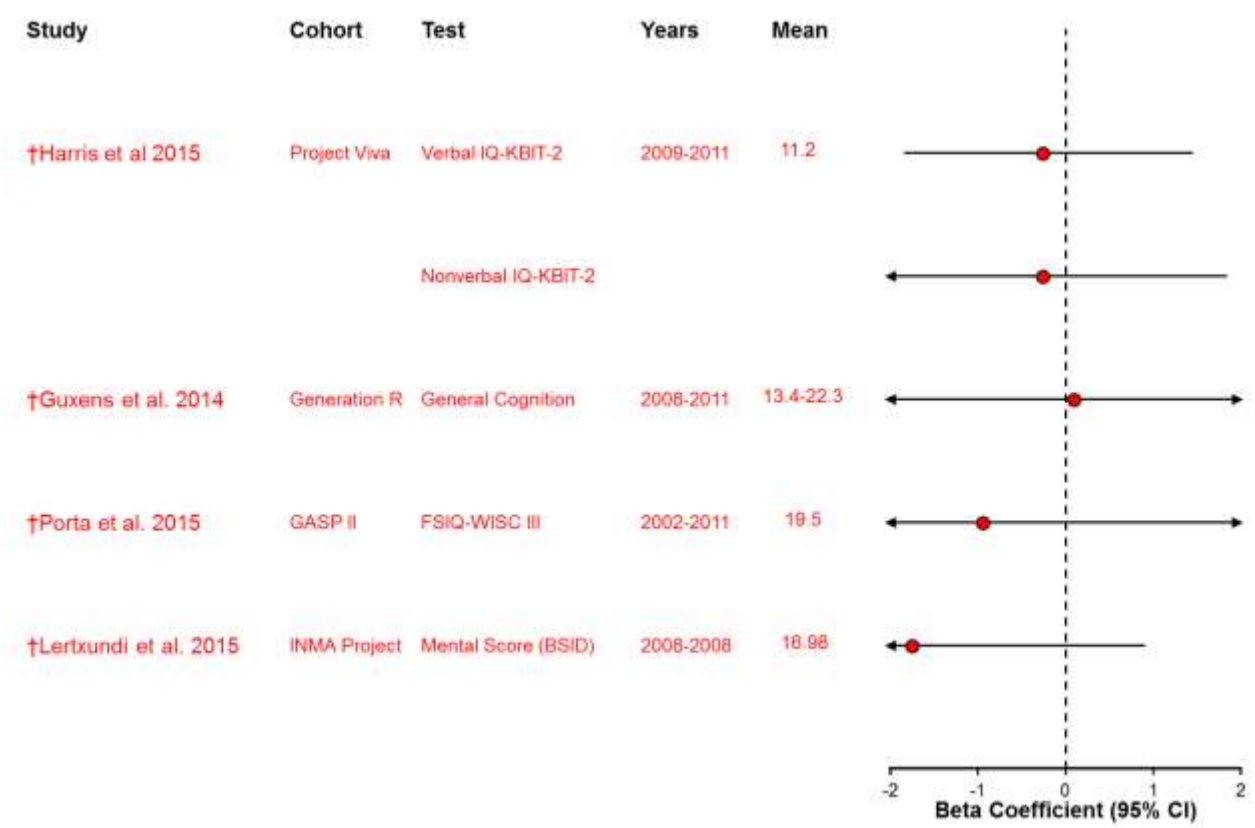
8.2.7 Neurodevelopmental Effects

There were no epidemiologic studies of neurodevelopmental effects in children available for review in the 2009 PM ISA. Currently there is a small body of literature examining the association of exposure to $PM_{2.5}$ during perinatal and childhood lifestages with cognitive and behavioral effects that do not provide consistent evidence of an association (Figure 8-7, Table 8-16). In addition, there is a limited number of studies examining the association of $PM_{2.5}$ during these lifestages with autism spectrum disorder (ASD). This set of studies report positive associations that are coherent with findings from an experimental animal study of $PM_{2.5}$ CAPs exposure demonstrating neuroinflammation and morphologic change that is associated with various human neuropathologies, including ASD.

8.2.7.1 Cognitive and Behavioral Effects

Harris et al. (2015) examined the effect of long-term $PM_{2.5}$ exposure during pregnancy and from birth through 6 years of age on cognition in children enrolled in Project Viva, which follows mother-infant pairs (N = 1,109) from birth through various lifestages during childhood. The weakly positive and negative associations with cognitive assessment scores that were reported did not provide evidence for an effect of $PM_{2.5}$ on cognition in these children. Porta et al. (2015) followed a cohort of infants born (n = 719) in Rome between 2003 to 2004 and administered the Wechsler Intelligence Scale for Children (WISC) III at age seven (n = 474). Authors reported associations with Full Scale [−0.95 (95% CI: −3.95, 2.05)], Verbal [0.22 (95% CI: −2.75, 3.20)] and Performance IQ [−2.05 (95% CI: −1.70, 0.60)], as well as results for several WISC subscales that provided little support for an association between pregnancy or childhood $PM_{2.5}$ exposures and cognitive effects. Guxens et al. (2014) reported no decrease in general cognition score in association with $PM_{2.5}$ exposure [β = 0.09 (95% CI: −2.95, 3.12)], although a decrease in psychomotor development was observed [β = −1.64 (95% CI: −3.47, 0.18)]. Lertxundi et al. (2015) reported decrements in motor scale score with increasing $PM_{2.5}$ concentrations but little evidence of an association with mental score on the Bayle Scale of Infant Development (BSID). Results persisted after adjustment for NO_2, and associations were relatively large closer to roads and pollution producing facilities. $PM_{2.5}$ exposures was associated with decreases on tests of attention (continuous performance and stroop) but not with other neurobehavioral tests in the COGNAC study (Saenen et al., 2016).



Circles represent beta coefficients; horizontal lines represent 95% confidence intervals. Red text and circles represent recent evidence not considered in previous ISAs or AQCDs. Concentrations are in μg/m^3. Results are standardized to a 5 μg/m^3 increase in $PM_{2.5}$ concentrations. Corresponding quantitative results are reported in Supplemental Table S8-5 (U.S. EPA, 2018).

8.2.7.2 Autism

Autism is a condition that includes a spectrum of impairments affecting social interaction, language development, and communication skills that often involves rigid and repetitive behaviors.

Epidemiologic Studies

At present, there is a European pooled cohort study that examined autistic traits and multiple U.S.-based case-control studies that examine ASD in association with $PM_{2.5}$ exposure during pregnancy. Guxens et al. (2015) observed no associations between $PM_{2.5}$ during pregnancy and either borderline clinical or clinical autistic traits using information from cohort studies across four European countries. Of the case-control studies examining ASD, two used monitors to assign $PM_{2.5}$ exposures (Becerra et al., 2013; Volk et al., 2013), while the others used LUR methods to assign exposure (Raz et al., 2015; Talbott et al., 2015). Positive associations were observed between $PM_{2.5}$ exposures and ASD in studies that used both monitors and LUR models to assign exposure and for various exposure periods used in different studies. Volk et al. (2013), Talbott et al. (2015), and Raz et al. (2015) observed positive associations similar in magnitude for both entire pregnancy exposure and first year of life exposure. Specifically, Volk et al. (2013) observed positive associations for both entire pregnancy exposure (OR range: 1.52, 95% CI: 1.46, 1.59) and first year of life exposure (OR: 1.54, 95% CI: 1.24, 1.92) in a California population. In a six-county region of southwestern Pennsylvania, Talbott et al. (2015) observed positive associations with $PM_{2.5}$ exposure during pregnancy (OR: 1.38, 95% CI: 0.80, 2.36]) and first year of life (OR: 1.74, 95% CI: 0.91, 3.30), as well as cumulative exposures from three months pre-conception through first year of life (OR: 1.97, 95% CI: 0.97, 4.04). Raz et al. (2015) reported a positive OR for ASD with entire pregnancy exposure, after adjusting for exposures nine months before and after pregnancy (OR: 1.74, 95% CI: 1.08, 2.47). In Los Angeles, Becerra et al. (2013) reported a positive OR for ASD with entire pregnancy exposure (OR: 1.07, 95% CI: 1.00, 1.16), though the magnitude was lower than that observed in the other studies. Building on the positive associations observed by Volk et al. (2013), follow-up studies provide some initial evidence for gene-environment interactions with $PM_{2.5}$ concentrations and MET receptor variants (Volk et al., 2014) but not for copy number variation (Kim et al., 2017). Interpretation of these results is limited by the lack of control for potential confounding by copollutants, the small number of studies, and uncertainty regarding critical exposure windows (Table 8-17).

Animal Toxicological Studies

Klocke et al. (2017) examined the effects of prenatal exposure (GD0.5 to GD16.5) to $PM_{2.5}$ CAPs in Sterling Forest, NY using B6C3F1 mice (Table 8-18). At postnatal day (PND) 11−15, both male and female offspring had increased microglial activation, an indicator of inflammation, in the corpus callosum ($p < 0.05$). Males had decreased total number of microglia ($p < 0.05$) and females trended in this direction (not significant) but had increased iron deposition in the corpus callosum ($p < 0.05$). In the hippocampus, female offspring had increases in activated microglia ($p < 0.01$) with no change in number of microglia; the male hippocampal microglia were not affected. In addition, both male and female offspring had ventriculomegaly, increased corpus callosum area and hypermyelination, and reduced hippocampal area ($p < 0.05$). Frontal cortex thickness was not affected by CAPs exposure. Various human neuropathologies are associated with ventriculomegaly including schizophrenia, ASD, and ADHD.

Table 8-18 Study-specific details from an animal toxicological study of long-term exposure and neurodevelopmental effects.

Study	Study Population	Exposure Details	Endpoints Examined
Klocke et al. (2017)	Male and female B6C3F1 mice (8−10 weeks old) were mated and then dams were exposed to Sterling Forest, NY CAPs.	Prenatal exposure to filtered air or Sterling Forest $PM_{2.5}$ CAPs for 6h/day during gestation (GD0.5 to GD 16.5). Mean CAPs concentration over the exposure period averaged 92.7 ± 19.2 (mean ± SD) μg/m^3 compared to 3.5 ± 0.9 μg/m^3 for FA controls. CAPs exposure levels ranged from 32.95 to 184.43 μg/m^3 over the duration of the exposure period. PM was a mixture of $PM_{2.5}$ and UFP	Offspring neuropathological outcomes including brain structure and size (ventriculomegaly), microglial activation (inflammation), myelination, corpus callosum iron content in association with myelination.

CAPs = concentrated ambient particles; FA = filtered air; GD = gestational day.

8.2.8 Components and Sources of $PM_{2.5}$

No studies relevant to our understanding of the effect of long-term exposure to components or sources of $PM_{2.5}$ were evaluated in the 2009 PM ISA (U.S. EPA, 2009). Currently, there are several studies of traffic exposures among children as well as a study of adults available for consideration (Table 8-18). These studies examine cognitive effects in the populations studied. Overall, the evidence base

remains limited and the few available studies do not provide evidence to support an independent effect of sources or components of $PM_{2.5}$ that is distinct from the effect long-term exposure to $PM_{2.5}$ mass.

Basagaña et al. (2016) conducted an analysis of the data previously examined by Sunyer et al. (2015) and described in Section 8.6.6. In this longitudinal repeated measures study, the authors report lower growth in memory and attentiveness in association with metrics for traffic-related $PM_{2.5}$ derived using constrained positive matrix factorization (PMF) based on 33 chemical species. Chen et al. (2016) conducted a repeated measures analysis of the association of long-term $PM_{2.5}$ and BC exposure with measures of attention, memory and processing in children. Long-term exposure to $PM_{2.5}$ was associated with decreased performance on measure of attention, while little evidence of associations with BC was provided by the study. Finally, the cross-sectional analysis of Project Viva participants reported by Harris et al. (2015) did not show an association between BC and cognitive effects. Among adults, Tonne et al. (2014) used a set of tests designed to measure reasoning, memory, semantic fluency, and phonemic fluency to examine the association with long-term exposure to $PM_{2.5}$ from traffic, estimated using a dispersion model. $PM_{2.5}$ from traffic was exhibited a similar pattern of association with cognition as with $PM_{2.5}$ mass.

8.2.9 Summary and Causality Determination

The evidence that long-term exposure to $PM_{2.5}$ can affect the nervous system has grown substantially since the 2009 PM ISA (U.S. EPA, 2009). There is evidence from animal toxicological studies demonstrating a link between long-term $PM_{2.5}$ exposure-mediated activation of the SNS and downstream cardiovascular effects. In addition, evidence for neuroinflammation and downstream consequences is well substantiated and coherent across experimental animal and epidemiologic studies. Specifically, toxicological studies in adult animals demonstrate neuroinflammation, neurodegeneration, indicators of Alzheimer's disease, impaired learning and memory, and altered behavior. High quality epidemiologic studies provide support, reporting changes in brain morphology (i.e., neurodegeneration), cognitive decrements and dementia in adult populations. The evidence characterizing the relationship between long-term exposure to $PM_{2.5}$ and effects on the nervous system is detailed below (Table 8-20), using the framework for causality determination described in the Preamble to the ISAs (U.S. EPA, 2015).

Animal toxicological studies of long-term $PM_{2.5}$ exposure provide evidence that the central nervous system mediates responses outside of the brain, i.e., peripheral responses. One study linked hypertension to an increase in sympathetic tone (Ying et al., 2014). Another study in a mouse model of diabetes linked exaggeration of the diabetic phenotype to hypothalamic inflammation (Liu et al., 2014). A relationship between hypothalamic inflammation and sympathetic tone was proposed (Ying et al., 2014).

Long-term exposure of adult animals resulted in inflammation and neurodegeneration in specific regions of the brain including the hippocampus (Fonken et al., 2011). Changes in the hippocampus were accompanied by impaired learning and memory and by altered behavior (Fonken et al., 2011). Long-term exposure to $PM_{2.5}$ was associated with accelerated global cognitive decline in longitudinal analysis of women enrolled in WHIMS (Cacciottolo et al., 2017). This decline was larger among those with APOE alleles thought to confer an increased risk of Alzheimer's disease. Further, morphologic changes (i.e., reduction in total WM, subcortical WM and cortical GM) compatible with these observations of cognitive decline were also observed in this cohort (Casanova et al., 2016; Chen et al., 2015). In a cross-sectional analysis of the Framingham Heart Offspring study Wilker et al. (2015) reported that total cerebral brain volume was smaller with increasing $PM_{2.5}$. Decrements on cognitive tests were observed in longitudinal analyses of the NHS and in the British Whitehall II cohort (Tonne et al., 2014; Weuve et al., 2012). Wilker et al. (2015) and Weuve et al. (2012) are notable in that they controlled for a wide range of covariates including SES and vascular factors. None of these studies considered copollutant confounding, however. Cross-sectional analyses were less consistent in their observation of associations between long-term $PM_{2.5}$ exposure and cognitive function. Specifically, cognitive impairment was not associated with long-term $PM_{2.5}$ exposure in the REGARDS (Loop et al., 2013) or SALIA cohorts (Schikowski et al., 2015) while positive associations were reported in U.S. surveys (Tzivian et al., 2016; Ailshire and

Crimmins, 2014) and in an analysis of clinical trial participants from southern California (Gatto et al., 2014).

Evidence for a relationship between long-term $PM_{2.5}$ exposure and Alzheimer's disease and dementia is provided by both animal toxicological and epidemiologic studies. Early markers of Alzheimer's disease pathology were increased in the temporal cortex of mice exposed to $PM_{2.5}$ CAPs for 9 months, but not 3 months (Bhatt et al., 2015). An association between long-term $PM_{2.5}$ exposure and all-cause dementia was observed among WHIMS participants (Cacciottolo et al., 2017) and with hospitalizations among Medicare recipients for Alzheimer's disease and dementia, which may be related to complications from the disease (Kioumourtzoglou et al., 2015). However, a large registry-based study conducted in China, where exposure levels are high relative to the U.S., reported no evidence of an association with Alzheimer's disease (Jung et al., 2014).

Although an experimental animal study demonstrating loss of dopaminergic neurons in the substantia nigra (Veronesi et al., 2005) provides biological plausibility for an association of long-term $PM_{2.5}$ exposure with Parkinson disease, associations were not consistently observed in epidemiologic studies. Incident case control or longitudinal analyses relying on neurologist confirmed Parkinson disease, provided no evidence of an association with $PM_{2.5}$ (Liu et al., 2016; Palacios et al., 2014). There was some evidence that long-term exposure to $PM_{2.5}$ was associated with hospital admission for Parkinson disease in the aforementioned study of Medicare recipients indicating the potential for long-term exposure to $PM_{2.5}$ to increase the risk of complications that require hospitalization in neurodegenerative disease patients (Kioumourtzoglou et al., 2015).

Several studies of the association of $PM_{2.5}$ exposure during pregnancy or other childhood lifestage with cognitive or motor development in children were conducted. Studies have generally found little evidence of association with cognitive development for entire pregnancy, third trimester or childhood exposures (Harris et al., 2015; Lertxundi et al., 2015; Porta et al., 2015; Guxens et al., 2014). Where decrements on tests of cognition were observed, confidence intervals were wide. Associations with ASD were observed in several epidemiologic studies but the interpretation of these findings was limited by the lack of control for potential confounding by copollutants, the small number of studies, and uncertainty regarding critical exposure windows. Biological plausibility for associations observed of $PM_{2.5}$ with ASD is provided by an animal toxicological study. Klocke et al. (2017) reported inflammatory and morphologic changes in corpus callosum and hippocampus, as well as ventriculomegaly in young animals exposed prenatally to $PM_{2.5}$ CAPs.

The strongest evidence of an effect of long-term exposure to $PM_{2.5}$ on the nervous system is provided by animal toxicological studies that show inflammation, oxidative stress, morphologic changes, and neurodegeneration in multiple brain regions following long-term exposure to $PM_{2.5}$ CAPs. These findings are coherent with a number of epidemiologic studies report consistent associations with cognitive decrements and with all cause dementia. **Overall, the collective evidence is sufficient to conclude that a causal relationship is likely to exist between long-term $PM_{2.5}$ exposure and nervous system effects.**

Table 8-20 Summary of evidence for a likely to be causal relationship between long-term $PM_{2.5}$ exposure and nervous system effects.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{2.5}$ Concentrations Associated with Effects[c]

8.3 Short-term $PM_{10-2.5}$ Exposure and Nervous System Effects

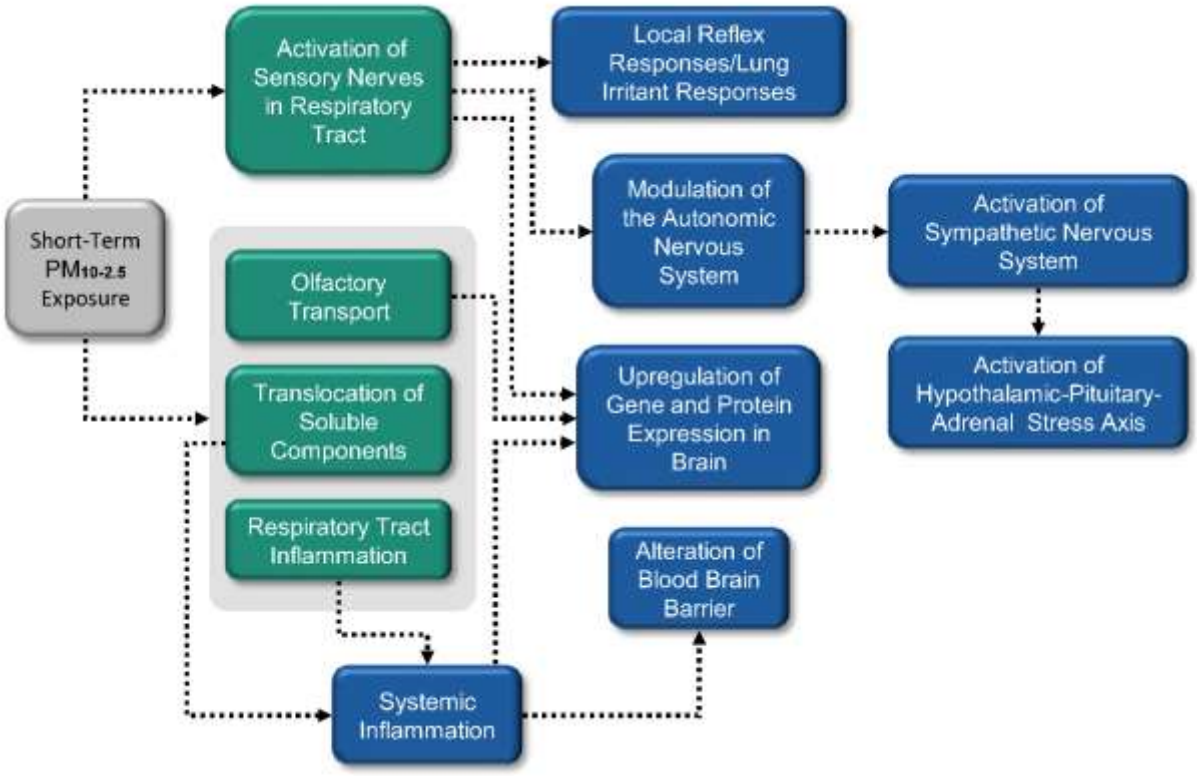
The previous ISA did not report any studies of nervous system effects as a result of short-term exposure to $PM_{10-2.5}$. Although the evidence continues to be limited, there are some recent studies available for review. The discussion opens with a discussion of biological plausibility (Section 8.1.1) that provides background for the subsequent sections in which groups of related endpoints are presented in the context of relevant disease pathways. These outcome groupings are activation of the SNS and HPA stress Axis (Section 8.1.2) and brain inflammation and oxidative stress (Section 8.1.3). The collective body of evidence is integrated[73] across and within scientific disciplines, and the rationale for the causality determination is outlined in Section 8.3.4.

[73] As detailed in the Preface, risk estimates are for a 10 µg/m3 increase in 24-hour avg PM10−2.5 concentrations unless otherwise noted.

8.3.1 Biological Plausibility

This section describes biological pathways that potentially underlie nervous system effects resulting from short-term exposure to $PM_{10–2.5}$. Figure 8-8 graphically depicts the proposed pathways as a continuum of upstream events, connected by arrows, that may lead to downstream events observed in epidemiologic studies. This discussion of "how" short-term exposure to $PM_{10–2.5}$ may lead to nervous system effects contributes to an understanding of the biological plausibility of epidemiologic results evaluated later in Section 8.3.

Once $PM_{10–2.5}$ deposits in the respiratory tract, it may be retained, cleared, or solubilized (see Chapter 4). $PM_{10–2.5}$ and its soluble components may interact with cells in the respiratory tract, such as epithelial cells, inflammatory cells, and sensory nerve cells. One way in which this may occur is through reduction-oxidative (redox) reactions. As discussed in Section 2.3.3, PM may generate ROS and this capacity is termed "oxidative potential". Furthermore, cells in the respiratory tract may respond to the presence of PM by generating ROS. Further discussion of these redox reactions, which may contribute to oxidative stress, is found in Section 5.1.1 of the 2009 PM ISA (U.S. EPA, 2009). In addition, poorly soluble particles may translocate to the interstitial space beneath the respiratory epithelium and accumulate in the lymph nodes (see CHAPTER 4). Immune system responses due to the presence of particles in the interstitial space may contribute to health effects. Inflammatory mediators may diffuse from the respiratory tract into the systemic circulation and lead to inflammation in extrapulmonary compartments (Section 6.3.1). Although $PM_{10–2.5}$ is mostly insoluble, it may contain some soluble components such as endotoxin and metals. Soluble components of $PM_{10–2.5}$ may translocate into the systemic circulation and contribute to inflammatory or other processes in extrapulmonary compartments. A fraction of $PM_{10–2.5}$ may deposit on the olfactory epithelium. Soluble components of $PM_{10–2.5}$ may be transported via the olfactory nerve to the olfactory bulb of the brain. The extent to which translocation into the systemic circulation or transport to the olfactory bulb occurs is currently uncertain. For further discussion of translocation and olfactory transport, see CHAPTER 4.



Note: The boxes above represent the effects for which there is experimental or epidemiologic evidence, and the dotted arrows indicate a proposed relationship between those effects. Progression of effects is depicted from left to right and color-coded (gray, exposure; green, initial event; blue, intermediate event; orange, apical event). Here, apical events generally reflect results of epidemiologic studies, which often observe effects at the population level. Epidemiologic evidence may also contribute to upstream boxes. When there are gaps in the evidence, there are complementary gaps in the figure and the accompanying text below.

Figure 8-8 Potential biological pathways for nervous system effects following short-term $PM_{10-2.5}$ exposure.

Evidence that short-term exposure to $PM_{10-2.5}$ may affect the nervous system generally informs one pathway that begins with activation of sensory nerves in the respiratory tract. This can trigger local reflex responses and transmit signals to regions of the central nervous system that regulate autonomic outflow. Altered autonomic tone may result in effects in other organs (Figure 8-8). Decrements in lung function seen immediately after a 4-hour exposure to $PM_{10-2.5}$ in an animal toxicological study by Amatullah et al. (2012) indicates that activation of sensory nerves in the respiratory tract may have triggered a reflex response in the lung or that modulation of the ANS may have contributed to the observed effects (Section 5.3.6.3). In addition, evidence from a controlled human exposure study supports a link between short-term $PM_{10-2.5}$ exposure and activation of the HPA stress axis (Liu et al., 2017). In this way, the ANS may mediate systemic responses due to exposure to $PM_{10-2.5}$. Currently there are no epidemiologic studies evaluating the relationship between short-term exposure to $PM_{10-2.5}$ and nervous system effects.

An animal toxicological study found upregulation of gene and protein expression in the brain following short-term exposure to $PM_{10–2.5}$ (Ljubimova et al., 2013). Whether this response was due to altered autonomic tone or to systemic inflammation or olfactory transport is uncertain. This study was conducted in rodents, which are obligatory nasal breathers (as opposed to humans who are oro-nasal breathers). Deposition of $PM_{10–2.5}$ in the tracheobronchial or pulmonary regions of the lung of rodents is expected to be minimal. An effect seen in the brain of rodents indicates that $PM_{10–2.5}$, which deposited in the nose, may have activated sensory nerves in the nose. It is also possible that soluble components may have translocated into the systemic circulation or have been transported from the olfactory epithelium in the nose to the olfactory bulb in the brain via the axons of olfactory sensory neurons. Responses seen in the controlled human exposure study by Liu et al. (2017), which also found evidence linking exposure to $PM_{10–2.5}$ to altered blood brain barrier function, may reflect different patterns of deposition in oro-nasal breathers.

Summary of Biological Plausibility

As described here, there is one proposed pathway by which short-term exposure to $PM_{10–2.5}$ may lead to nervous system effects. Stimulation of receptors on sensory nerves, possibly in the nose, may trigger local reflex responses or transmit signals to the regions of the central nervous system that regulate autonomic outflow, resulting in activation of the SNS and the HPA stress axis. Experimental studies in animals and humans contribute all the evidence of upstream and downstream events. This proposed pathway will be used to inform a causality determination, which is discussed later in the chapter (Section 8.3.4).

8.3.2 Activation of the Sympathetic Nervous System and the Hypothalamic-Pituitary-Adrenal (HPA)Stress Axis

A controlled human exposure study examined the effects of a 130 minute exposure to $PM_{10–2.5}$ CAPs on urinary and blood biomarkers associated with neural effects (Liu et al., 2017). Associations between exposure to $PM_{10–2.5}$ CAPs and decreases in biomarkers related to blood brain barrier integrity, including blood S100 calcium-binding protein B and neuron-specific enolase, were observed at 21 hours post-exposure ($p < 0.1$). In addition, exposure to $PM_{10–2.5}$ CAPs was associated with increases in stress-related markers such as urinary vanillylmandelic acid and cortisol at 21 hours post-exposure ($p < 0.05$) and decreases in blood cortisol at 1 and 21 hours post-exposure ($p < 0.05$). Since vanillylmandelic acid is the primary metabolite resulting from breakdown of the stress-related hormones epinephrine and norepinephrine, its presence in urine indicates that exposure to $PM_{10–2.5}$ CAPs led to secretion of epinephrine and/or norepinephrine into the blood by the adrenal medulla subsequent to activation of the HPA stress axis. Increased levels of urinary cortisol, which is secreted into the blood by the adrenal cortex, also indicates that exposure to $PM_{10–2.5}$ CAPs led to activation of the HPA stress axis (Table 8-21).

Table 8-21 Study-specific details from a controlled human exposure study of short-term exposure to $PM_{10-2.5}$ and activation of the sympathetic nervous system (SNS)/hypothalamic-pituitary-adrenal (HPA) stress axis.

Study/Study Population	Pollutant	Exposure Details	Endpoints Examined
Liu et al. (2017) Species: Human Health status: Healthy nonsmokers Sex: 29 females, 26 males Age: 18−60 yr Study design: Single-blind randomized cross-over trial Single-blind randomized cross-over trial	CAPs from Toronto, ON Particle sizes: 2.5−10 µm Control: HEPA filtered ambient air or HEPA-filtered medical air (ultrafine study)	Route: Face mask inhalation Dose/concentration: 212.9 ± 52.0 µg/m^3 Duration of exposure: 130 min Time to analysis: 1 and 21 h	Urinary and blood markers of neural effects

CAPs = concentrated ambient particles; HEPA = high efficiency particulate absorber.

8.3.3 Brain Inflammation and Oxidative Stress

An animal toxicological study examined changes in global gene expression in the brain, as well as expression of Arc and Rac genes and their protein products, in Fischer 344 rats exposed to $PM_{10-2.5}$ CAPs in Riverside, CA for 2 weeks (Ljubimova et al., 2013). No changes in global gene expression were found. However, increased Arc gene expression ($p < 0.05$) and increased Arc immunostaining were observed. In contrast, exposure to $PM_{2.5}$ CAPs and UFP CAPs had no effects on these genes or their protein products (Table 8-22).

Table 8-22 Study-specific details from an animal toxicological study of short-term exposure to $PM_{10-2.5}$ and brain inflammation and oxidative stress.

Study/Study Population	Pollutant	Exposure Details	Endpoints Examined
Ljubimova et al. (2013) Species: Rat Sex: Male Strain: Fisher 344 Age/Weight: 3−7 weeks	CAPs from Riverside, CA (summer) Particle size 3,000 nm Control: Filtered air	Route: Whole body inhalation Dose/Concentration: 58 ± 7 µg/m³ Duration: 5 h/day, 4 days duration: 5 h/day, 4 days/week for 0.5 mo	Brain tissue—Immunohistochemistry Gene expression—mRNA

CAPs = concentrated ambient particles.

8.3.4 Summary and Causality Determination

There were no studies of the effect of $PM_{10-2.5}$ on the nervous system effects in adults or children reviewed in the 2009 PM ISA. The evidence characterizing the relationship between short-term exposure to $PM_{10-2.5}$ and effects on the nervous system is detailed below (Table 8-23), using the framework for causality determination described in the Preamble to the ISAs (U.S. EPA, 2015). The evidence base consists of a limited number of experimental studies without supporting epidemiologic studies. The toxicological study examined the potential for inhalation of $PM_{10-2.5}$ to affect the nervous system and found altered gene expression in the brain (Ljubimova et al., 2013). The controlled human exposure study indicated activation of the HPA stress axis in relation to short-term exposure to $PM_{10-2.5}$(Liu et al., 2017). **Overall, the evidence is inadequate to infer the presence or absence of a causal relationship between short-term $PM_{10-2.5}$ exposure and nervous system effects.**

Table 8-23 Summary of evidence that is inadequate to infer the presence or absence of a causal relationship between short-term $PM_{10-2.5}$ exposure and nervous system effects.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{2.5}$ Concentrations Associated with Effects[c]
Limited controlled human exposure study evidence	Changes in levels of metabolite of epinephrine/epinephrine and cortisol in urine indicate HPA stress axis activation	Liu et al. (2017)	212.9 µg/m^3
Lack of epidemiologic evidence	No studies of the association between short-term exposure to PM10-2.5 and nervous system effects reviewed		
Limited biological plausibility	Limited toxicological evidence of altered gene expression in brain	Ljubimova et al. (2013)	58 µg/m^3

[a]Based on aspects considered in judgments of causality and weight of evidence in causal framework in Table I and Table II of the Preamble.

[b]Describes the key evidence and references, supporting or contradicting, contributing most heavily to causality determination and, where applicable, to uncertainties or inconsistencies. References to earlier sections indicate where full body of evidence is characterized.

[c]Describes the $PM_{2.5}$ concentrations with which the evidence is substantiated (for experimental studies, ≤2 mg/m^3).

HPA = hypothalamic-pituitary-adrenal; SNS = sympathetic nervous system.

8.4 Long-term $PM_{10-2.5}$ Exposure and Nervous System Effects

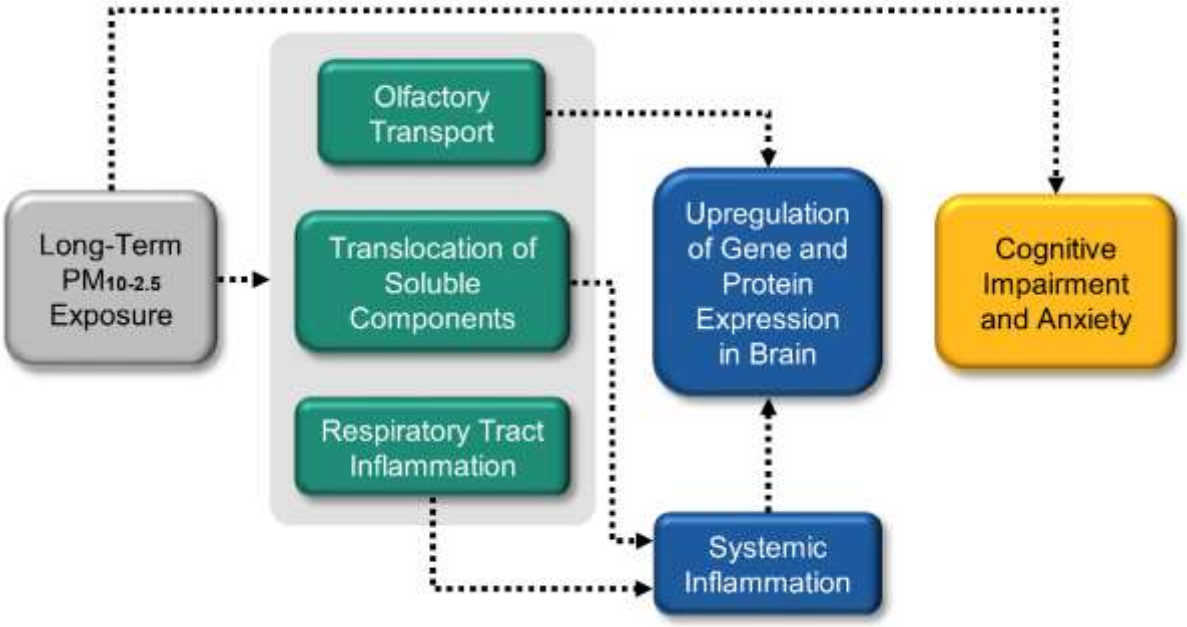
The previous ISA did not report any studies of nervous system effects as a result of long-term exposure to $PM_{10-2.5}$. There are some recent studies available for review. The discussion opens with a discussion of biological plausibility (Section 8.1.1) that provides background for the subsequent sections in which groups of related endpoints are presented in the context of relevant disease pathways. These outcome groupings are brain inflammation and oxidative stress (Section 8.4.2), cognitive and behavioral effects in adults (Section 8.4.3), and neurodevelopmental effects (Section 8.4.4). Finally, the collective body of evidence is integrated[74] across and within scientific disciplines, and the rationale for the causality determination is outlined in Section 8.1.6.

[74] As detailed in the Preface, risk estimates are for a 5 µg/m3 increase in annual PM10−2.5 concentrations unless otherwise noted.

8.4.1 Biological Plausibility

This section describes biological events that potentially underlie nervous system effects resulting from long-term exposure to $PM_{10-2.5}$. Figure 8-9 graphically depicts the continuum of upstream events, connected by arrows, that may lead to downstream events observed in epidemiologic studies. This discussion of "how" long-term exposure to $PM_{10-2.5}$ may lead to nervous system effects contributes to an understanding of the biological plausibility of epidemiologic results evaluated later in Section 8.4.

Once $PM_{10-2.5}$ deposits in the respiratory tract, it may be retained, cleared, or solubilized (see Chapter 4). $PM_{10-2.5}$ and its soluble components may interact with cells in the respiratory tract, such as epithelial cells, inflammatory cells, and sensory nerve cells. One way in which this may occur is through reduction-oxidative (redox) reactions. As discussed in Section 2.3.3, PM may generate ROS and this capacity is termed "oxidative potential". Furthermore, cells in the respiratory tract may respond to the presence of PM by generating ROS. Further discussion of these redox reactions, which may contribute to oxidative stress, is found in Section 5.1.1 of the 2009 PM ISA (U.S. EPA, 2009). In addition, poorly soluble particles may translocate to the interstitial space beneath the respiratory epithelium and accumulate in the lymph nodes (see Chapter 4). Immune system responses due to the presence of particles in the interstitial space may contribute to health effects. Inflammatory mediators may diffuse from the respiratory tract into the systemic circulation and lead to inflammation in extrapulmonary compartments (Section 6.4.1). Although $PM_{10-2.5}$ is mostly insoluble, it may contain some soluble components such as endotoxin and metals. Soluble components of $PM_{10-2.5}$ may translocate into the systemic circulation and contribute to inflammatory or other processes in extrapulmonary compartments. A fraction of $PM_{10-2.5}$ may deposit on the olfactory epithelium. Soluble components of $PM_{10-2.5}$ may be transported via the olfactory nerve to the olfactory bulb of the brain. The extent to which translocation into the systemic circulation or transport to the olfactory bulb occurs is currently uncertain. For further discussion of translocation and olfactory transport, see Chapter 4.



Note: The boxes above represent the effects for which there is experimental or epidemiologic evidence, and the dotted arrows indicate a proposed relationship between those effects. Progression of effects is depicted from left to right and color-coded (gray, exposure; green, initial event; blue, intermediate event; orange, apical event). Here, apical events generally reflect results of epidemiologic studies, which often observe effects at the population level. Epidemiologic evidence may also contribute to upstream boxes. When there are gaps in the evidence, there are complementary gaps in the figure and the accompanying text below.

Figure 8-9 Potential biological pathways for nervous system effects following long-term $PM_{10-2.5}$ exposure.

Evidence that long-term exposure to $PM_{10-2.5}$ may affect the nervous system is very sparse (Figure 8-9). Unlike the case for short-term exposure to $PM_{10-2.5}$, there is a lack of evidence that long-term $PM_{10-2.5}$ exposure results in activation of sensory nerves in the respiratory tract. An animal toxicological study found upregulation of gene and protein expression in the brain following long-term exposure to $PM_{10-2.5}$ (Ljubimova et al., 2013). Whether this response occurred secondarily to systemic inflammation or olfactory transport is uncertain. This study was conducted in rodents, which are obligatory nasal breathers. Deposition of $PM_{10-2.5}$ in the tracheobronchial or pulmonary regions of the lung of rodents is expected to be minimal. An effect seen in the brain of rodents indicates that soluble components of $PM_{10-2.5}$ that was deposited in the nose, may have translocated into the systemic circulation or have been transported from the olfactory epithelium in the nose to the olfactory bulb in the brain via the axons of olfactory sensory neurons. Currently, epidemiologic evidence is limited to studies linking long-term $PM_{10-2.5}$ exposure to impaired cognition and to anxiety. The evidence of upstream events is insufficient to support a pathway that could be used to inform a causality determination, which is discussed later in the chapter (Section 8.4.5).

8.4.2 Brain Inflammation and Oxidative Stress

The previous ISA did not report any studies of nervous system effects as a result of long-term exposure to $PM_{10–2.5}$. The body of evidence continues to be limited (Table 8-24) and consists of an animal toxicological study that examined changes in global gene expression in the brain, as well as expression of Arc and Rac genes and their protein products in Fischer 344 rats exposed to $PM_{10–2.5}$ CAPs from Riverside, CA for 10 months (Ljubimova et al., 2013). No changes in global gene expression were found. However, exposure to $PM_{10–2.5}$ CAPs upregulated Arc at 1 and 3 months and downregulated Arc at 10 months ($p < 0.05$). Expression of Rac1 was increased following 10 months of exposure to $PM_{10–2.5}$ CAPs ($p < 0.01$). Immunostaining for Arc and Rac1 protein following 10-month exposure to $PM_{10–2.5}$ CAPs demonstrated no increases. In contrast, exposure to $PM_{2.5}$ CAPs and UFP CAPs had no effects on these genes or their protein products.

Table 8-24 Study-specific details from an animal toxicological study of long-term exposure to $PM_{10–2.5}$ and brain inflammation and oxidative stress.

Study/Study Population	Pollutant	Exposure Details	Endpoints Examined
Ljubimova et al. (2013) Species: Rat Sex: Male Strain: Fisher 344 Age/Weight: 3−7 weeks	CAPs from Riverside, CA (summer) Particle size: 3,000 nm Control: Filtered air	Route: Whole body inhalation Dose/Concentration: 58 ± 7 µg/m^3 Duration: 5 h/day, 4 days/week for 1, 3, and 10 mo	Brain tissue—Immunohistochemistry Gene expression—mRNA

CAPs = concentrated ambient particles.

8.4.3 Cognitive and Behavioral Effects in Adults

There were no studies examining the association of $PM_{10–2.5}$ with nervous system effects in adults reviewed in the 2009 PM ISA. Although the evidence remains limited, a small number of studies indicate the potential for long-term exposure to $PM_{10–2.5}$ to affect the nervous system of adults (Table 8-24).

The evidence relevant to the effect of long term exposure to $PM_{10–2.5}$ is limited to a small number of epidemiologic studies. Among women enrolled in the NHS, Weuve et al. (2012) reported faster cognitive decline in association with increased $PM_{10–2.5}$ exposure. The magnitude of the change between successive 2−year outcome measurement [−0.018 (95% CI: −0.035, −0.002)] persisted after adjustment for potential confounders (i.e., age, education, physical activity, alcohol consumption.). The correlation between long-term $PM_{2.5}$ and $PM_{10–2.5}$ concentrations was low (spearman correlation 0.20). Notably, the

association with cognitive decline remained after additional adjustment for cardiovascular risk factors and SES. In another analysis of the NHS cohort, Power et al. (2015) observed a small positive association between high anxiety and the annual average concentration of $PM_{10–2.5}$ [OR: 1.03 (95% CI: 0.99, 1.06)]. Associations generally weakened with shorter averaging times in this study. A large imprecise association between long-term exposure to $PM_{10–2.5}$ and mild cognitive impairment (MCI) was observed in a cross-sectional analysis of the HNR study [OR: 1.69 (95% CI: 0.90, 3.18)] (Tzivian et al., 2016). The association was stronger when MCI was defined to identify cases of amnestic MCI (i.e., objective impairment in at least one memory domain).

8.4.4 Neurodevelopmental Effects

There were no studies examining the association of $PM_{10–2.5}$ with neurodevelopmental effects reviewed in the 2009 PM ISA. The limited number of recently available studies do not provide strong evidence of an association (Table 8-25).

In a prospective study of children born in Rome and followed through age 7 when the WISC-III was administered to measure cognitive function, Porta et al. (2015) reported small (relative to the size of the confidence interval), imprecise associations between $PM_{10–2.5}$ and decrement on FSIQ in fully adjusted models [−1.10 (95% CI: −2.80, 0.50)]. A slightly larger decrease was observed on the Performance IQ subtest. Raz et al. (2015) reported little evidence association between PM10-2.5 and ASD in a case control study nested within the NHS cohort [e.g. OR: 1.07 (95%CI: 0.92, 1.24) third trimester exposure, which was the strongest association]. Findings from the Guxens et al. (2014) analysis of six European cohorts did not support a strong association with reduced general cognition or global psychomotor development [Coefficient: 0.59 (95%CI: −0.99, 2.17) and Coefficient: 0.42 (95% CI: −1.28, 0.45), respectively].

Table 8-25 Characteristics of the studies examining the association of long-term $PM_{10-2.5}$ exposures with cognitive function, behavioral and neurodevelopmental effects.

8.4.5 Summary and Causality Determination

There were no studies of the effect of $PM_{10-2.5}$ on the nervous system effects included in the 2009 PM ISA. Several recent epidemiologic studies that report the association of long-term exposure to $PM_{10-2.5}$ with cognitive and behavioral effects in adults but not with neurodevelopmental effects in children, are available for review. The evidence characterizing the relationship between long-term exposure to $PM_{2.5}$ and effects on the nervous system is detailed below (Table 8-25), using the framework for causality determination described in the Preamble to the ISAs (U.S. EPA, 2015).

Although there is a limited number of studies overall, the evidence base includes well-conducted epidemiologic studies reporting associations with impaired cognition and anxiety in longitudinal analyses of women enrolled in the NHS (Power et al., 2015; Weuve et al., 2012). Studies of long-term exposure during pregnancy or childhood were not consistently associated with neurodevelopmental effects. There is uncertainty stemming from exposure assessment methods relying on the difference method to estimate $PM_{10-2.5}$ concentration (Sections 2.4.2) and related uncertainties due to the potentially uncharacterized spatial variation in $PM_{10-2.5}$ (Section 2.5 and Section 3.3.1.1). None of the available studies adjusted for copollutant exposures. An experimental animal study examined the potential for inhalation of $PM_{10-2.5}$ CAPs to affect the nervous system and found altered gene expression in the brain (Ljubimova et al., 2013). **Overall, the evidence is suggestive of, but not sufficient to infer, a causal relationship between long-term $PM_{10-2.5}$ exposure and nervous system effects.**

Table 8-26 Summary of evidence that is suggestive of, but not sufficient to infer, a causal relationship between long-term $PM_{10-2.5}$ exposure and nervous system effects.

†Studies published since the 2009 PM ISA.

8.5 Short-term UFP Exposure and Nervous System Effects

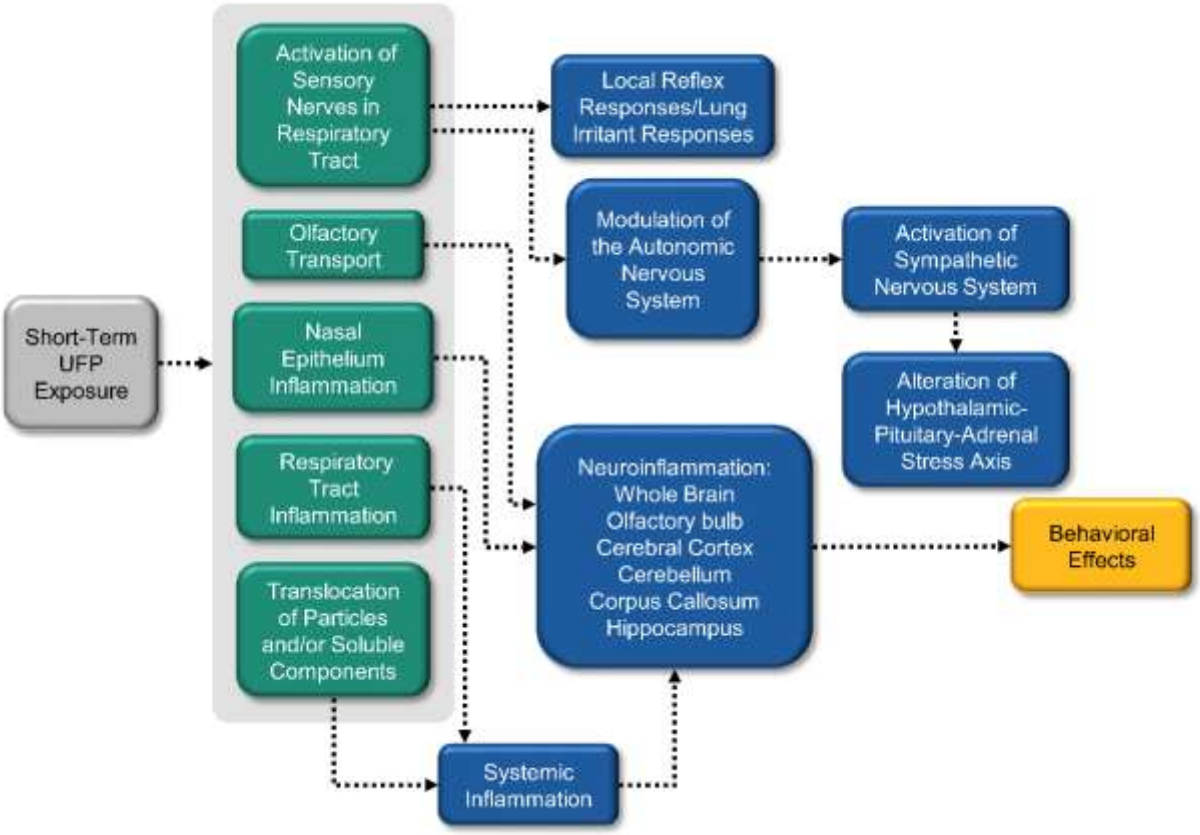
The previous ISA reported limited evidence of a relationship between exposure to ultrafine PM (UFP) and nervous system effects. An experimental study demonstrated that inhalation of UFP CAPs enhanced pro-inflammatory responses in the brains of mice that had been sensitized and challenged with ovalbumin (Campbell et al., 2005). Non-allergic mice were not tested. In addition, experimental studies in rodents previously found that inhaled laboratory-generated UFP can translocate from the olfactory epithelium to the olfactory bulb via the axons of olfactory sensory neurons (Elder et al., 2006; Oberdörster et al., 2004). Furthermore, magnetite UFP (10−150 nm), likely derived from combustion sources, have recently been found in frontal tissue from brains of humans (Maher et al., 2016). These findings suggest that ambient UFP may reach the brain via olfactory transport; however, other routes of translocation have not been ruled out (see Chapter 4).

The discussion of short-term UFP exposure and nervous system effects opens with a discussion of biological plausibility (Section 8.1.1) that provides background for the subsequent sections in which groups of related endpoints are presented in the context of relevant disease pathways. These outcome groupings are activation of the SNS and HPA stress axis (Section 8.5.2), brain inflammation and oxidative stress (Section 8.5.3), cognitive and behavioral effects in adults (Section 8.5.4). Finally, the collective body of evidence is integrated across and within scientific disciplines, and the rationale for the causality determination is outlined in Section 8.1.6.

8.5.1 Biological Plausibility

This section describes biological pathways that potentially underlie nervous system effects resulting from short-term exposure to UFP. Figure 8-10 graphically depicts the proposed pathways as a continuum of upstream events, connected by arrows, that may lead to downstream events observed in epidemiologic studies. This discussion of "how" short-term exposure to UFP may lead to nervous system effects contributes to an understanding of the biological plausibility of epidemiologic results evaluated later in Section 8.5.

Once UFP deposits in the respiratory tract, it may be retained, cleared, or solubilized (see Chapter 4). UFP and its soluble components may interact with cells in the respiratory tract, such as epithelial cells, inflammatory cells, and sensory nerve cells. One way in which this may occur is through reduction-oxidative (redox) reactions. As discussed in Section 2.3.3, PM may generate ROS and this capacity is termed "oxidative potential". Furthermore, cells in the respiratory tract may respond to the presence of PM by generating ROS. Further discussion of these redox reactions, which may contribute to oxidative stress, is found in Section 5.1.1 of the 2009 PM ISA (U.S. EPA, 2009). In addition, poorly soluble particles may translocate to the interstitial space beneath the respiratory epithelium and accumulate in the lymph nodes (see Chapter 4). Immune system responses due to the presence of particles in the interstitial space may contribute to health effects. Inflammatory mediators may diffuse from the respiratory tract into the systemic circulation and lead to inflammation in extrapulmonary compartments (Section 6.5.1). UFP and its soluble components may translocate into the systemic circulation and contribute to inflammatory or other processes in extrapulmonary compartments. A fraction of UFP may deposit on the olfactory epithelium. UFP and its soluble components may be transported via the olfactory nerve to the olfactory bulb of the brain. The extent to which translocation into the systemic circulation or transport to the olfactory bulb occurs is currently uncertain. For further discussion of translocation and olfactory transport, see Chapter 4.



Note: The boxes above represent the effects for which there is experimental or epidemiologic evidence, and the dotted arrows indicate a proposed relationship between those effects. Progression of effects is depicted from left to right and color-coded (gray, exposure; green, initial event; blue, intermediate event; orange, apical event). Here, apical events generally reflect results of epidemiologic studies, which often observe effects at the population level. Epidemiologic evidence may also contribute to upstream boxes. When there are gaps in the evidence, there are complementary gaps in the figure and the accompanying text below.

Figure 8-10 Potential biological pathways for nervous system effects following short-term UFP exposure.

Evidence that short-term exposure to UFP may affect the nervous system generally informs two different pathways (Figure 8-10). The first pathway begins with the activation of sensory nerves in the respiratory tract that can trigger local reflex responses and transmit signals to regions of the central nervous system that regulate autonomic outflow. The second pathway begins with pulmonary inflammation, leading to systemic inflammation and resulting in inflammation in the brain. Inflammation may lead to a worsening of neurodegenerative disease. Evidence for these pathways is described below.

Activation of Sensory Nerves and Modulation of the Autonomic Nervous System (ANS)

With regard to the first pathway, activation of sensory nerves in the respiratory tract may trigger local reflex responses in the lungs or modulate the ANS. Changes in lung function observed in controlled human exposure (Jr et al., 2008) and epidemiologic (McCreanor et al., 2007) (Mirabelli et al., 2015) studies potentially link short-term UFP exposure to the triggering of local reflex responses. However, inflammation (see below) may also play a role in lung function changes observed following short-term UFP exposure.

Evidence for changes in the HPA stress axis is provided by a controlled human exposure study that demonstrated an increase in a marker of the HPA stress axis in association with UFP exposure (Liu et al., 2017). Decreased levels of norepinephrine in the hypothalamus and decreased levels of serum glucocorticoids were observed in an animal toxicological study (Allen et al., 2014b) and indicate that UFP exposure may lead to other perturbations of the SNS and HPA stress axis.

Inflammation

With regard to the second pathway, deposition of UFP in the respiratory tract may lead to pulmonary inflammation (see Section 5.5.1) and to systemic inflammation (see Section 6.5.1), which in turn may lead to inflammation in the brain. Brain inflammation may be due to peripheral immune activation (Fonken et al., 2011) or to systemic circulation of UFP that results in particle uptake in the brain (Ljubimova et al., 2013). Inflammation in the brain may alternatively occur following olfactory transport of poorly soluble particles or their soluble components or to a neuroendocrine stress response resulting from activation of the HPA stress axis (Kodavanti, 2016).

Animal toxicological studies demonstrated neuroinflammation in several brain regions, including olfactory bulb, cerebral cortex, cerebellum, corpus callosum, and hippocampus following short-term UFP exposure (Cheng et al., 2016), (Allen et al., 2014b), (Tyler et al., 2016), (Campbell et al., 2005). Some responses were sex-specific (Allen et al., 2014b). Inflammation, oxidative stress, and apoptotic responses were also observed in nasal epithelium (Cheng et al., 2016). These changes preceded changes measured in olfactory bulb, cerebral cortex, and cerebellum in the same study. Evidence of these time-dependent and region-specific responses indicates that both olfactory transport and systemic inflammation may have played a role in responses to UFP exposure. In addition, paracrine signaling of inflammatory mediators between the nasal epithelium and proximal regions of the brain may have contributed to inflammation. In Tyler et al. (2016), inflammation in the brain occurred in the absence of pulmonary or systemic inflammation, pointing to a direct effect of UFP on the brain. Behavioral effects were found in conjunction with neuroinflammation in one study (Allen et al., 2013).

Summary of Biological Plausibility

As described here, there are two proposed pathways by which short-term exposure to UFP may lead to nervous system effects. The first pathway begins with activation of sensory nerves in the respiratory tract and may lead to triggering of lung reflex responses and modulation of the ANS resulting in increased activity of the SNS and stimulation of the HPA stress axis. In this way, the ANS may mediate systemic responses resulting from UFP exposure. The second proposed pathway begins with pulmonary/systemic inflammation or olfactory transport of UFP and may lead to pro-inflammatory effects in the brain and subsequently to behavioral effects. Animal toxicological and controlled human exposure studies provide the evidence for upstream and downstream events. There are no epidemiologic studies that evaluated the relationship between short-term exposure to UFP and nervous system effects. The proposed pathways will be used to inform a causality determination, which is discussed later in the chapter (Section 8.5.5).

8.5.2 Activation of the Sympathetic Nervous System and the Hypothalamic-Pituitary-Adrenal (HPA) Stress Axis

8.5.2.1 Controlled Human Exposure Study

A controlled human exposure study (Table 8-27) examined the effects of a 130 minute exposure to UFP CAPs on urinary and blood biomarkers associated with neural effects (Liu et al., 2017). An association between exposure to UFP CAPs and an increase in urinary vanillylmandelic acid, a stress-related biomarker, was observed at 1-hour post-exposure ($p < 0.1$). Vanillylmandelic acid is the primary metabolite resulting from the breakdown of the stress hormones epinephrine and norepinephrine. Its presence in urine indicates that exposure to UFP CAPs led to secretion of epinephrine and/or norepinephrine into the blood by the adrenal medulla subsequent to activation of the HPA stress axis.

Table 8-27 Study-specific details from a controlled human exposure study of short-term exposure to UFP and activation of the sympathetic nervous system (SNS) and hypothalamic-pituitary-adrenal (HPA) stress axis.

Study/Study Population	Pollutant	Exposure Details	Endpoints Examined
Liu et al. (2017) Species: Human Health status: Healthy nonsmokers Sex: 29 females, 26 male Age: 18−60 yr	CAPs from Toronto, ON Particle sizes: <0.3 µm	Route: Face mask inhalation Dose/concentration: 135.8 ± 67.2 µg/m^3 Particle number count 227,767 ± 63,902	Urinary and blood markers of neural effects

Study/Study Population	Pollutant	Exposure Details	Endpoints Examined
Study design: Single-blind randomized cross-over trial	Control: HEPA filtered ambient air or HEPA-filtered medical air (ultrafine study)	Duration of exposure: 130 min Time to analysis: 1 and 21 h	

CAPs = concentrated ambient particles; HEPA = high efficiency particulate absorber.

8.5.2.2 Animal Toxicological Study

Allen et al. (2014b) reported changes in neurotransmitters in adult mice exposed for 4 days to UFP CAPs beginning at PND 56 (Table 8-28). Brain tissue was analyzed at 9 months. Neurotransmitters were altered by exposure to CAPs in a sex- and brain region-specific manner. Most notably, exposure resulted in decreased norepinephrine in the hypothalamus of male mice and increased norepinephrine in the midbrain of female mice ($p < 0.05$). Allen et al. (2014b) also examined serum corticosterone levels in male and female mice exposed to UFP CAPS. Blood samples were collected at PND 60 and at about 6 months of age. At both time points, exposure decreased serum corticosterone levels in males ($p < 0.05$), but had no effect in females.

Table 8-28 Study-specific details from an animal toxicological study of short-term exposure to UFP and activation of the sympathetic nervous system (SNS) and hypothalamic-pituitary-adrenal (HPA) stress axis.

Allen et al. (2014b) Species: Mouse Sex: male and female Strain: C57BL/6J Age/Weight: Adult exposure at PND 56-60	CAPs collected in Rochester, NY from a "nearby highly trafficked roadway" using the Harvard University Concentrated Ambient Particle System Particle size: ≤100 nm Control: HEPA-filtered room air	Route: Whole body inhalation Dose/Concentration: 67.9 µg/m^3 Particle number: 180,000−200,000 particles/cm^3 Duration: 4 h/day, 4 days Time to analysis: 9 mo of age for brain tissue analysis PND 60 and 6 mo of age for blood collection	Brain tissue—Region specific levels of monoamines, amino acids Blood—corticosterone

CAPs = concentrated ambient particle; HEPA = high efficiency particulate absorber; PND = postnatal day.

8.5.3 Brain Inflammation and Oxidative Stress

Several animal toxicological studies provide evidence for brain inflammation and oxidative stress following short-term exposure to UFP (Table 8-29). Cheng et al. (2016) examined the effects of exposure to UFP on inflammatory and oxidative stress responses in olfactory epithelium, olfactory bulb, cerebral cortex, and cerebellum. Ambient UFP was collected near a freeway in Los Angeles, CA and re-aerosolized in order to expose C57BL/6J mice for 5, 20, and 45 hours over 3 weeks. Increases in oxidative stress markers, 4-hydroxy-2-nonenal and 3-nitrotyrosine, were seen after 5 hours of exposure in olfactory epithelium ($p < 0.05$), but not in the other regions. The number of IBA−1 positive-macrophages, an indicator of injury or inflammation, increased in olfactory epithelial turbinates and in the olfactory bulb after 5 hours of exposure ($p < 0.05$). Exposure for 45 hours resulted in increased oxidative stress markers, decreased levels of olfactory marker protein (expressed by mature olfactory sensory nerves), and increased levels of cleaved caspase and a related protein, PARP1, in nasal epithelium ($p < 0.05$). Caspase and PARP1 are markers of apoptosis. In olfactory bulb, oxidative stress markers were increased after 45 hours of exposure to UFP ($p < 0.05$). TNFα mRNA was increased after 20 hours and protein levels were increased after 45 hours in the nasal epithelium and olfactory bulb ($p < 0.05$). Exposure for 45 hours resulted in increased TNFα mRNA and protein in cerebral cortex and cerebellum ($p < 0.05$). CD88 mRNA was increased in olfactory bulb, as well as in cerebral cortex and cerebellum, after 20 and 45 hours of exposure ($p < 0.05$). This study demonstrated rapid responses to inhaled UFP in olfactory epithelium, and to a lesser extent, in olfactory bulb. Responses to UFP inhalation in cerebral cortex and cerebellum required longer exposures. This delay suggests a role for systemic inflammation, rather than particle translocation, in mediating the effects of UFP in these brain regions. Decreased olfactory marker protein and increased markers of apoptosis suggest an impact of UFP exposure on olfactory sensory neurons.

In addition, Allen et al. (2014b) reported changes in GFAP and IBA−1 in adult mice exposed for 4 days to UFP CAPs beginning on PND 56. Brain tissue was analyzed at 9 months. Exposure to CAPs resulted in microglial activation, measured as IBA−1 immunoreactivity, in the corpus callosum of the male mice ($p < 0.05$). A trend was observed in astrocyte activation, measured as GFAP immunoreactivity, in the cortex of the male mice. Microglial activation is an indicator of inflammation and astrocyte activation is an indicator of injury. No CAPs-related changes in either GFAP or IBA−1 were observed in the corpus callosum or cortex brain regions of female mice. Furthermore, Tyler et al. (2016) also reported changes in inflammatory markers in C67BL/6 and ApoE knockout mice exposed for 6 hours to UFP that were generated from motor vehicle exhaust. Increased mRNA levels for CCL5, CXCL1, TGF-β, and TNF-α in hippocampus of C67BL/6 mice ($p < 0.05$) and increased mRNA levels for IL−1β, IL−6, TGF-β, and TNF-α in hippocampus of ApoE knockout mice ($p < 0.05$) were observed. Minimal inflammatory effects were seen in BALF in either mouse strain although increased uptake of UFP was seen in bronchial macrophages in ApoE knockout mice (see Section 5.6.3). In contrast, exposure to UFP CAPs from Riverside, CA for 2 weeks did not induce any changes in global gene expression in the brain, or expression of Arc and Rac genes and their protein products, in Fischer 344 rats (Ljubimova et al., 2013).

Table 8-29 Study-specific details from animal toxicological studies of short-term exposure to UFP and brain inflammation and oxidative stress.

ApoE = apolipoprotein E; CAPs = concentrated ambient particles; DEE = diesel engine exhaust; GEE = gasoline engine exhaust; GFAP = glial fibrillary acidic protein; PND = postnatal day; IBA−1 = ionized calcium binding adaptor molecule.

8.5.4 Cognitive and Behavioral Effects

8.5.4.1 Epidemiologic Studies

Wang et al. (2014) examined the association of UFP (2-week average concentration) with depressive symptoms among older adults in the MOBILIZE study and reported findings that did support an effect of UFP on increased CESD-R score ≥ [OR=1.04 (95%CI: 0.68,1.57). Uncharacterized temporal and spatial variation in UPF concentration was an uncertainty in this study because PN concentration was measured using one monitor up to 20 km from the participant's residence.

8.5.4.2 Animal Toxicological Studies

In an animal toxicological study, Allen et al. (2013) investigated behavioral effects of short-term exposure to UFP CAPs (Table 8-30). Adult C57BL/6J mice were exposed for 4 days to UFP CAPs beginning at PND 56. Behavioral testing to evaluate responding for delayed reward was carried out. Exposure to UFP CAPs resulted in changes in mean wait time/fixed ratio completion time ($p < 0.05$), one of the behaviors related to delay of reward. Locomotor activity was evaluated and was not altered by exposure to UFP CAPs. Thus, hyperactivity was unlikely to explain the enhanced bias towards immediate rewards. When mice were exposed both postnatally (Section 8.6.5) and as adults, interactions were found for fixed ratio overall rate, fixed ratio completion time, and fixed ratio resets ($p < 0.05$).

Table 8-30 Study-specific details from animal toxicological studies of short-term UFP exposure and cognitive and behavioral effects.

Study/Study Population	Pollutant	Exposure Details	Endpoints Examined
Allen et al. (2013) Species: Mouse Sex: male and female Strain: C57BL/6J Age/Weight: Adult exposure at PND 56−60	CAPs collected in Rochester, NY from a "nearby highly trafficked roadway" using the Harvard University Concentrated Ambient Particle System Particle size: ≤100 nm Control: HEPA-filtered room air	Route: Whole body inhalation Dose/Concentration: Adult exposure mean 67.9 µg/m^3 Particle number: Mean 180,000−200,000 particles/cm^3 Duration: 4 h/day, 4 days Time to analysis: PND 71	Behavioral tests: • Preference for immediate reward • Learning/memory—novel object recognition • Locomotion

CAPs = concentrated ambient particles; HEPA = high efficiency particulate absorber; PND = postnatal day.

8.5.5 Summary and Causality Determination

The 2009 PM ISA reported limited animal toxicological evidence of a relationship between short-term exposure to UFP and nervous system effects, without supporting epidemiologic studies. Several recent experimental studies add to this evidence base. The evidence for the relationship between short-term exposure to UFP and effects on the nervous system is summarized in Table 8-31, using the framework for causality determination described in the Preamble to the ISAs (U.S. EPA, 2015).

Multi-day exposures of adult mice to UFP resulted in oxidative stress, astrocyte and microglial activation, increased cytokine levels, increased markers of apoptosis, and altered neurotransmitter levels in brain-region specific patterns (Cheng et al., 2016), (Allen et al., 2014b), (Tyler et al., 2016), (Campbell et al., 2005). Cheng et al. (2016) demonstrated the time-dependence of oxidative stress and inflammatory responses, with early changes occurring in nasal epithelium and olfactory bulb and later changes occurring in cerebellum and cerebral cortex. This finding suggests that early effects may be due to UFP translocation from nasal olfactory epithelium to olfactory bulb via olfactory sensory nerves, while later effects in more distal regions of the brain may be due to systemic inflammation. Possibly, the close proximity of the nose to the brain may enhance the ability of inflammatory mediators released by nasal epithelium to reach the brain. In addition, a controlled human exposure study links HPA stress axis activation to short-term exposure to UFP (Liu et al., 2017). Animal toxicological studies found decreases in hypothalamic norepinephrine and serum cortisol in males, but not in females, and effects on behavior related to mediating delay of reward (Allen et al., 2014b).

The strongest evidence for a relationship between short-term UFP exposure and nervous system effects is provided by animal toxicological studies that show inflammation and oxidative stress in multiple brain regions following exposure to UFP. There is a lack of evidence from epidemiologic studies because UFP is not typically measured. In addition, a study in humans found evidence for activation of the HPA stress axis in association with UFP exposure. **Overall, the collective evidence is suggestive of, but not sufficient to infer, a causal relationship between short-term UFP exposure and nervous system effects.**

Table 8-31 Summary of evidence for a suggestive of, but not sufficient to infer, a causal relationship between short-term UFP exposure and nervous system effects.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{2.5}$ Concentrations Associated with Effects[c]
Brain Inflammation and Oxidative Stress			
Evidence from multiple animal toxicological studies	Inflammation observed in several brain regions. Time-dependent changes in inflammatory and oxidative stress markers in one study	Cheng et al. (2016) Allen et al. (2014b) Tyler et al. (2016)	343 µg/m^3 67.9 µg/m^3 371.3 µg/m^3
Activation of the Hypothalamic-Pituitary-Adrenal Stress Axis			
Limited evidence from a controlled human exposure study Inconsistent evidence from an animal toxicological study	Change in level of metabolite of epinephrine/epinephrine in urine indicates HPA stress axis activation Brain region- and sex-dependent changes in norepinephrine; decreases in serum cortisol in males	Liu et al. (2017) Allen et al. (2014b)	135.8 µg/m^3 67.9 µg/m^3
Cognitive and Behavioral Effects			
Limited evidence from an animal toxicological study	Altered behavior related to mediating delay of reward which is not due to hyperactivity	Allen et al. (2013)	67.9 µg/m^3
Overall			
Lack of evidence from epidemiologic studies	Concentration data are not frequently available	Section 3.5

†Studies published since the 2009 PM ISA.

8.6 Long-term UFP Exposure and Nervous System Effects

The previous ISA reported one study involving long-term exposure to UFP. Subchronic exposure of Apo E knockout mice to UFP CAPs resulted in pro-inflammatory changes in the cortical region of the brain, including activation of cell signaling pathways and upregulation of cytokine genes (Kleinman et al.,

2008). Furthermore, magnetite UFP (10−150 nm), likely derived from combustion sources, have recently been found in frontal tissue from brains of humans (Maher et al., 2016). These findings suggest that ambient UFP may reach the brain via olfactory transport; however other routes of translocation have not been ruled out (see Chapter 4).

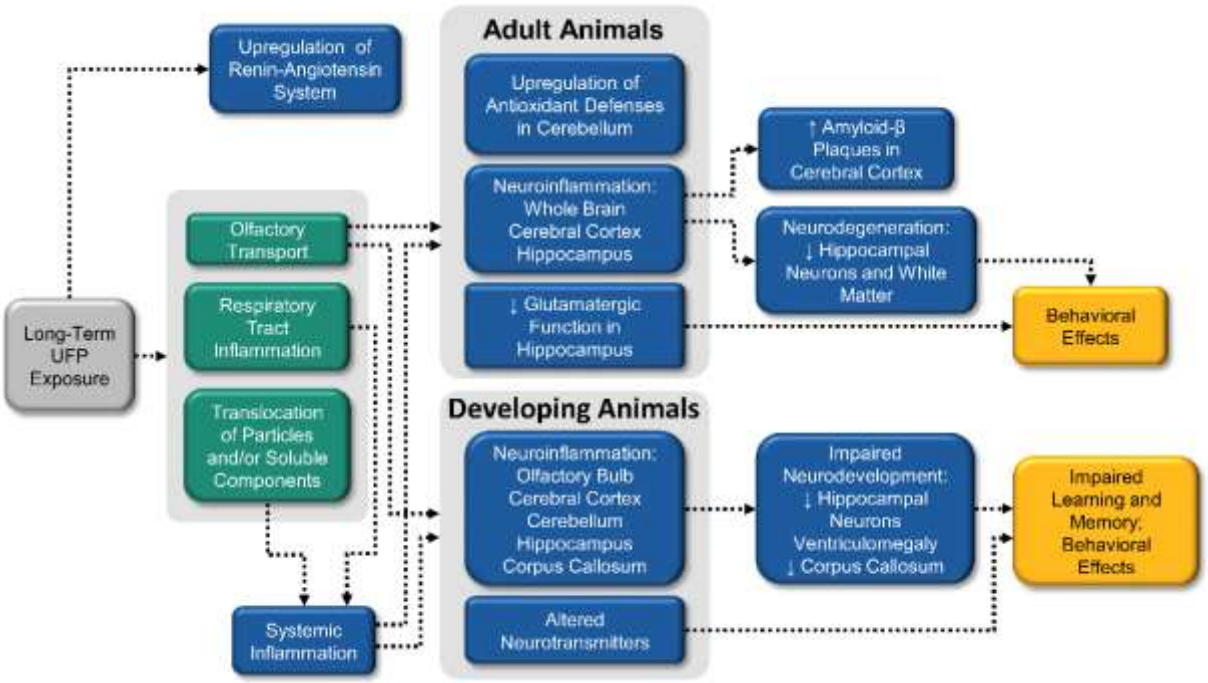
The discussion of long-term UFP exposure and nervous system effects opens with a discussion of biological plausibility (Section 8.1.1) that provides background for the subsequent sections in which groups of related endpoints are presented in the context of relevant disease pathways. These outcome groupings are activation of the SNS and HPA stress axis (Section 8.6.2), brain inflammation and oxidative stress (Section 8.6.3), morphologic changes in the brain (Section 8.6.4), cognitive and behavioral effects (Section 8.6.5) and neurodevelopmental effects (Sections 8.6.6). Finally, the collective body of evidence is integrated across and within scientific disciplines, and the rationale for the causality determination is outlined in Section 8.6.7.

8.6.1 Biological Plausibility

This section describes biological pathways that potentially underlie nervous system effects resulting from long-term exposure to UFP. Figure 8-11 graphically depicts the proposed pathways as a continuum of upstream events, connected by arrows, that may lead to downstream events observed in epidemiologic studies. This discussion of "how" long-term exposure to UFP may lead to nervous system effects contributes to an understanding of the biological plausibility of epidemiologic results evaluated later in Section 8.6.

Once UFP deposits in the respiratory tract, it may be retained, cleared, or solubilized (see Chapter 4). UFP and its soluble components may interact with cells in the respiratory tract, such as epithelial cells, inflammatory cells, and sensory nerve cells. One way in which this may occur is through reduction-oxidative (redox) reactions. As discussed in Section 2.3.3, PM may generate ROS and this capacity is termed "oxidative potential". Furthermore, cells in the respiratory tract may respond to the presence of PM by generating ROS. Further discussion of these redox reactions, which may contribute to oxidative stress, is found in Section 5.1.1 of the 2009 PM ISA (U.S. EPA, 2009). In addition, poorly soluble particles may translocate to the interstitial space beneath the respiratory epithelium and accumulate in the lymph nodes (see Chapter 4). Immune system responses due to the presence of particles in the interstitial space may contribute to health effects. Inflammatory mediators may diffuse from the respiratory tract into the systemic circulation and lead to inflammation in extrapulmonary compartments (Section 6.6.1). UFP and its soluble components may translocate into the systemic circulation and contribute to inflammatory or other processes in extrapulmonary compartments. A fraction of UFP may deposit on the olfactory epithelium. UFP and its soluble components may be transported via the olfactory nerve to the olfactory bulb of the brain. The extent to which translocation into the systemic circulation or

transport to the olfactory bulb occurs is currently uncertain. For further discussion of translocation and olfactory transport, see Chapter 4.



Note: The boxes above represent the effects for which there is experimental or epidemiologic evidence, and the dotted arrows indicate a proposed relationship between those effects. Shading around multiple boxes denotes relationships between groups of upstream and downstream effects. Progression of effects is depicted from left to right and color-coded (gray, exposure; green, initial event; blue, intermediate event; orange, apical event). Here, apical events generally reflect results of epidemiologic studies, which often observe effects at the population level. Epidemiologic evidence may also contribute to upstream boxes. When there are gaps in the evidence, there are complementary gaps in the figure and the accompanying text below.

Figure 8-11 Potential biological pathways for nervous system effects following long-term UFP exposure.

Evidence that long-term exposure to UFP may affect the nervous system generally informs one pathway (Figure 8-11). This pathway begins with pulmonary inflammation and leads to systemic inflammation and to neuroinflammation in both adult and developing animals. Neurodegeneration in adult animals and neurodevelopmental disorders in developing animals may be downstream effects of neuroinflammation and changes in neurotransmitters. Evidence for this pathway is described below.

In addition, there is evidence for two upstream events that support a possible involvement of the RAS and the SNS. Aztatzi-Aguilar et al. (2015) found upregulation of the RAS in the lung and heart in adult animals following long-term exposure to UFP (Section 5.6.3, Section 6.6.4). Allen et al. (2014b)

found increased levels of norepinephrine in the cerebral cortex and decreased levels of serum glucocorticoids in developing animals exposed to UFP postnatally. Given that the changes in RAS were observed in adult animals and the changes in norepinephrine and glucocorticoids were observed in developing animals, the relationship between these events is uncertain.

Inflammation

Deposition of UFP in the respiratory tract may lead to pulmonary inflammation (see Section 5.6.1) and to systemic inflammation (see Section 6.6.1), which in turn may lead to neuroinflammation. Neuroinflammation may be due to peripheral immune activation (Fonken et al., 2011) or to systemic circulation of UFP that results in particle uptake in the brain (Ljubimova et al., 2013). Neuroinflammation may alternatively occur following olfactory transport of poorly soluble particles or their soluble components or to a neuroendocrine stress response resulting from activation of the HPA stress axis (Kodavanti, 2016).

In adult animals, inflammatory responses were seen in whole brain, cerebral cortex, and hippocampus following long-term UFP exposure (Kleinman et al., 2008), (Morgan et al., 2011), (Cacciottolo et al., 2017), and (Tyler et al., 2016). Inflammation was accompanied by upregulation of antioxidant defense enzymes in the cerebellum (Zhang et al., 2012) and decreased markers of glutamatergic function in the hippocampus (Woodward et al., 2017). Neurodegeneration was demonstrated in the hippocampus, as indicated by decreased neurite area and decreased white matter (Woodward et al., 2017) (Cacciottolo et al., 2017). The antioxidant response, the glutamatergic response, and the neurodegeneration response were age-dependent effects that were observed in young adult rodents but not in middle-aged ones. In addition, increased amyloid-β plaques and other markers of Alzheimer's disease were seen in cerebral cortex following exposure to UFP (Cacciottolo et al., 2017). This response was dependent on the presence of several APOE alleles that are known to confer susceptibility to Alzheimer's disease. Neurodegeneration and changes in glutamatergic function occurred in conjunction with behavioral effects in adult mice exposed to UFP (Cacciottolo et al., 2017).

Neuroinflammation was also seen in developing animals exposed to UFP during the postnatal period (Allen et al., 2014a). Brain regions affected included the olfactory bulb, cerebral cortex, cerebellum, and corpus callosum. These changes occurred early after exposure and were persistent, especially in males. Morphologic changes, including ventriculomegaly, reduction in corpus callosum size, and hypomyelination of the corpus callosum were observed, especially in males (Allen et al., 2014a) (Allen et al., 2015). Postnatally-exposed rodents exhibited changes in neurotransmitters that were specific to brain region and sex (Allen et al., 2014a). Impaired learning and memory and behavioral effects were observed in developing mice exposed to UFP postnatally (Allen et al., 2014b), (Allen et al., 2013) and prenatally (Davis et al., 2013). Alterations in morphology and neurotransmitters may contribute to the observed changes in learning, memory, and behavior.

Summary of Biological Plausibility

There is one proposed pathway by which long-term UFP exposure may lead to nervous system effects. It begins with pulmonary inflammation/systemic inflammation or olfactory transport of UFP and leads to neuroinflammation. In adult animals, neuroinflammation may lead to neurodegeneration and the development of Alzheimer's disease, as well as to behavioral effects. In developing animals, neuroinflammation may lead to altered neurodevelopment and neurotransmitters. Both may contribute to impaired learning and memory and to behavioral effects. Animal toxicological and controlled human exposure studies provide the evidence for the upstream and downstream events, and there are no epidemiologic studies that evaluated the relationship between long-term UFP exposure and nervous system effects. This pathway will be used to inform a causality determination, which is discussed later in the chapter (Section 8.6.7).

8.6.2 Activation of the Sympathetic Nervous System and the Hypothalamic-Pituitary-Adrenal (HPA) Stress Axis

In an animal toxicological study, Allen et al. (2014a) investigated changes in neurotransmitters in the brains of weanling mouse pups exposed postnatally to UFP CAPs (Table 8-32). Sex-specific alterations in neurotransmitter levels were observed. In males, glutamate was increased in the hippocampus at PND 14 and 55, dopamine turnover was increased in the midbrain and cortex at PND 14 and 55, and norepinephrine was increased in the cortex at PND 55 ($p < 0.05$). In females, gamma-aminobutyric acid was reduced in the hippocampus, homovanillic acid and dopamine were increased in the midbrain, and serotonin was increased in the hippocampus at PND 14 and 55 ($p < 0.05$). In addition, norepinephrine was increased in the cortex at PND 55 ($p < 0.05$); dopamine turnover was increased in the hippocampus and reduced in the midbrain at PND 14 ($p < 0.05$).

Table 8-32 Study-specific details from an animal toxicological study of long-term exposure to UFP and activation of the sympathetic nervous system (SNS) and hypothalamic-pituitary-adrenal (HPA) stress axis.

Study/Study Population	Pollutant	Exposure Details	Endpoints Examined
Allen et al. (2014a) Species: Mouse Sex: male and female Strain: C57BL/6J Age/Weight: weanling Postnatal exposure at PND 4−7, 10−13	CAPs collected in Rochester, NY from a "nearby highly trafficked roadway" using the Harvard University Concentrated Ambient Particle System Particle size: ≤200 nm Control: HEPA-filtered room air	Route: Whole body inhalation Dose/Concentration: Prenatal exposure mean 96.4 µg/m^3 Particle number: 200,000 particles/cm^3 Duration: 4 h/day, 4 days/week Time to analysis: 24 h (PND 14) and 40 days (PND 55) after postnatal exposure or PND 270	Brain tissue—Region-specific neurotransmitter (HPLC) levels

CAPs = concentrated ambient particles; HEPA = high efficiency particulate absorber; HPLC = high performance liquid chromatograph; PND = postnatal day.

8.6.3 Brain Inflammation and Oxidative Stress

Several animal toxicological studies examined inflammatory and oxidative responses in the brains of C67BL/6J mice exposed to re-aerosolized UFP collected near a freeway in Los Angeles, CA. (Table 8-33). Morgan et al. (2011) exposed young mice (3 months) for 10 weeks and examined inflammatory responses in the cerebral cortex and the hippocampus. In the cerebral cortex, increases in mRNA of the innate immune receptor CD14 were observed in addition to increases in mRNA of the microglial marker CD68 and the astrocyte marker GFAP ($p < 0.05$). In the hippocampus, IL−1α and TNFα mRNA were increased ($p < 0.05$). Decreases in protein levels of GluA1, a glutamate receptor, were observed ($p < 0.05$), although levels of GluA2, synaptophysin, and PSD−95 were unchanged in the hippocampus. These findings indicate changes in glutamatergic functions, in addition to microglial and astrocyte activation and increased markers of inflammation.

Similarly, effects of 10-weeks exposure to UFP were studied in both young (3 months) and middle-aged (18 months) C67BL/6J mice (Woodward et al., 2017) (Zhang et al., 2012). In Cacciottolo et al. (2017), microglial activation was assessed by IBA−1 immunostaining and found to be increased in young mice, but not middle-aged mice. These changes were seen in CA1 stratum oriens and DG polymorphic layer areas of the hippocampus ($p < 0.05$) but not in the CA1 stratum radiatum, DG molecular layer, corpus callosum, and alveus. Exposure to UFP decreased by 50% the level of

glutamatergic receptor protein subunit GluA1 and increased by 10−fold TNFα mRNA in the hippocampus of young mice ($p < 0.05$). Other glutamatergic protein subunits were unaffected in young mice. Exposure to UFP had no effect on these parameters in middle-aged mice. However, age alone had an effect, with GluA1 levels decreased by 50% in middle-aged mice compared to young mice ($p < 0.05$). In Zhang et al. (2012), increases in GCLC and GCLM mRNA, as well as protein levels, were found in the cerebellum of young mice (3 months) similarly exposed ($p < 0.05$). Increases in mRNA for NAPDH quinone oxidoreductase and heme oxygenase 1 were also observed ($p < 0.05$). These Phase II regulated detoxifying enzymes are important in defense against oxidative stress. In middle-aged mice (18 months), UFP exposure resulted only in an increase in GCLM mRNA ($p < 0.05$).

Furthermore, Tyler et al. (2016) reported changes in markers related to inflammation in C57BL/6 and ApoE knockout mice exposed to UFP that was generated from motor vehicle exhaust. A 30-day exposure resulted in an increase in mRNA for CCL5 in the hippocampus of C57BL/6 mice and an increase in mRNA for CXCL1, IL−6, and TGF-β in the hippocampus of ApoE knockout mice. Minimal inflammatory effects were seen in BALF, although increased uptake of UFP was seen in bronchial macrophages (see Section 5.6.3). In contrast, exposure to UFP CAPs from Riverside, CA for 2 weeks did not induce any changes in global gene expression in the brain, or expression of Arc and Rac genes and their protein products, in Fischer 344 rats (Ljubimova et al., 2013).

Table 8-33 Study-specific details from animal toxicological studies of long-term exposure to UFP and brain inflammation and oxidative stress.

Study/Study Population	Pollutant	Exposure Details	Endpoints Examined
Ljubimova et al. 8.6.4 Morphologic Changes

2 Animal toxicological studies investigated morphologic changes in the brain following long-term
3 UFP exposure (Table 8-34). Effects of a 10-week exposure to UFP collected from a Los Angeles freeway
4 on brain morphology were evaluated in both young (3 months) and middle-aged (18 months) C67BL/6J
5 mice (Cacciottolo et al., 2017). Exposure to UFP decreased neurite area in specific hippocampal regions
6 of young mice (i.e., the stratum oriens and stratum radiatum CA1 regions but not the DG or CA3 regions,
7 $p < 0.05$). No changes in neurite area were seen in the forceps major of the corpus callosum or

hippocampal alveus in young mice or in any of the examined areas in middle-aged mice as a result of UFP exposure. Changes in white matter were assessed by staining for myelin basic protein. Middle-aged mice had decreased myelin basic protein in specific hippocampal regions, (i.e., CA1 stratum oriens and DG polymorphic layer compared with young mice, $p < 0.05$). Exposure to UFP resulted in changes in myelin basic protein in the hippocampal stratum oriens of young mice ($p < 0.05$). No UFP exposure-related changes were seen in middle-aged mice. However, age alone had an effect, with myelin basic protein decreased by 50% in the CA1 striatum oriens and 45% in the DG polymorph layer of the hippocampus of middle-aged mice compared with young mice ($p < 0.05$).

Using the same exposure system, Cacciottolo et al. (2017) examined the effect of UFP exposure and the presence of APOE alleles on the development of pathology related to Alzheimer's disease in mice. In wild type mice, 10-weeks inhalation of UFP resulted in decreased neurite density in the hippocampus at 7 months of age. This involved selective loss of hippocampal CA1 neurons ($p < 0.005$) but not DG neurons. In addition, the density of GluR1 receptor subunits, but not other synaptic proteins involved in hippocampal-based memory, was decreased in the hippocampus of wild type mice ($p < 0.005$). In mice carrying transgenes for human APOE ϵ3 or ϵ4 alleles in combination with five familial AD mutations (EFAD mice), similar changes were observed at 7 months of age following 15-weeks inhalation of UFP ($p < 0.01$). These changes were not dependent on the number of alleles (E3FAD vs E4FAD). However, exposure to UFP resulted in increases in amyloid deposits in the cerebral cortex of E4FAD mice but not E3FAD mice ($p < 0.05$). Similarly, amyloid-β oligomers in soluble extracts of cerebral cortex were increased in E4FAD mice but not E3FAD mice ($p < 0.05$). APOE alleles are known to confer susceptibility to Alzheimer's disease which is characterized by the accumulation of amyloidβ and cognitive effects. APOE ϵ4 confers greater susceptibility to women than men. While EFAD mice are known to accumulate amyloid aggregates at an early age, wild type C67Bl/6J do not develop amyloid aggregates at any age.

8.6.5 Cognitive and Behavioral Effects

An animal toxicological study investigated cognitive and behavioral effects following long-term UFP exposure (Table 8-35). Effects of a 10-week exposure to UFP collected from a Los Angeles freeway were studied in both young (3 months) and middle-aged (18 months) C67BL/6J mice (Cacciottolo et al., 2017). There were no age- or UFP exposure-related changes in short- or long-term memory, as assessed by the novel object recognition test, or in working memory, as assessed by the spontaneous alternation of behavior test. However, UFP exposure decreased exploratory behavior by 30% ($p < 0.01$) in middle-aged mice and activity in both age groups ($p < 0.05$). Middle aged mice also responded to UFP exposure with weight loss ($p < 0.05$) that was reversible upon cessation of exposure and that correlated with changes in locomotor activity ($p < 0.05$).

HEPA = high efficiency particulate absorber.

8.6.6 Neurodevelopmental Effects

8.6.6.1 Epidemiologic Studies

Sunyer et al. (2015) enrolled students (n = 2,715, 7−10 years old) from 39 schools in Barcelona, Spain in order to study the relationship between cognitive development and traffic related pollutants including UFP (Table 8-36). Schools were selected from high and low pollution areas and matched by school socioeconomic index. The study was longitudinal in design with repeated cognitive testing during an approximately one-year period. The outcomes, validated tests of working memory and attention, were selected because they measure cognitive functions that are typically under development during the lifestages of the children participating (i.e., 7−10 years old). Authors reported a 12 month decrease in both working [−4.9 (95% CI: −10, 0.22) per IQR increase in UFP] and superior working memory [−5 (95% CI: −9.1, −0.96) per IQR Increase in UFP]. A 12 month increase in inattentiveness was also reported [3.9 (0.31, 7.6) per IQR increase in UFP].

8.6.6.2 Animal Toxicological Studies

Several animal toxicological studies examined the effects of long-term UFP exposure on neurodevelopment (Table 8-37). Davis et al. (2013) measured markers of glutamate receptors, neuronal growth cones, synaptic proteins, kinases, and glial proteins in the hippocampus of young C57BL/6J mice exposed prenatally to UFP collected from a Los Angeles freeway. Dams were exposed to UFP prior to conception, mated with unexposed males, and then exposed to UFP during gestation. Thus, exposure occurred throughout oocyte maturation and gestation. Prenatal exposure to UFP resulted in a decrease in protein levels of JNK1, a protein kinase, in the hippocampus of neonatal offspring ($p \leq 0.05$). Many markers of inflammation and other processes were unchanged. Davis et al. (2013) also investigated internalizing disorders using specific behavioral testing in the offspring. Male offspring exhibited behavioral sequelae, with decreased latency to immobility and increased duration of immobility in the tail-suspension test ($p < 0.05$), a test of propensity for mental health impairment or depression and low resilience to stress; females were refractory to change with these endpoints. Female and male offspring did not display changes in tests of anxiety. Prenatal UFP exposure was associated with changes in internalizing behavior of depression but not anxiety in male offspring; internalizing behavior of female offspring was not affected by prenatal UFP exposure.

Allen et al. (2015); Allen et al. (2014a) investigated the effects of exposure to UFP CAPs in weanling mouse pups during PND 4−7 and PND 10−13. This post-gestational time period, which is considered equivalent to the third trimester in humans, is marked by rapid neuro- and gliogenesis. Mice were sacrificed at PNDs 14, 55, and 270. UFP CAPs exposure altered GFAP immunostaining, an indicator of astrocyte activation, in a sex-specific manner. GFAP immunostaining was reduced in the hippocampus of male mice at PND 14 and in the corpus callosum of male mice at PND 14 and PND 55 ($p < 0.05$). However, GFAP was increased at PND 14 in the amygdala ($p \leq 0.05$). In females, GFAP immunostaining increased in hippocampus, corpus callosum, and anterior commissure on PND 14 ($p < 0.05$), but not on PND 55. UFP CAPs exposure also altered IBA−1 immunostaining, an indicator of glial activation, in a sex-specific manner. In males, IBA−1 immunostaining was increased in the anterior commissure at PND 14 and PND 55, in the hippocampus at PND 55, and in the corpus callosum at PND 270 ($p < 0.05$). No changes were seen in females. Findings of early (astrocyte and microglial) and persistent (microglial) activation, especially in males, suggest that astrocyte and microglial activation may be important mediators of responses to UFP CAPs exposure.

Allen et al. (2014a) and Allen et al. (2015) also examined morphologic changes in the brains of these weanling mouse pups exposed postnatally to UFP CAPs. Ventriculomegaly was observed in PND 14 male ($p \leq 0.05$), but not female mice. This effect in male mice persisted in young adulthood (PND 55) and at PND 270 ($p \leq 0.05$). Ventriculomegaly is related to poor neurodevelopmental outcomes in children, which tend to be higher in males. In addition, exposure to UFP CAPs resulted in a reduction in

the size of the corpus callosum in both sexes at PND 14 ($p \leq 0.05$) and a male-specific decrease in myelination in the corpus callosum at PND 14 ($p \leq 0.05$). Striatal and frontal cortex myelination was unaffected by exposure to UFP CAPs in either sex. Findings of ventriculomegaly, reductions in corpus callosum size, and hypomyelination, especially in males, are consistent with morphologic changes associated with neurodevelopmental disorders such as ASD in humans.

Allen et al. (2013) and Allen et al. (2014b) investigated behavioral effects in male and female mice exposed to UFP CAPs, as described above. Behavioral testing was carried out on PND 71 and animals were sacrificed one month later. Some mice were exposed a second time to UFP CAPs beginning at PND 56 for 4 days. In the first study, Allen et al. (2013) found that postnatal exposure to UFP CAPs resulted in enhanced preference for immediate reward. This was evidenced by changes in fixed ratio overall rate, run rate, inter-response time, fixed ratio resets, and responses per reinforcer ($p < 0.05$). Additionally, interactions were found for fixed ratio overall rate, fixed ratio completion time, and fixed ratio resets ($p < 0.05$) in mice that were exposed both postnatally and as adults. Locomotor activity was evaluated and found to not be altered by exposure to UFP CAPs, indicating that hyperactivity was unlikely to explain the behavioral alterations. In the second study, Allen et al. (2014b) measured initial fixed interval schedule controlled behavior, which is related to preference for immediate reward, and a measure of impulsivity. Novel object recognition, which is an indicator of learning and short-term memory, and locomotor activity were also determined. Postnatal exposure to UFP CAPs resulted in greater impulsivity-linked behavior. In males, postnatal exposure resulted in decreases in overall rate and run rate ($p < 0.05$) while in females, adult exposure resulted in increases in overall rate and run rate ($p < 0.05$). Indices of novel object recognition were decreased by postnatal UFP CAPs exposure in male (change in time with novel object) and female (change in time/approaches to novel object) mice ($p < 0.05$). Interactions resulting from exposure during both the postnatal and adult lifestage were noted for both sets of behavioral tests. Spontaneous locomotor behavior was impaired in both males and females as a result of exposure to UFP CAPs during both lifestages ($p < 0.05$). Furthermore, levels of serum corticosterone and some brain region-specific neurotransmitters were correlated with measures of impulsivity-linked behavior in male mice exposed during the postnatal period and in female mice exposed as adults ($p < 0.05$).

Altogether, these results indicate that prenatal and postnatal exposure to UFP CAPs led to neurotoxic changes which persisted over time. These effects included neuroinflammation, morphologic changes, and behavioral effects.

8.6.7 Summary and Causality Determination

The 2009 PM ISA reported limited animal toxicological evidence of a relationship between long-term exposure to UFP and nervous system effects, without supporting epidemiologic studies. Recent animal toxicological studies substantially add to this evidence base by demonstrating neuroinflammation, Alzheimer's disease-related pathology, neurodegeneration, and altered neurodevelopment. Recent epidemiologic studies are very limited in number. The evidence for the relationship between long-term exposure to UFP and effects on the nervous system is summarized in Table 8-38, using the framework for causality determination described in the Preamble to the ISAs (U.S. EPA, 2015).

Studies of long-term exposure of adult mice to UFP from traffic-dominated sources provide evidence of inflammation and oxidative stress in the whole brain, hippocampus, and cerebral cortex (Cacciottolo et al., 2017; Tyler et al., 2016; Zhang et al., 2012; Morgan et al., 2011; Kleinman et al., 2008). Astrocyte activation and altered glutamatergic functions were also seen in these studies. Neurodegeneration, as indicated by decreased neurite density and white matter, occurred in specific regions of the hippocampus in UFP exposed mice (Cacciottolo et al., 2017). Many responses, including neurodegeneration, were greater in young compared with middle-aged mice. However, one of the measured behavioral effects was altered to a greater degree by UFP exposure in middle-aged mice compared with young mice (Cacciottolo et al., 2017). Pathologic changes characteristic of Alzheimer's disease (i.e., amyloid deposits and amyloid-β oligomers in the cortex) were seen in a mouse model of Alzheimer's disease, but not in wild type mice following exposure to UFP (Cacciottolo et al., 2017).

Prenatal exposure to UFP resulted in altered behavioral indices in adult male, but not female, mice (Davis et al., 2013). Postnatal exposure to UFP CAPs led to developmental neurotoxicity in a group of studies from the same laboratory (Allen et al., 2015; Allen et al., 2014b; Allen et al., 2014a; Allen et al., 2013). Activation of microglia and astrocytes, indicative of inflammation and injury, respectively, was observed along with alterations in brain morphology and neurotransmitters, and changes in serum corticosterone and behavior. Some effects were sex-specific, notably the persistent ventriculomegaly found in male mice (Allen et al., 2015; Allen et al., 2014a). Long-term exposure to UFP was associated with effects on cognitive development in children (Sunyer et al., 2015). However, uncertainties remain as a result of inadequate assessment of potential copollutant confounding, the spatial variation in UFP concentrations, and exposure measurement error.

The strongest evidence is provided by animal toxicological studies showing inflammation, oxidative stress, and neurodegeneration in adult mice and Alzheimer's disease pathology in a susceptible animal model. In addition, pre- and early postnatal exposure to UFP results in behavioral effects, inflammation, and persistent morphologic changes. Epidemiologic studies of UFP were lacking. **Overall, the collective evidence is sufficient to conclude that a causal relationship is likely to exist between long-term UFP exposure and nervous system effects.**

Table 8-38 Summary of evidence for a likely to be causal relationship between long-term UFP exposure and nervous system effects.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{2.5}$ Concentrations Associated with Effects[c]
Brain Inflammation and Oxidative Stress			
Consistent evidence from multiple toxicological studies	Evidence of inflammation in whole brain, cerebral cortex, and hippocampus; evidence of oxidative stress in cerebellum	(Kleinman et al., 2008) †(Morgan et al., 2011) †(Cacciottolo et al., 2017) †(Tyler et al., 2016) †(Zhang et al., 2012)	114.2 µg/m^3 468 µg/m^3 342 49 µg/m^3 371.3 µg/m^3 200−400 µg/m^3
Activation of the Sympathetic Nervous System			
Inconclusive evidence	Changes in norepinephrine in cortex but levels in hypothalamus were not determined	†(Allen et al., 2014a)	96.4 µg/m^3

Table 8-38 (Continued): Summary of evidence for a likely to be causal relationship between long-term exposure to ultrafine particulate and nervous system effects.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{2.5}$ Concentrations Associated with Effects[c]
Morphologic Changes

CHAPTER 9 REPRODUCTIVE AND DEVELOPMENTAL EFFECTS

Summary of Causality Determinations for Particulate Matter (PM) Exposure and Male and Female Reproduction and Fertility, and Pregnancy and Birth Outcomes

This chapter characterizes the scientific evidence that supports causality determinations for short- and long-term PM exposure and reproductive and developmental outcomes. The types of studies evaluated within this chapter are consistent with the overall scope of the ISA as detailed in the Preface (Section P 3.1). In assessing the overall evidence, strengths and limitations of individual studies were evaluated based on scientific considerations detailed in the Appendix. The evidence presented throughout this chapter support the following causal conclusions. More details on the causal framework used to reach these conclusions are included in the Preamble to the ISA (U.S. EPA, 2015).

Size Fraction	Causality Determination
Male and Female Reproduction and Fertility	
$PM_{2.5}$	Suggestive of, but not sufficient to infer
$PM_{10-2.5}$	Inadequate to infer
UFP	Inadequate to infer
Pregnancy and Birth Outcomes	
$PM_{2.5}$	Suggestive of, but not sufficient to infer
$PM_{10-2.5}$	Inadequate to infer
UFP	Inadequate to infer

This chapter evaluates the scientific evidence related to the potential effects of PM ($PM_{2.5}$, $PM_{10-2.5}$, and ultrafine particles [UFP]) on reproductive and developmental outcomes in three sections including (1) Male and Female Reproduction and Fertility; (2) Pregnancy and Birth Outcomes; and (3) Developmental Effects. The body of literature characterizing reproductive and developmental effects associated with exposure to PM is large and has grown considerably since the 2009 PM ISA (U.S. EPA, 2009). Well-designed studies with consideration of potential confounding and other sources of bias are emphasized in this section (see APPENDIX 1 for study evaluation guidelines). In order to evaluate and characterize the evidence for the effects of PM on reproductive and developmental effects in a consistent, cohesive and integrated manner, results from both short-term and long-term exposure periods are included in a single section and are identified accordingly in the text and tables throughout this section. Because

the length of gestation in rodents is 18−24 days, on average, animal toxicological studies investigating the effects of PM generally are short-term exposure periods. For comparison, an epidemiologic study that uses the entire pregnancy as the exposure period is considered to have a long-term exposure period (about 40 weeks, on average). A major issue in studying environmental exposures and reproductive and developmental effects (including infant mortality) is selecting the relevant exposure period, since the biological plausibility leading to these outcomes and the critical periods of exposure are not completely understood. Thus, multiple exposure periods are evaluated in many epidemiologic studies, including long-term (months to years) exposure periods, such as entire pregnancy, individual trimesters or months of pregnancy, and short-term (days to weeks) exposure periods such as the days and weeks immediately preceding birth. Thus, the biological plausibility for the effects of PM on reproductive and developmental outcomes will combine short-term and long-term exposures in each particle size class ($PM_{2.5}$, UFP, and coarse PM). Further, infants and fetal development processes may be particularly sensitive to PM exposure, and although the physical mechanisms are not always fully understood the impacts from PM exposure at these critical windows of development may have permanent, lifelong effects.

Separate causality determinations are made for the two sections Male and Female Fertility and Reproduction; Pregnancy and Birth Outcomes. For developmental effects, summaries are included in this section of the ISA and full descriptions as well as causality determinations are found in the specific health endpoint (respiratory, cardiovascular, metabolic and neurological disease) section.

9.1 $PM_{2.5}$ Exposure and Reproductive and Developmental Effects

The body of literature characterizing male and female reproduction and fertility with $PM_{2.5}$ exposure is large and has grown considerably since the 2009 PM ISA (U.S. EPA, 2009). The evidence from the 2009 PM ISA determined that there was a suggestive causal relationship between long-term $PM_{2.5}$ exposure and reproductive and developmental outcomes. Effects of $PM_{2.5}$ exposure on sperm have been studied in both the animal toxicology and the epidemiologic literature. The strongest effects in the epidemiologic literature come from studies on sperm motility with $PM_{2.5}$ associated with impaired motility. The toxicological literature also has $PM_{2.5}$-dependent effects on sperm including impaired spermatogenesis and spermiation. Other studies from epidemiologic literature on sperm morphology have inconsistent results. Studies of female reproduction in association with $PM_{2.5}$ exposure cover estrus, ovulation, reproduction, and fertility. In rodents, ovulation and estrus are affected by $PM_{2.5}$ exposure. In the epidemiologic literature, results on human fertility and fecundity in association with $PM_{2.5}$ exposure is limited, but evidence from IVF shows a modest association of $PM_{2.5}$ concentrations with decreased odds of becoming pregnant. The toxicological evidence provides biological plausibility to these outcomes and shows multiple sensitive windows for PM exposure's effects. In the pregnancy and birth outcomes section of this document, studies on fetal growth, birth weight, preterm birth and preterm rupture of membranes show positive associations with $PM_{2.5}$ exposure in some animal toxicology and epidemiologic studies.

The toxicological evidence gives biological plausibility to these outcomes and shows multiple sensitive windows for PM exposure's effect on pre-term birth and low birth weight. Multiple epidemiologic and toxicological studies of birth defects show that PM is associated with cardiovascular birth defects, albeit of different types. The studies of fetal growth, birth weight, and infant mortality, increased in number in this ISA but generally continue to lack controls for confounding by other air pollutants, and show sensitivity to PM exposure across multiple trimesters of the pregnancy. Studies on sperm had mixed effects with epidemiologic studies of sperm focused on motility and toxicological studies focused on spermatogenesis. Studies of fertility in females showed effects on estrus in animal toxicology studies. Pregnancy outcomes showed mixed effects with $PM_{2.5}$ exposure and gestational diabetes, but when analyzed by trimester, the 2nd trimester showed the strongest effects, especially with gestational diabetes. In animal toxicological studies, the structure and vascularization of the placenta and umbilical cord were affected by $PM_{2.5}$ exposure. Developmental outcomes included cardiovascular, respiratory, and neurological outcomes like autism and are covered in more detail in those respective sections. More detailed information on male and female reproduction and fertility, pregnancy and birth outcomes, and developmental effects follows below.

9.1.1 Male and Female Reproduction and Fertility

9.1.1.1 Biological Plausibility

This section describes biological pathways that potentially underlie reproductive and developmental health effects specific to male and female reproduction and fertility resulting from exposure to $PM_{2.5}$. Figure 9-1 graphically depicts the proposed pathways as a continuum of upstream events, connected by arrows, that may lead to downstream events observed in epidemiologic studies. This discussion of "how" exposure to $PM_{2.5}$ may lead to effects on Reproduction and Fertility contributes to an understanding of the biological plausibility of epidemiologic results evaluated later in Section 9.1.

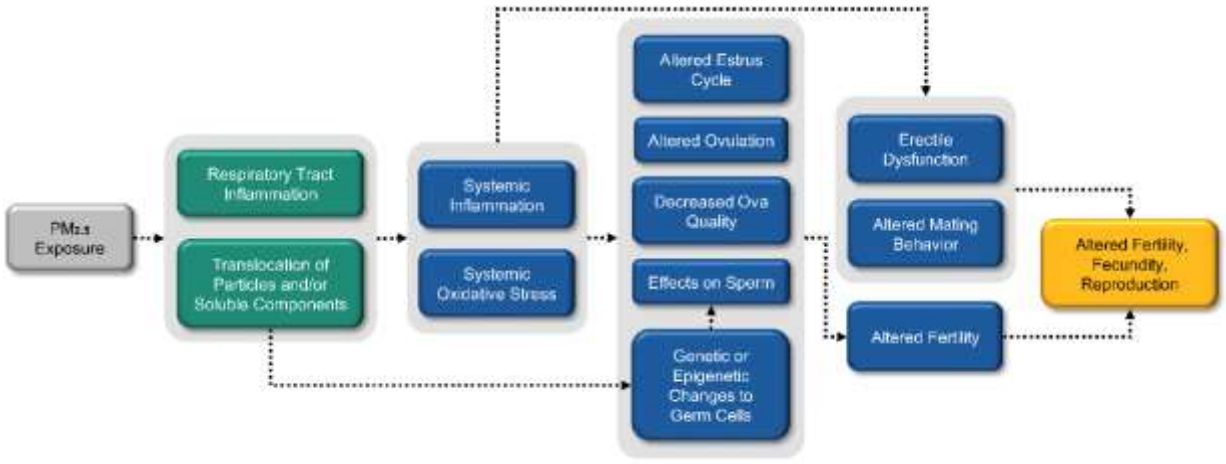

Figure 9-1 Potential biological pathways for male and female reproduction and fertility effects following $PM_{2.5}$ exposure

[a] Note: The boxes above represent the effects for which there is experimental or epidemiologic evidence, and the dotted arrows indicate a proposed relationship between those effects. Shading around multiple boxes denotes relationships between groups of upstream and downstream effects. Progression of effects is depicted from left to right and color coded (grey, exposure; green, initial event; blue, intermediate event; orange, apical event). Here, apical events generally reflect results of epidemiologic studies, which often observe effects at the population level. Epidemiologic evidence may also contribute to upstream boxes. When there are gaps in the evidence, there are complementary gaps in the figure and the accompanying text below.

When considering the available health evidence, there are plausible pathways connecting inhalation of $PM_{2.5}$ to the apical reproductive and developmental events reported in epidemiologic studies (Figure 9-1). The biological plausibility for $PM_{2.5}$-induced effects on reproduction and fertility is supported by evidence from the 2009 PM ISA (U.S. EPA, 2009) and by new evidence. Once these pathways are initiated, there is evidence from experimental and epidemiologic studies that $PM_{2.5}$ inhalation may result in a series of physiological responses that could lead to male and female reproductive effects and altered fertility (e.g., fertility, fecundity, reproduction). The evidence for the initial events (Figure 9-1) that could result in inhalation of $PM_{2.5}$ having on effects fertility and reproduction includes translocation of particles less than 200 nm and/or their soluble components (Chapter 4); and respiratory tract inflammation (Chapter 6). Inhalation of $PM_{2.5}$ can result in translocation of particles or soluble factors from the lungs (see Chapter 5) which then can increase respiratory tract inflammation, which can be followed by systemic inflammation, e.g., C-reactive protein (CRP, see Chapter 5), even increasing CRP during pregnancy (Lee et al., 2011b). Soluble components of $PM_{2.5}$, and poorly soluble particles that are part of the $PM_{2.5}$ fraction and smaller than approximately 200 nm, may translocate into the systemic circulation and contribute to inflammatory or other processes in extrapulmonary compartments. Beyond these events, there is also evidence from experimental and epidemiologic studies demonstrating that exposure to $PM_{2.5}$ could result in a coherent series of physiological responses that provide biological plausibility for the associations reported in epidemiologic

and laboratory animal studies including altered fertility, fecundity and reproduction (Veras et al., 2009), (Legro et al., 2010), (Slama et al., 2013).

As depicted in Figure 9-1, these initial events can give rise to intermediate events including systemic inflammation from epidemiologic evidence of increased CRP during pregnancy (Lee et al., 2011b), animal studies of altered estrous cycle (Veras et al., 2009), altered ovulation (Veras et al., 2009), or decreased ova quality (Veras et al., 2009), erectile dysfunction in epidemiologic studies (Tallon et al., 2017) genetic and epigenetic changes to sperm and other effects on sperm in epidemiologic studies(Hammoud et al., 2009), (Radwan et al., 2015), (Hansen et al., 2010), and laboratory animal studies(Pires et al., 2011).

Laboratory animals provide the biological plausibility for effects on female reproduction with $PM_{2.5}$ inhalation. Briefly, inhalation of $PM_{2.5}$ affects the female and altered estrous cyclicity, ova quality and ovulation. After inhalation of $PM_{2.5,}$ there is elongation of the estrous cycle in female rodents that had been exposed to $PM_{2.5}$ for two generations (Veras et al., 2009), which reduced the total number of estrous cycles over a set time period (Veras et al., 2009). In laboratory animals the inhalation of $PM_{2.5}$ also decreased numbers of ovarian follicles at the antral stage with fewer follicles reaching this terminal stage just before ovulation in 2nd generation offspring (Veras et al., 2009). Also, ova quality is decreased (Veras et al., 2009).

Then there are intermediate effects on sperm after $PM_{2.5}$ inhalation, decreasing sperm quality (Hammoud et al., 2009) or motility(Radwan et al., 2015) in epidemiologic studies, or in rodents decreasing the number of sperm (Pires et al., 2011), affecting spermiation (Pires et al., 2011) or induction of genetic and epigenetic changes to sperm of rodents exposed to $PM_{2.5}$ (Yauk et al., 2008). Sertoli cells, which are important for the process of spermatogenesis, are decreased in laboratory animals after prenatal $PM_{2.5}$ exposure (Pires et al., 2011) and testicular weight and volume are decreased with prenatal $PM_{2.5}$ exposure (Pires et al., 2011). Epidemiologic studies show $PM_{2.5}$ exposure is associated with erectile dysfunction (Tallon et al., 2017).

In laboratory animal studies, parental (male and female) inhalation of $PM_{2.5}$ altered fertility and altered fecundity in the 1st (F1) and 2nd generation (F2) offspring after continuous inhalation of $PM_{2.5}$ from preconception (Veras et al., 2009). Inhalation of $PM_{2.5}$ by laboratory animals resulted in increased time required for a successful mating and fertility and pregnancy indices were significantly changed due to $PM_{2.5}$ inhalation (Veras et al., 2009). In these same animals with inhalation of $PM_{2.5,}$ there was a significant increase in rate of the post-implantation loss in G1 and G2 animals (Veras et al., 2009). In epidemiologic studies, increased $PM_{2.5}$ exposure in the month prior to conception was associated with reduced fecundability (Slama et al., 2013) and increased $PM_{2.5}$ during ovulation induction was associated with decreased odds of achieving pregnancy by IVF (Legro et al., 2010). Together, these mechanisms provide plausible pathways by which inhalation of $PM_{2.5}$ could progress from the initial events noted above to altered fertility, fecundity, and reproduction. A schematic characterizing the biological plausibility of $PM_{2.5}$ on reproduction and fertility is shown in Figure 9-1.

$PM_{2.5}$ inhalation could lead to reproductive and developmental health effects on male reproduction, female reproduction or fertility following multiple pathways. Pathways leading to effects in female fertility could begin with particle translocation or solubility of particle contents and inflammation, and oxidative stress that may lead to changes along the female reproduction pathway that impact estrus, ova quality, and ovarian follicle formation. Male reproductive outcomes affected by $PM_{2.5}$ exposure and translocation or solubilization of particle contents can involve inflammation or oxidative stress as well as genetic and epigenetic changes that can contribute to impacts on male reproduction including effects on sperm in laboratory animals and epidemiologic studies and erectile dysfunction in humans. Effects on fertility can begin with the initial particle translocation and solubility, oxidative stress and inflammation, with effects on overall fertility including an increase in rate of the post-implantation loss in laboratory animals as well as epidemiologic evidence of reduced fecundability and decreased odds of achieving pregnancy. While experimental studies involving animals contribute most of the evidence of upstream effects, epidemiologic studies found associations between $PM_{2.5}$ exposure and various outcomes. Together, these proposed pathways provide biological plausibility for epidemiologic results of reproductive and developmental health effects and will be used to inform a causality determination, which is discussed later in the chapter (Section 9.1.5).

9.1.1.2 Male Reproduction

Epidemiologic Evidence of Male Reproductive Function

A limited amount of research has been conducted to examine the association between $PM_{2.5}$ and male reproductive outcomes. In the studies of sperm parameters, there is some evidence for decreased motility (Hammoud et al., 2009), including after adjustment for some copollutants (i.e., NO_X, CO) (Radwan et al., 2015), and evidence for association with abnormal morphology is inconsistent, with a study finding higher percent abnormal sperm with higher $PM_{2.5}$ levels (Radwan et al., 2015) and a U.S. study reporting no evidence of associations between $PM_{2.5}$ exposure and sperm morphology (Hansen et al., 2010). Among participants in the National Social Life, Health, and Aging Project (NSHAP), Tallon et al. (2017) observed positive associations between exposure to annual $PM_{2.5}$ concentrations and erectile dysfunction in men aged 57−85 years (OR: 1.26; 95% CI: 0.81, 1.96)[75]. Effect estimates were similar in magnitude and precision when $PM_{2.5}$ concentrations were averaged over 1, 2, 3, 4, 5, 6, or 7 years. In summary, there are some association between $PM_{2.5}$ exposure and some sperm parameters, though the number of studies is limited.

[75] As detailed in the Preface, risk estimates are for a 5 µg/m3 increase in $PM_{2.5}$ concentrations unless otherwise noted.

Toxicological Evidence of Male Reproductive Function

The role of particulate matter exposure on male reproductive function has been explored in a limited number of animal toxicology studies evaluating endpoints including daily sperm production, male reproductive success, male reproductive organ histology and weight or hormonal concentrations and are separated below based on early life PM exposure or adult PM exposure. The results from these studies are summarized in Table 9-1. The 2009 PM ISA (U.S. EPA, 2009) did not include male reproductive studies that are in scope for the current ISA.

In recent work, spermatogenesis was affected in adult animals after prenatal and/or early postnatal exposure of mice to $PM_{2.5}$ (ambient air versus filtered air) from high traffic areas of Sao Paulo, Brazil. Pires et al. (2011) assessed germ cell count, rates of proliferation and apoptosis, spermatid retention and spermatogenic cycle timing. Animals were exposed 24 hour/day for 120 days prior to mating and then throughout pregnancy (prenatal) or for 10 days after birth (postnatal) to ambient or filtered Sao Palo air. Prenatal exposure to ambient air resulted in reduced body weights ($p < 0.001$) and reduced testicular weights ($p = 0.012$) and volume ($p = 0.013$), decreased tubular diameter ($p = 0.004$), and decreased number of elongated spermatids in pre- and postnatal-exposed animals versus filtered air controls. When compared to any other single exposure or the control animals, pre- and postnatal exposure caused significantly higher spermatid head retention at stages VIII−XII, a marker of defective spermiation ($p = 0.004$). No significant changes were detected in Leydig cell, Sertoli cell, spermatogonia, spermatocyte, or round spermatid numbers, or germ cell proliferation, apoptosis, or frequency of spermatogenic stages. The particulate portion of ambient air exposure was responsible for multiple decrements in spermatogenesis in adult animals after early life $PM_{2.5}$ exposure.

Table 9-1 Recent toxicological studies of male reproduction.

Study	Study Population	Exposure Details	Endpoints Examined
(Pires et al., 2011)	Balb/c pregnant mice and male offspring, N = 60, prenatal and postnatal exposure to ambient PM until 90 days of age.	Pregnant dams and male offspring, 120 days (premating through PND 90). $PM_{2.5}$ conc: 16.61 μg/m^3 nonfiltered air, 2.29 μg/m^3 filtered air. $PM_{2.5}$ levels were measured gravimetrically by collecting $PM_{2.5}$ particles from cellulose filters obtained using a Harvard impactor.	Effects of pre- and postnatal ambient $PM_{2.5}$ exposure on offspring testis weights, germ cell proliferation, testis morphology, apoptotic germ cells.

In conclusion, mixed effects were seen for associations of $PM_{2.5}$ exposure with male reproductive outcomes. Prenatal and/or early postnatal exposure of mice to $PM_{2.5}$ reduced testicular weight, volume

and tubular diameter, decreased number of elongated spermatids and affected spermiation. Epidemiologic evidence showed positive associations of $PM_{2.5}$ with sperm motility and erectile dysfunction.

9.1.1.3 Female Reproduction

Infertility affects approximately 11% of all women ages 15−44 in the U.S. (Chandra et al., 2013), and can have negative psychological impacts and affect quality of life; infertility and subfertility may also potentially signal poorer physiological health. For example, those with fertility problems are more likely to experience adverse pregnancy and birth outcomes if they do become pregnant (Hansen et al., 2005; Helmerhorst et al., 2004; Jackson et al., 2004). Outcomes evaluated in this section include fecundity, the biologic capacity to reproduce, and fertility, the ability to conceive or induce conception. Researchers may also investigate potential mechanistic links between pregnancy conditions and biomarkers and later birth outcomes; such as pregnancy related hypertension, which is a leading cause of perinatal and maternal mortality and morbidity (Lee et al., 2012b).

Epidemiologic Evidence for Female Reproductive Function

Epidemiologic studies related to fecundity or fertility were not identified for inclusion in the 2009 PM ISA (U.S. EPA, 2009). Recent studies of female reproductive function frequently use populations undergoing assisted reproductive treatment, as these populations have a large amount of data collected on them during treatment and defined menstrual cycles and start points. However, populations undergoing assisted reproductive treatment may be less healthy than the general population of reproductive age. In cohorts recruited from the general population, exact timing can be difficult to determine due to reliance on participant recall, particularly if they are surveyed well after initiation of pregnancy attempts. Many pregnancies are unplanned, which also adds a level of complication to quantifying fertility. Overall, a limited body of evidence provides modest evidence that both short- and long-term $PM_{2.5}$ exposure is associated with decreased fecundability, but did not observe associations between $PM_{2.5}$ exposure and fertility.

Several recent epidemiologic studies examined the association between exposure to air pollutants and the reproductive function or fertility. Gametes (i.e., ova and sperm) may receive higher exposures while outside of the human body, as occurs with assisted reproduction. A recent study estimated daily concentrations of criteria pollutants at addresses of women undergoing their first in vitro fertilization (IVF) cycle and at their IVF labs from 2000 to 2007 in the northeastern U.S. (Legro et al., 2010). Increasing $PM_{2.5}$ concentration estimated at the patient's address during ovulation induction (short-term exposure, ~12 days) was associated with a decreased odds of achieving pregnancy (determined by serum pregnancy test; OR: 0.90; 95% CI: 0.82, 0.99) or an intrauterine pregnancy (determined by ultrasound; OR: 0.90; 95% CI: 0.82, 0.99). These authors observed generally null associations with odds of a live birth after pregnancy was established when $PM_{2.5}$ concentrations were averaged over a number of

exposure periods during pregnancy. The results of this study indicate that short-term $PM_{2.5}$ exposure during ovulation was detrimental and reduced the likelihood of becoming pregnant. Among the general population in the Czech Republic, increased $PM_{2.5}$ exposure in the 30 days before initiation of unprotected intercourse also was associated with reduced fecundability [fecundability ratio: 0.93 (95% CI: 0.88, 0.98), (Slama et al., 2013)].

In an analysis of the Nurses' Health Study II Mahalingaiah et al. (2016), observed null associations with infertility and long-term $PM_{2.5}$ exposure using national spatiotemporal models. They also found no evidence of association with endometriosis, a condition potentially linked to infertility (i.e., attempting to get pregnant for at least one year without success) (Mahalingaiah et al., 2014). Interpolation methods were used to estimate monthly $PM_{2.5}$ concentrations before 1999 in both of these analyses. Of the other recent studies, a cross-sectional study in Spain also reported null associations with fertility rates based on number of live births per 1,000 women aged 15−44 years (Nieuwenhuijsen et al., 2014), while a study of almost 2,000 couples in the Czech Republic found increased $PM_{2.5}$ exposure in the 60 days before initiation of unprotected intercourse was associated with reduced fecundity (Slama et al., 2013). Slama et al. (2013) also examined exposure in the 30 days post-conception as a negative control and observed no evidence of association between $PM_{2.5}$ and fecundity in this period, providing greater certainty for the observed effect of $PM_{2.5}$ exposure on fecundity in their study.

In summary, recent epidemiologic studies showed short-term $PM_{2.5}$ exposure during ovulation was detrimental and reduced the likelihood of becoming pregnant in women undergoing IVF, and in a separate study increased $PM_{2.5}$ exposure in the 30 days before initiation of unprotected intercourse also was associated with reduced fecundability. Little evidence exists in the literature for laboratory animal studies on this outcome. Overall, there appears to be some association between $PM_{2.5}$ exposure and reproductive function (i.e., fecundity outcomes), though the number of studies is limited. In addition, each of these studies account for fertility or fecundity in a different manner, making it difficult to directly compare results across studies. Studies of female reproductive function are summarized in Supplemental Table S9-1 (U.S. EPA, 2018).

Animal Toxicological Evidence for Female Reproduction

Multiple animal toxicological studies of female fertility and estrus from the 2009 PM ISA (U.S. EPA, 2009) reported altered estrous cycles, increased time necessary for mating, smaller litter sizes with increased resorptions and fetal deaths, decreased fertility index, and increased pregnancy index in rodents exposed to $PM_{2.5}$, often ambient air in Sao Paulo, Brazil (Veras et al., 2009). $PM_{2.5}$ inside both chambers and in the outside environment was determined gravimetrically using Harvard impactors.

$PM_{2.5}$ exposure preconception, during gestation or in utero can potentially affect litter size by changing the number of pups conceived or by inducing pup loss during pregnancy or decreasing the number of fertilizations or implantation sites. The 2009 PM ISA (U.S. EPA, 2009) reported significant

changes to litter size with $PM_{2.5}$ exposure. In recent work, litter size was not affected by prenatal exposure of B6C3F1 hybrid mice to Sterling Forest, NY $PM_{2.5}$ CAPs (Klocke et al., 2017) 6 hour each day for most of gestation. Across multiple studies, preconception plus gestational exposure of dams to $PM_{2.5}$ significantly decreased litter size, but paternal exposure plus gestational exposure or gestational exposure alone were not sufficient to affect litter size. More details of these studies are in Table 9-2 below.

Table 9-2 Key toxicological studies of effects of $PM_{2.5}$ on female reproductive function.

Study	Population	Exposure Details	Endpoints Examined
(Klocke et al., 2017)	Male and female B6C3F1 mice (8−10 weeks old) were mated and then dams were exposed to Sterling Forest CAPs.	Prenatal exposure to filtered air or Sterling Forest CAPs for 6 hours/day during gestation (GD0.5 to GD 16.5). Mean CAPs concentration over the exposure period averaged 92.696±19.16 (mean ± SD) μg/m^3 compared to 3.526±0.87 μg/m^3 for FA controls. CAPs exposure levels ranged from 32.95 to 184.43 μg/m^3 over the duration of the exposure period.	Reproductive success.

In conclusion, a recent study exists on animal reproductive success (litter size) with null findings, but no other new studies in the animal toxicology literature on female fertility or estrous cycle have been published since the 2009 PM ISA (U.S. EPA, 2009). The recent epidemiologic literature contains studies on infertility with a U.S. study showing null associations with $PM_{2.5}$ and a Czech study showing positive associations of infertility with $PM_{2.5}$. Epidemiologic associations between $PM_{2.5}$ and endometriosis were null.

9.1.2 Pregnancy and Birth Outcomes

9.1.2.1 Biological Plausibility

This section describes biological pathways that potentially underlie reproductive and developmental health effects of pregnancy, birth weight, and birth outcomes resulting from exposure to $PM_{2.5}$. Figure 9-2 graphically depicts the proposed pathways as a continuum of upstream events, connected by arrows, that may lead to downstream events observed in epidemiologic studies. This discussion of "how" exposure to $PM_{2.5}$ may lead to reproductive and developmental health effects contributes to an understanding of the biological plausibility of epidemiologic results evaluated later in Section 9.1.2.

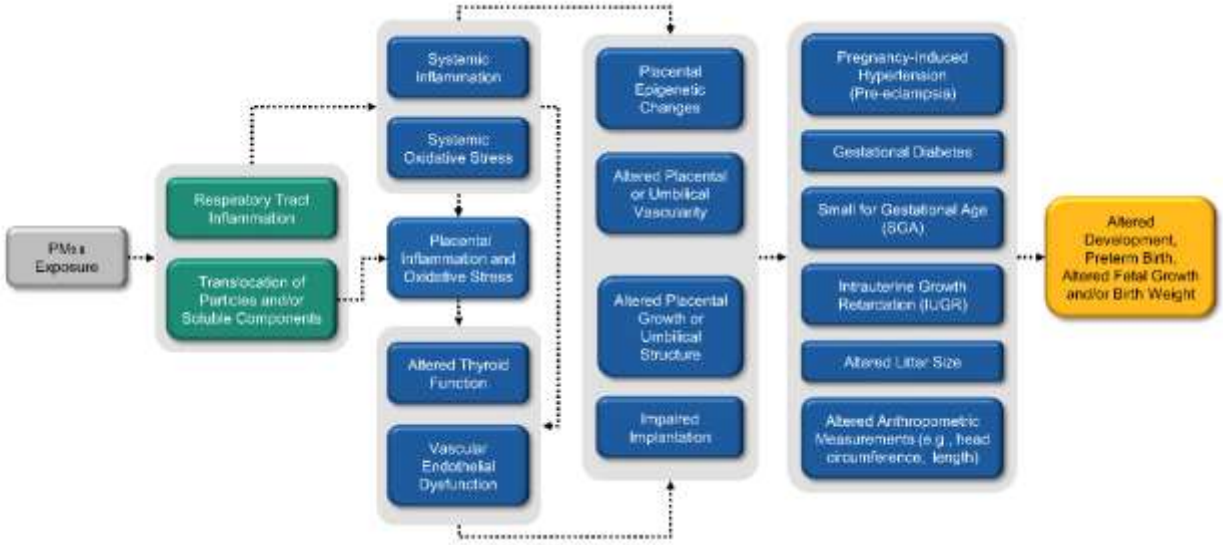

Figure 9-2 Potential biological pathways for pregnancy and birth outcomes following $PM_{2.5}$ exposure

[a] Note: The boxes above represent the effects for which there is experimental or epidemiologic evidence, and the dotted arrows indicate a proposed relationship between those effects. Shading around multiple boxes denotes relationships between groups of upstream and downstream effects. Progression of effects is depicted from left to right and color coded (grey, exposure; green, initial event; blue, intermediate event; orange, apical event). Here, apical events generally reflect results of epidemiologic studies, which often observe effects at the population level. Epidemiologic evidence may also contribute to upstream boxes. When there are gaps in the evidence, there are complementary gaps in the figure and the accompanying text below.

Evidence is accumulating that $PM_{2.5}$ exposure may affect pregnancy and birth outcomes. The evidence from the 2009 PM ISA (U.S. EPA, 2009) and new evidence indicates multiple initial events after $PM_{2.5}$ inhalation contribute to effects on pregnancy and birth outcomes including translocation of particles/soluble components (Valentino et al., 2016); systemic inflammation or oxidative stress. Beyond these initial events, there is also evidence from experimental and epidemiologic studies demonstrating that $PM_{2.5}$ inhalation could result in a coherent series of physiological responses that provide biological plausibility for the associations reported in epidemiologic studies and animal toxicological studies that contribute to the apical endpoint of altered development, preterm birth, altered fetal growth or birth weight. The initial event of systemic oxidative stress is demonstrated in the epidemiologic literature with $PM_{2.5}$-dependent increased odds of elevated c-RP levels during pregnancy (Lee et al., 2011b) or in nonpregnant individuals (Devlin et al., 2014). $PM_{2.5}$-dependent reproductive organ specific inflammation includes placental oxidative stress and intrauterine inflammation (Nachman et al., 2016; Saenen et al., 2016), altered umbilical cord blood lymphocyte distribution (Herr et al., 2010), and increased inflammation along the lipoxygenase pathway in cord blood (5-LOX, 12/15 LOX pathways) (Martens et al., 2017). With increased $PM_{2.5}$ exposure intermediate endpoints emerge with the epidemiologic literature showing altered fetal thyroid function (Janssen et al., 2016; Lavigne et al., 2016a) and altered fetal metabolism (Janssen et al., 2016; Lavigne et al., 2016a). With increased $PM_{2.5}$ exposure, changes to metabolism are seen with increased risk of gestational diabetes (Hu et al., 2015) during the second

trimester. Impaired fetal or maternal thyroid function during a pregnancy can impact the pregnancy, birth outcomes and development. As shown in Figure 9-2, the initial mechanisms can contribute to downstream intermediate effects in laboratory animals including placental or umbilical cord vascularity changes (Veras et al., 2012), endothelial dysfunction (Veras et al., 2012), altered thyroid function (Janssen et al., 2016; Lavigne et al., 2016a) or altered umbilical cord structure (Veras et al., 2012), and in epidemiologic studies of placental genetic or epigenetic changes (Janssen et al., 2013), altered placental growth (Saenen et al., 2015) and impaired implantation (Saenen et al., 2015). One pathway shows impaired placental development including epidemiologic evidence of increased placental inflammation (Saenen et al., 2016), altered expression of placental genes (decreased placental tissue *Bdnf* and *Syn1*) (Saenen et al., 2015), and at the epigenetic level, and human placenta global hypo-methylation with $PM_{2.5}$ exposure (Janssen et al., 2013). Laboratory animal evidence includes altered placental vascularity (Veras et al., 2008), decreased blood vessel diameter on maternal side of placenta and increased capillary surface area on fetal side of placenta (Veras et al., 2008), and decreased placental weight (Veras et al., 2008) (Blum et al., 2017). The line of evidence for effects on the umbilical cord shows $PM_{2.5}$-dependent impairment of the umbilical cord with the epidemiologic literature showing altered cord lymphocyte distribution (Saenen et al., 2016), increased cord blood inflammatory markers (e.g., upregulation of the 5-LOX pathway) (Martens et al., 2017), and laboratory animal evidence of impaired cord artery vascularity (increased endothelin receptor A levels and cord endothelial dysfunction) (Veras et al., 2012), and decreased cord tensile strength (Veras et al., 2012). Decreased fetal growth (Jedrychowski et al., 2010), decreased birth weight (Jedrychowski et al., 2010) and preterm birth (Brauer et al., 2008), (Salihu et al., 2012), (Ha et al., 2014) (Blum et al., 2017) have the strongest evidence in association with $PM_{2.5}$ inhalation and these aforementioned upstream biomarkers provide biological plausibility for these associations. $PM_{2.5}$ exposure has been shown to be associated with pregnancy induced hypertension or pre-eclampsia, gestational diabetes, anthropometric measurements (crown to rump length), IUGR or SGA (Section 9.1.1). There are plausible mechanisms by which inhalation of $PM_{2.5}$ could progress from the initial events noted above to altered growth and development, birth weight, or preterm birth. Supporting evidence is included in Figure 9-2. Together, these proposed pathways provide biological plausibility for epidemiologic results of reproductive and developmental health effects and will be used to inform a causality determination, which is discussed later in the chapter (Section 9.1.5).

In conclusion, decreased fetal growth, decreased birth weight and preterm birth have the strongest evidence in association with $PM_{2.5}$ exposure and these upstream biomarkers provide biological plausibility for these associations. There are plausible mechanisms by which inhalation exposure to $PM_{2.5}$ could progress from the initial events noted above to altered growth and development, birth weight, or preterm birth. Supporting evidence is included in Figure 9-2.

9.1.2.2 Maternal Health during Pregnancy

Epidemiologic Evidence for Effects on Maternal Health during Pregnancy

Studies of maternal health during pregnancy include a number of outcomes, but primarily focus on gestational hypertension disorders and gestational diabetes. Pregnancy-associated hypertension is a leading cause of perinatal and maternal mortality and morbidity. A large body of research has linked changes in blood pressure to ambient air pollution; however, evidence is inconsistent for $PM_{2.5}$ (Section 6.2.6 and Section 6.3.7). A few recent studies have examined whether increases in $PM_{2.5}$ concentrations are associated with hypertensive disorders of pregnancy including preeclampsia (see Supplemental Table S9-1(U.S. EPA, 2018) for study details). The results of these studies were not consistent. The methods by which exposure was assigned in these studies may contribute to the heterogeneity in associations observed across these studies. For example, examination of a cohort from Orange and Los Angeles counties in California revealed that the direction of the association between a composite outcome of gestational hypertensive disorders and $PM_{2.5}$ changed based on how concentrations were determined, either using the CALINE4 model (positive association; OR 1.47; 95% CI: 1.24, 1.68) or the nearest monitor (negative association; OR 0.90; 95% CI: 0.53, 1.54) (Wu et al., 2011; Wu et al., 2009). A cohort study conducted across the U.S. that estimated $PM_{2.5}$ concentrations using a modified CMAQ model across hospital catchment areas reported no evidence of association with preeclampsia for women with or without asthma (Mendola et al., 2016b). A study of around 3,500 women in Washington State observed no associations between preeclampsia and exposure to $PM_{2.5}$ in the seven months following conception when using a LUR exposure model (Rudra et al., 2011). While a larger cohort from Jacksonville, FL, using monitors within 20 km for assignment and with similar average $PM_{2.5}$ concentrations, reported positive odds ratios with any hypertensive disorder and $PM_{2.5}$ exposure in the first and second trimesters (OR: 1.09; 95% CI: 0.99, 1.20; OR: 1.24; 95% CI: 1.11, 1.39, respectively) (Xu et al., 2014). Two meta-analyses have estimated positive odds ratios (ORs 1.15−1.47) for $PM_{2.5}$ and preeclampsia, however both had large heterogeneity scores, and therefore a combined effect may be inappropriate (Hu et al., 2014; Pedersen et al., 2014).

Several studies evaluated the association between short- and long-term $PM_{2.5}$ exposure and gestational hypertension. Two long-term exposure studies of blood pressure report inconsistent effects, with a Pittsburgh study observing null associations (Lee et al., 2012b) and a Polish study reporting positive associations between second trimester $PM_{2.5}$ exposure and blood pressure measured in the third trimester (Jedrychowski et al., 2012). In addition, a study that evaluated short-term $PM_{2.5}$ exposure and blood pressure observed higher blood pressure associated with increased $PM_{2.5}$ in hours 0−4 before delivery in women with gestational hypertension and preeclampsia, but not among normotensive women or women with chronic hypertension (Männistö et al., 2014).

All of the recent studies of gestational diabetes were conducted in areas with average $PM_{2.5}$ concentrations less than 12 $\mu g/m^3$ and provide limited evidence for an association between $PM_{2.5}$ exposure and gestational diabetes. In a nationwide cohort using a specialized CMAQ model and hospital catchment area for exposure, Robledo et al. (2015) reported null associations with $PM_{2.5}$ exposure in the preconception period (OR: 0.97; 95% CI: 0.94, 1.02) and first trimester (OR: 0.98; 95% CI: 0.94, 1.03). In a Florida based study using a hierarchical Bayesian exposure modeling approach, Hu et al. (2015) observed similar results after adjustment for ozone for the first trimester, and also observed increased odds of gestational diabetes with second trimester exposures. These studies were both large, with hundreds of thousands of women in each. In a study of around 2,000 women that compared exposure assignment with monitor values to that with satellite derived concentrations, Fleisch et al. (2014) observed positive associations with impaired glucose tolerance and $PM_{2.5}$ exposure in the second trimester, but null associations with gestational diabetes. In a larger cohort using only satellite derived concentrations Fleisch et al. (2016) again observed no evidence of association between $PM_{2.5}$ in the first or second trimesters and gestational diabetes.

In other outcomes related to pregnancy, $PM_{2.5}$ exposure has been associated with increased odds of high C-reactive protein (Lee et al., 2011b) and altered umbilical cord lymphocyte distributions (Herr et al., 2010), both potentially linked to inflammatory mechanisms for PM, and decreased placental gene expression potentially related to neurodevelopment (Saenen et al., 2015). Recently, $PM_{2.5}$ exposures have also been found to be associated with placental stress measures and intrauterine inflammation (Nachman et al., 2016; Saenen et al., 2016), along with fetal metabolic and fetal thyroid function (Janssen et al., 2016; Lavigne et al., 2016a). Examining short-term $PM_{2.5}$ exposure, Lee et al. (2011b) report elevated ORs for abnormal C-reactive protein levels. The small body of evidence across various pregnancy-related endpoints limits the ability to judge coherence and consistency across these studies, though the positive associations observed in these studies demonstrate that $PM_{2.5}$ exposure could result in physiological responses that contribute to adverse pregnancy outcomes (e.g., preterm birth, altered fetal growth or birth weight).

In summary, there is some evidence for an effect of $PM_{2.5}$ exposure on maternal health during pregnancy. Studies of maternal health during pregnancy are summarized in Supplemental Table S9-1 (U.S. EPA, 2018).

Toxicological Evidence for Effects on Pregnancy

The placenta appears to be a tissue that is sensitive to the downstream effects of $PM_{2.5}$ exposure. The 2009 PM ISA (U.S. EPA, 2009) provided evidence of changes in placental vascularity with $PM_{2.5}$ exposure, including $PM_{2.5}$ dependent decreased placental weight (GD17) with decreased blood vessel diameter on maternal side of placenta and increased capillary surface area on fetal side of placenta (Veras et al., 2008). Recent studies continue to show effects on the placenta in response to $PM_{2.5}$ exposure. Blum et al. (2017) exposed pregnant B6C3F1 hybrid mice to Sterling Forest $PM_{2.5}$ CAPs 6 hours/day and found

that placental weight was significantly decreased with 3rd trimester $PM_{2.5}$ exposure and significantly increased with PM exposure over the entire pregnancy ($p < 0.05$); placental weight was not affected by 1st or 2nd trimester $PM_{2.5}$ exposure. The effect of $PM_{2.5}$ exposure on placental inflammation was followed a 1-hour daily exposure to Sao Palo $PM_{2.5}$ CAPs before and during pregnancy (Blum et al., 2017). Rats were exposed prior to mating and gestational exposure was started at implantation on GD6 and continued through GD19. Animals were exposed for 1 hour/day to CAPs or to HEPA filtered air (de Melo et al., 2015). Placental IL-4 was significantly increased on the fetal side of the placenta ($p < 0.05$) when the dam had combined CAPs exposure before pregnancy and during pregnancy only; none of the other cytokines assessed (IL-1b, IL-4, IL-6, IL-10, INF-g, TNF-a, and Toll-like receptor 4) in both placenta and serum were significantly increased by $PM_{2.5}$ exposure; also, no other exposure paradigms induced significant changes in cytokines. IL-4 protein levels are significantly increased in the fetal portion of the placenta with PM exposure before and during pregnancy, indicating placental inflammation after PM exposure.

More recent work has evaluated the effects of $PM_{2.5}$ on the mouse umbilical cord structural anatomy, microscopic vascular morphology, and markers of oxidative stress (Veras et al., 2012). Dams were exposed to $PM_{2.5}$ (filtered or unfiltered ambient air, Table 9-3 below). The reproductive and developmental outcomes from these animals were reported in previous publications and were covered in the 2009 PM ISA (Veras et al., 2009; Veras et al., 2008). The mean cross-sectional area of umbilical cords from $PM_{2.5}$-exposed group was significantly lower than the filtered air group ($p < 0.001$). The smaller cross-sectional area was due to a significant 28% decrease in total volume of porous mucoid connective tissue (MCT) of the umbilical cord ($p = 0.002$) and the decrease MCT was attributed to a significant 60% loss of collagen in the MCT ($p = 0.002$). PM-exposure resulted in increased oxidative stress or greater levels of immunostaining for 15-F2t-isoprostane in the walls of cord arteries and veins ($p < 0.0001$). Additionally, $PM_{2.5}$ exposure resulted in increased endothelin receptor A levels in cord arteries and veins ($p < 0.0001$), and no changes in endothelin receptor B. Collectively, the results suggest that the reduced birth weights previously reported following particulate exposures may be associated with decreased tensile properties of the umbilical cord due to loss of collagen and with altered blood flow to the fetus.

These studies demonstrate that gestational exposure to $PM_{2.5}$ alters murine umbilical cords and their vessels as well as the placenta, which could potentially deregulate vascular tone, an important contributor to proper fetal development. A summary of the animal toxicological studies of $PM_{2.5}$ exposure is included below in Table 9-3.

Table 9-3 Key toxicological studies of $PM_{2.5}$ exposure and pregnancy and birth outcomes.

Study	Study Population	Exposure Details	Endpoints Examined
(Veras et al., 2012)	BalbC mice (n = 12 dams, per group, fetuses examined in each group). Exposure to ambient air in São. Paulo near high traffic density. Conducted June to November 2006.	Dams were exposed to filtered or unfiltered air (average $PM_{2.5}$ levels, 6.4 µg/m^3 or 32.8 µg/m^3, respectively).	Mouse umbilical cord structural anatomy, microscopic vascular morphology, and markers of oxidative stress.
(de Melo et al., 2015)	Pregnant Female Wistar Rats	Rats were exposed 5 times per week during the 3 weeks before pregnancy and/or 1 time per day each day during pregnancy, starting on GD6 and though GD19. Animals were exposed to $PM_{2.5}$ (ambient $PM_{2.5}$ concentration of 600 mg/m^3 for 1 h). There were 4 exposure paradigms including filtered air (FA) before and during pregnancy (control), PM CAPs before pregnancy +FA during pregnancy, FA before pregnancy + CAPs during pregnancy, or CAPs both before and during pregnancy.	Placental development and systemic inflammation (cytokines, TLR4), pregnant dam blood counts.
(Blum et al., 2017)	Pregnant B6C3F1 hybrid mice, n = 8−17 dams per exposure.	Mice were exposed 6 hours/day to Sterling Forest CAPs during the pregnancy (entire pregnancy or 1st trimester, 2nd trimester, or 3rd trimester). Average daily CAPS concentration ranged from 113 to 192.5 µg/m^3.	Placental weight

9.1.2.3 Fetal Growth, Birth Weight, and Body Length at Birth

Fetal growth can be difficult to quantify; typically, small for-gestational age (SGA) or intrauterine growth restriction (IUGR) are used as dichotomous metrics to characterize suboptimal fetal growth. SGA represents a statistical description of a small neonate, whereas the term IUGR is reserved for those with clinical evidence of abnormal growth. SGA is defined as infants with a birth weight below the 10th percentile for gestational age, usually with consideration for sex and race as well, and is often used interchangeably with IUGR. There are a number of limitations in using SGA/IUGR as a metric of poor fetal growth. One is that a percentile based measure will always quantify a certain percentage of the infant population as growth restricted whether or not this is truly the case (Wollmann, 1998). For example, in term infants, it is unlikely that 10% are actually growth restricted. Whereas in preterm infants, it is likely that more than 10% are growth restricted; therefore, SGA cases would be overestimated in term infants and underestimated in preterm infants. In addition, exact definitions shift between studies and some studies use alternate definitions of SGA/IUGR. For example, some studies use the birth weight distribution of their study population for defining SGA, which will naturally not be identical for every

study population, and others use country standards, which are likely to be more stable, although they may need to be updated with time (Salihu et al., 2012; Brauer et al., 2008).

Birth weight is a measure of fetal growth and an important indicator of future infant and child health. Birth weight is determined by gestational age and intrauterine growth, as well as maternal, placental, fetal and environmental factors. Environmental insults affecting birth weight may occur throughout pregnancy. Implantation or formation of the placenta may be disrupted in the earliest weeks of pregnancy, leading to decreased nutrition throughout pregnancy; or inflammation might result in arterial resistance within the umbilical cord during the later trimesters resulting in poor fetal nutrition. As the largest gains in birth weight occur during the last weeks of gestation, this may be a particularly vulnerable period for birth weight outcomes. Information on birth weight is routinely collected for vital statistics; given that measures of birth weight do not suffer the same uncertainties as gestational age or growth restriction, it is one of the most studied outcomes within air pollution and reproductive health. Birth weight may be examined as a continuous outcome or dichotomous outcome as low birthweight (LBW) (less than 2,500 g or 5 lbs, 8 oz).

There are many methodological issues relating to the study of outdoor air pollution and adverse birth outcomes; and several articles reviewing these methods characterize these challenges (Chen et al., 2010; Woodruff et al., 2009; Ritz and Wilhelm, 2008; Slama et al., 2008). Some of the key challenges to interpretation of birth outcome study results include: the difficulty in assessing exposure as most studies use existing monitoring networks to estimate individual exposure to ambient air pollution; the need for detailed exposure data, and potential residential movement of mothers during pregnancy; the inability to control for potential confounders such as other risk factors that affect birth outcomes (e.g., smoking, correlated air pollutants); evaluating the exposure window (e.g., trimester) of importance; and limited evidence on the physiological modes of action for these effects (Ritz and Wilhelm, 2008; Slama et al., 2008). Some studies have specifically investigated the effects of residential mobility during pregnancy, generally finding movement to similar areas and limited to no effects on PM exposure levels and effect estimates (Pereira et al., 2016; Chen et al., 2010), though a review reported that there may be differences by covariates (Bell and Belanger, 2012). Recently, an international collaboration was formed to better understand the relationships between air pollution and adverse birth outcomes and to examine some of these methodological issues through standardized parallel analyses of data sets across countries (Woodruff et al., 2010) with a study of term birth weight from this collaboration is included in this assessment (Dadvand et al., 2013b). Some of the key challenges to interpretation of these study results include the difficulty in assessing exposure as most studies use existing monitoring networks to estimate individual exposure to ambient PM; the inability to control for potential confounders such as other risk factors that affect birth outcomes; evaluating the exposure window of importance; uncertainty surrounding exposure measurement error, spatial and temporal heterogeneity and limited evidence on the physiological mechanism of these effects. Study of these outcomes can be difficult given the need for detailed data and potential residential movement of mothers during pregnancy. Another uncertainty is whether PM effects differ by the child's sex.

Epidemiologic Evidence for Fetal Growth, Birth Weight, and Body Length at Birth

Studies evaluated in the 2009 PM ISA (U.S. EPA, 2009) generally observed positive associations between $PM_{2.5}$ exposure averaged over the first or second trimester and growth restriction. Among recent studies examining SGA, the evidence is less consistent, with some studies reporting no evidence that increases in $PM_{2.5}$ were associated with increases in odds of SGA (Ha et al., 2017; Stieb et al., 2015; Hannam et al., 2014; Lee et al., 2013), while several others observed that increases in $PM_{2.5}$ were associated with increases in odds of SGA, though magnitude and precision of effects varied (Hyder et al., 2014; Salihu et al., 2012; Rich et al., 2009; Brauer et al., 2008). In the single study of infant anthropometrics and $PM_{2.5}$, small decrements in length and head circumference with log-increases in $PM_{2.5}$ were observed (Jedrychowski et al., 2010).

The 2009 PM ISA (U.S. EPA, 2009) concluded that a limited number of studies conducted in the U.S. observed positive associations between $PM_{2.5}$ exposure and LBW, but that the evidence from studies conducted outside of the U.S. was inconsistent. Many recent studies evaluate the association between $PM_{2.5}$ exposure and birth weight, including studies of LBW and birth weight as a continuous measure. Similar to the results reported in the 2009 PM ISA (U.S. EPA, 2009), when examining the entire body of available literature as a whole, the evidence for an effect of $PM_{2.5}$ on birth weight remains inconsistent. For example, among studies that examine LBW, many report positive associations (i.e., increased odds of LBW) with $PM_{2.5}$ exposure (Ha et al., 2017; Cândido da Silva et al., 2014; Dadvand et al., 2014; Ha et al., 2014; Harris et al., 2014; Hyder et al., 2014; Laurent et al., 2014; Dadvand et al., 2013b; Pedersen et al., 2013; Trasande et al., 2013; Ebisu and Bell, 2012; Salihu et al., 2012; Morello-Frosch et al., 2010). A number also report null or negative effect estimates (Ha et al., 2017; Lavigne et al., 2016b; Brown et al., 2015; Stieb et al., 2015; Fleischer et al., 2014; Fleischer, 2014; Gray et al., 2014; Vinikoor-Imler et al., 2014; Laurent et al., 2013; Madsen et al., 2010; Brauer et al., 2008; Parker and Woodruff, 2008). Similar results are reported for studies that examine change in the continuous measure of birth weight, with some reporting associations between $PM_{2.5}$ exposure and decreases in birth weight (Erickson et al., 2016; Tu et al., 2016; Stieb et al., 2015; Gehring et al., 2014; Hyder et al., 2014; Pedersen et al., 2013; Kloog et al., 2012; Darrow et al., 2011; Gehring et al., 2011; Gray et al., 2011; Gray et al., 2010; Morello-Frosch et al., 2010), and others reporting null associations or showing increases in birth weight (Tu et al., 2016; Fleisch et al., 2015; Lakshmanan et al., 2015; Hannam et al., 2014; Vinikoor-Imler et al., 2014; Laurent et al., 2013; Geer et al., 2012; Darrow et al., 2011; Gehring et al., 2011; Bell et al., 2010; Jedrychowski et al., 2010; Madsen et al., 2010; Slama et al., 2010; Parker and Woodruff, 2008). The entire body of available studies are characterized in Supplemental Table S9-2 (U.S. EPA, 2018).

When evaluating studies of $PM_{2.5}$ exposure and fetal growth or birth weight conducted in North America, where the most consistent associations were observed in the 2009 PM ISA (U.S. EPA, 2009), the results of recent studies are less consistent. There are several studies examining fetal growth and birthweight condected in North America with reported mean $PM_{2.5}$ concentrations less than 12 $\mu g/m^3$ (Table 9-4). For example, Brauer et al. (2008) investigated SGA (defined to the cohort) and LBW using

both inverse distance weighting (IDW) from monitors and LUR exposure metrics in Vancouver. Increases in $PM_{2.5}$ over the whole pregnancy period were associated with increased odds of SGA with both exposure metrics, though confidence intervals were wider with the IDW method (OR IDW = 1.10 [0.90, 1.28], OR LUR = 1.10 [1.00, 1.16]) (Brauer et al., 2008). For LBW, ORs for the different exposure metrics were divergent, with a negative association when using IDW and a positive OR when using LUR to assign exposure, though both sets of CIs were wide (Brauer et al., 2008). Another study set across 24 cities in Canada using LUR methods involving both monitors and satellite data reported near null odds ratios for SGA and LBW with $PM_{2.5}$ across the full pregnancy period in fully adjusted models; mean changes in birth weight were negative with increasing $PM_{2.5}$ in the fully adjusted model (Stieb et al., 2015).

[a]This table includes studies conducted in North America in locations where the annual average $PM_{2.5}$ concentration was 20 µg/m³ or less; a complete list of all fetal growth and birth weight studies is included in Supplemental Table S9-2 (U.S. EPA, 2018).

CMAQ = community multiscale air quality modeling system, C-RP = C-reactive protein, EP = entire pregnancy, FR = fecundity ratio M1 = 1st month of pregnancy, IRR = incidence rate ratio, M7 = 7th month of pregnancy, OR = odds ratio, RR = risk or rate ratio, T1 = 1st trimester of pregnancy, T2 = 2nd trimester of pregnancy, T3 = 3rd trimester of pregnancy.

[b]All estimates reported per 5 µg increase in $PM_{2.5}$ unless otherwise stated.

†Studies published since the 2009 Integrated Science Assessment for Particulate Matter.

In the U.S., a Florida study of over 100,000 births using nearest monitor reported $PM_{2.5}$ exposure averaged across the whole pregnancy period to be associated with increased odds of SGA (defined by national standards) and LBW (Salihu et al., 2012). Another Florida cohort study on LBW, using the EPA's Hierarchical Bayesian Prediction Model output for $PM_{2.5}$ and ozone, reported increased ORs with increasing $PM_{2.5}$ exposure for all trimesters after adjustment for ozone (Table 9-4); ORs with the highest magnitude were observed with exposures during the 2nd trimester (Ha et al., 2014). Hyder et al. (2014) investigated associations between $PM_{2.5}$ and fetal growth using exposure assignment for the entire pregnancy period though monitors or through two different satellite models in a Connecticut cohort. They reported increased odds ratios for SGA all methods, though odds ratios from the satellite based methods were of higher magnitude (Hyder et al., 2014). ORs for LBW were elevated for satellite methods, but near null for analyses using monitors, and change in birth weight was negative for all methods, with larger magnitude in satellite analyses (Hyder et al., 2014). Kloog et al. (2012) used a satellite model for $PM_{2.5}$ across the last 30 and 90 days of pregnancy, as well as the full pregnancy period, and observed decreases in birth weight with increasing $PM_{2.5}$ concentrations in Massachusetts. Lakshmanan et al. (2015)

investigated birth weight in a small Boston cohort (n = 670) using modeled air pollution data involving satellite data and LUR across the full pregnancy period. A slightly larger (n = 2,114) study conducted in eastern Massachusetts, also using modeled satellite data for $PM_{2.5}$ exposure in the third trimester, observed an association with lower birth weight only at the highest quartile of exposure (Fleisch et al., 2015). In a southern California study using both monitors and CALINE4 model output (mean $PM_{2.5}$ = 4.25 μg/m^3), Laurent et al. (2013) report null associations with LBW and increases in birth weight with increases in $PM_{2.5}$ for the entire pregnancy period.

In summary, many recent studies evaluated the relationship between $PM_{2.5}$ exposure and fetal growth and birth weight, and some provide evidence for a positive association for these outcomes. Similar to the results of the 2009 PM ISA (U.S. EPA, 2009), studies in North America generally report detrimental effects on fetal growth with $PM_{2.5\ exposure}$, including a study that adjusted for ozone as a copollutant (Ha et al., 2014). However, recent studies have provided limited evidence to inform uncertainties identified in the last review, including uncertainties related to potential copollutant confounding, the critical window of exposure and plausible biological mechanisms by which $PM_{2.5}$ exposure could result in reduced fetal growth (Section 9.1.2). Studies of fetal growth and birth weight are summarized in Supplemental Table S9-2(U.S. EPA, 2018).

Toxicological Evidence for Fetal Growth, Birth Weight, and Body Length at Birth

Recent studies have examined the effects of $PM_{2.5}$ on fetal growth and birth weight. A summary of these data is included in Table 9-5. The 2009 PM ISA (U.S. EPA, 2009) provided evidence of decreased birth weight with $PM_{2.5}$ exposure during the first week of gestation. Near term C-section birth weight of the pups was significantly decreased when dams were exposed daily to $PM_{2.5}$ (ambient Sao Paulo, Brazil, air for 6 hours/day during the first week of gestation versus filtered air) (Rocha et al., 2008). Multiple recent studies examined effects of PM exposure on birth weight and pup length at birth with mixed findings, possibly due to different exposure windows. Pregnant FVB mice were exposed for 6 hours/day to Columbus, OH, CAPS and bore pups with significantly decreased birthweight (p = 0.012) (Gorr et al., 2014). In a separate study, average birth weight and crown-rump length were not affected by prenatal exposure [6 hours/day, of B6CF1 mice to Sterling Forest CAPs for 6 hours/day during most of gestation (Klocke et al., 2017)]. In another study of B6CF1 mice exposed to Sterling Forest CAPs or to filtered air for 6 hours/day had low birth weight associated with PM exposure during the 1st and 2nd trimester or exposure over the entire pregnancy (p < 0.05) (Blum et al., 2017). Fetal growth was also assessed in pups collected near term by C-section at GD17 (length, body weight, placental weight) (Blum et al., 2017). Third trimester PM exposure or exposure during the entirety of pregnancy was associated with decrements in fetal growth (weight and body length, [p < 0.05]); body length was also significantly decreased with 1st trimester PM exposure (p < 0.05). Placental weight was significantly decreased with 3rd trimester PM exposure and significantly increased with PM exposure over the entire pregnancy (p < 0.05) (Blum et al., 2017). Birth length was significantly decreased with PM exposure for any period

of PM exposure during pregnancy including 1st, 2nd, or 3rd trimester or the entire pregnancy (Blum et al., 2017). The multiple studies mentioned above assessed birth weight or length in pups after prenatal $PM_{2.5}$ exposure and the majority of these animal toxicology studies show that PM exposure is associated with decreased birth weight of pups or decreased body length at birth (Table 9-5).

Table 9-5 Recent animal toxicological studies of $PM_{2.5}$ exposure and effects on fetal growth and birth weight.

Study	Population N, Sex; Age (mean ± SD)	Exposure Details (Concentration; Duration)	Endpoints Examined
(Blum et al., 2017)	Pregnant B6C3F1 hybrid mice, n = 8−17 dams per exposure.	Mice were exposed 6 h/day to Sterling Forest CAPs during the pregnancy (entire pregnancy or 1st trimester, 2nd trimester, or 3rd trimester). Average daily CAPS concentration ranged from 113 to 192.5 μg/m^3.	Fetal growth at GD17 (body length, body weight)
(Gorr et al., 2014)	Pregnant and lactating FVB mice	Ohio OASIS-1 aerosol concentration system was used to expose dams and pups placed in exposure chambers from GD1 through weaning offspring at 3 weeks. Male offspring at 3 mo of age were then isolated for assessments.	Birth weight
(Klocke et al., 2017)	Male and female B6C3F1 mice (8−10 weeks old) were mated and then dams were exposed to Sterling Forest CAPs.	Prenatal exposure to filtered air or Sterling Forest CAPs for 6 h/day during gestation (GD0.5 to GD 16.5). Mean CAPs concentration over the exposure period averaged 92.696 ± 19.16 (mean ± SD) μg/m^3 compared to 3.526 ± 0.87 μg/m^3 for FA controls.	Birth weight and crown-rump length

Toxicology Evidence for Changes in Anogenital Distance

Measurements of anogenital distance, a marker of androgenization using measurement of the perineum, were collected in pups at PND10 and PND21 (Blum et al., 2017). Pregnant animals were exposed to Sterling forest CAPS for 6 hours/day during one-third of pregnancy or a trimester (1st, 2nd, or 3rd) or during the entirety of pregnancy. In female offspring, significantly decreased AGD was reported with $PM_{2.5}$ exposure in the 1st trimester (PND10 and PND21) and with $PM_{2.5}$ exposure over the entire pregnancy (PND21). Shorter AGD in female rodents is associated with variation in reproductive traits in adulthood (1st estrus, timing of vaginal opening, lordosis) (Zehr et al., 2001). In male pups, AGD mirrored that of female pups at PND21 but not at PND10 (Blum et al., 2017). Both males and females had shortened AGD with 1st trimester CAPs exposure or exposure for the entire pregnancy. AGD length was also sensitive to 2nd trimester in male offspring. The effect of $PM_{2.5}$ exposure in decreasing the AGD is consistent with an anti-androgenic effect of PM exposure on pups.

Toxicological Evidence for Altered Sex Ratio in Litters at Birth

Sex ratio, the ratio of males to females in a litter of animals, is often measured to try to understand if an environmental exposure can contribute to a shift in the ratio of sexes of animals born, an effect that is known to be modulated by stress or other environmental exposures. In a recent study where B6CF1 mice were exposed to Sterling Forest CAPs or to filtered air for 6 hours/day, sex ratio was unaffected by PM exposure at multiple gestational exposure windows (1st, 2nd, or 3rd trimester) and the entirety of pregnancy (Blum et al., 2017).

9.1.2.4 Preterm Birth

Preterm birth (PTB), delivery that occurs before 37 weeks of completed gestation, is a marker for fetal underdevelopment and is related to subsequent adverse health outcomes (e.g., infant mortality, neurodevelopmental problems, growth issues) (Mathews and MacDorman, 2010; Saigal and Doyle, 2008; IOM, 2007; Gilbert et al., 2003). PTB is characterized by multiple etiologies (spontaneous, premature rupture of membranes, or medically induced), and identifying exact causes of PTB is difficult. It is likely that some mechanistic pathways are shared between the three groups; however, isolated causes are also likely to exist. Few, if any, studies distinguish between these three groups in examining associations between air pollution and PTB, though some investigations of premature rupture of membrane (PROM) have been conducted. There is substantial uncertainty surrounding the biological mechanisms leading to PTB, and multiple mechanisms may exist simultaneously.

Epidemiologic Evidence for Preterm Birth and Premature Rupture of Membranes (PROM)

The 2009 PM ISA (U.S. EPA, 2009) included limited number studies evaluating the relationship between $PM_{2.5}$ exposure and PTB, each of which reported a positive association. A number of uncertainties affecting interpretation of the evidence for an association between $PM_{2.5}$ exposure and PTB were identified in the 2009 PM ISA (U.S. EPA, 2009), such as identifying the relevant exposure period. The number of studies evaluating the relationship between $PM_{2.5}$ exposure and PTB has grown considerably in the last decade, and the majority of recent studies report positive associations between $PM_{2.5}$ exposure and PTB, frequently for exposures averaged over the entire pregnancy period (Defranco et al., 2016; Hao et al., 2016; Laurent et al., 2016; Lavigne et al., 2016b; Mendola et al., 2016a; Pereira et al., 2015; Ha et al., 2014; Padula et al., 2014; Pereira et al., 2014a; Chang et al., 2013; Lee et al., 2013; Kloog et al., 2012; Salihu et al., 2012; Warren et al., 2012; Gehring et al., 2011; Wilhelm et al., 2011; Wu et al., 2011; Wu et al., 2009; Brauer et al., 2008). However, while the body of literature has grown considerably since the last review, the evidence from these studies is less consistent than reported in the 2009 PM ISA (U.S. EPA, 2009). Several recent studies report null (Giorgis-Allemand et al., 2017; Mendola et al., 2016a; Hannam et al., 2014; Hyder et al., 2014; Pereira et al., 2014a; Salihu et al., 2012;

Gehring et al., 2011; Rudra et al., 2011; Darrow et al., 2009) or negative (Johnson et al., 2016; Mendola et al., 2016a; Stieb et al., 2015; Pereira et al., 2014a) effect estimates. All of these studies are characterized in Supplemental Table S9-3 (U.S. EPA, 2018).

Many of the studies of $PM_{2.5}$ and preterm birth are conducted in North America, where annual average $PM_{2.5}$ concentrations have decreased considerably in the last decade, and are summarized in Table 9-6. All of the studies included in the 2009 PM ISA (U.S. EPA, 2009) relied on fixed-site monitors to assign exposure $PM_{2.5}$. While many more recent studies have used satellite-based methods or statistical models to assign $PM_{2.5}$ exposure, several recent studies estimated $PM_{2.5}$ concentrations from fixed-site monitors in order to assign exposure. In a study of a cohort from Hillsborough county Florida, Salihu et al. (2012) report ORs elevated from the null with $PM_{2.5}$ exposure using nearest monitor to assign entire pregnancy exposure. In a longitudinal cohort from Rochester NY, which followed 3,264 women over 7,121 pregnancies, positive effect estimates were reported for all trimester exposures, with the highest magnitude with exposures in the first trimester (OR: 1.69, 95% CI: 1.22, 2.29) (Pereira et al., 2015). Effect estimates from this study, which used nearest monitor for exposure assignment, were similar for all buffer distances around monitors (Pereira et al., 2015). Brauer et al. (2008) reported positive ORs using both LUR and IDW in a Vancouver cohort with entire pregnancy exposure (OR: 1.34, 95% CI: 1.05, 1.69). A small Washington state study using LUR to estimate $PM_{2.5}$ exposure over the last 3 months of pregnancy, and a study in New York City utilizing combinations of fixed-site monitoring data and air survey data reported null associations (Johnson et al., 2016; Rudra et al., 2011).

Some recent studies used statistical models or satellite-based methods to estimate exposure to $PM_{2.5}$ when evaluating associations with PTB. In a California-based population, (Wu et al., 2011) observed increased odds of PTB with higher levels of $PM_{2.5}$ estimated with the CALINE 4 dispersion model and averaged over the entire pregnancy period. They also observed higher magnitude effect estimates with very PTB (<30-weeks gestational age) compared to moderate PTB (<35-weeks gestational age) or PTB (<37-weeks gestational age). In a study of a Florida cohort, using the EPA's hierarchical Bayesian CMAQ model output for $PM_{2.5}$ concentrations, Ha et al. (2014) reported positive ORs across all trimesters and for entire pregnancy exposures (entire pregnancy OR: 1.14, 95% CI: 1.10, 1.18). The magnitude of the estimate effects was increased after adjustment for ozone in exposure for first and second trimesters and entire pregnancy (entire pregnancy OR after adjustment for ozone: 1.29, 95% CI: 1.20, 1.38), while those for the third trimester remained positive, but were somewhat attenuated (Ha et al., 2014). Hao et al. (2016) reported a positive association with PTB using fused CMAQ model estimates of $PM_{2.5}$ concentrations in Georgia (U.S.) Lavigne et al. (2016b) and Kloog et al. (2012) observed increased ORs for entire pregnancy exposure to $PM_{2.5}$ estimated with satellite-based models for a cohort of more than 800,000 women in Ontario, Canada and a large Massachusetts cohort, respectively.

Several recent studies evaluated the association between $PM_{2.5}$ exposure and PTB using both fixed-site monitoring data and satellite-based methods to assign exposure. In a cohort set in both Massachusetts and Connecticut, Hyder et al. (2014) reported null associations between PTB and $PM_{2.5}$

exposure over the entire pregnancy period; this study used fixed-site monitors and two separate satellite-based models to estimate exposures; results were consistently null or negative across exposure assignment metrics. Finally, a study of over 2.78 million births across Canada, using a both fixed-site monitor and satellite-based LUR metrics to estimate exposures over the entire pregnancy period, reported inverse ORs with increasing $PM_{2.5}$ exposure (Stieb et al., 2015).

There were no studies included in the 2009 PM ISA (U.S. EPA, 2009) that examined the relationship between $PM_{2.5}$ exposure and PROM. Recent studies evaluate the relationship between both short- and long-term $PM_{2.5}$ exposure and PROM. Effect estimates are inconsistent across recent studies of PROM for long-term $PM_{2.5}$ exposure. An Australian cohort reported elevated ORs with exposure to $PM_{2.5}$ in the second and third trimesters (Pereira et al., 2014b). A U.S. cohort reported relative risks below the null for both PROM and preterm PROM (Wallace et al., 2016), and a small Rochester, NY cohort (n = 3,264) followed over multiple pregnancies reported null associations (Pereira et al., 2015).

Several recent studies examined the association between short-term $PM_{2.5}$ exposure and PTB. Darrow et al. (2009) report null associations using a time-series design with 1-week lagged exposures. Also, using a time-series design, Arroyo et al. (2015) observed positive associations with a 1-day lagged $PM_{2.5}$ exposure, and exposure during week 17 of gestation (Arroyo et al., 2016). Symanski et al. (2014) and Rappazzo et al. (2014) separated PTB into multiple categories based on gestational age. Both observed positive and negative associations depending on combined exposure and outcome period, Symanski et al. (2014) with 4-week exposures, and Rappazzo et al. (2014) with exposures during individual weeks of pregnancy. Warren et al. (2012) also examined exposures at individual weeks of pregnancy, observing elevated associations through week 22 of pregnancy. An additional U.S. study observed positive associations with PROM and $PM_{2.5}$ concentrations estimated from a modified CMAQ model in the 5 hours before hospital admission (Wallace et al., 2016).

In summary, a number of recent studies expand and extend the evidence included in the 2009 PM ISA (U.S. EPA, 2009) for relationship between $PM_{2.5}$ exposure and PTB, though the larger body of literature is somewhat less consistent than the small body of evidence in the 2009 PM ISA. Among studies conducted in North America, where mean $PM_{2.5}$ concentrations tended to be below 12 $\mu g/m^3$, generally positive associations were observed between PTB and $PM_{2.5}$ exposure. This pattern of positive associations was consistent across studies that used fixed-site monitors, statistical models, or satellite-based methods to assign exposure. Addressing an uncertainty identified in the 2009 PM ISA (U.S. EPA, 2009), a study that included a copollutant model including $PM_{2.5}$ and ozone reported the positive association between $PM_{2.5}$ exposure and PTB to be robust to adjustment for ozone. However, timing of exposure, another uncertainty identified in the 2009 PM ISA (U.S. EPA, 2009), varies considerably across these studies and remains an uncertainty in interpreting the results of these studies. In addition to PTB, recent studies also evaluated the relationship between short- and long-term $PM_{2.5}$ exposure and PROM, and outcome that was not included in the 2009 PM ISA (U.S. EPA, 2009). These studies report inconsistent results across studies examining both short- and long-term $PM_{2.5}$ exposures.

†Studies published since the 2009 Integrated Science Assessment for Particulate Matter.

Toxicological Evidence for Preterm birth

The 2009 PM ISA (U.S. EPA, 2009) contained no animal studies of preterm birth. A more recent study monitored pup gestational day at birth to determine if pups were born preterm after CAPs exposure (6 hours/day) during specific windows or trimesters of pregnancy. B6CF1 mouse preterm birth was associated with 2nd, 3rd, or entire pregnancy exposure to Sterling Forest CAPs (Blum et al., 2017). $PM_{2.5}$ exposure during certain periods of pregnancy was associated with preterm birth in mouse pups.

9.1.2.5 Birth Defects

Birth defects are structural and functional abnormalities that can cause physical disability, intellectual disability, and other health problems; they are a leading cause of infant mortality and developmental disability in the U.S. Periods of sensitivity to birth defect development are known for many anomaly types; for example, the critical period of cardiac organogenesis, and thus heart defects, is post-conception weeks 3−8. This knowledge of critical periods means that there are fewer uncertainties around timing of exposure for birth defects compared to other birth outcomes. Birth defects as a category are uncommon, occurring in approximately 3% of live births, and low numbers of specific birth defects can lead to wide confidence intervals in epidemiologic studies investigating environmental causes of birth defects.

Epidemiologic Evidence for Birth Defects

The 2009 PM ISA (U.S. EPA, 2009) synthesized small numbers of studies of PM and birth defects; these often focused on PM10 as the exposure of interest. Though overall numbers remain small, there are several new studies of $PM_{2.5}$ and birth defects, typically cardiac or orofacial defects. These studies are primarily conducted within the U.S., and study populations often arise from states with active birth defect registries, where experts will seek out infants with records of birth defects. One study used data from the National Birth Defects Prevention Study, a large multistate initiative with detailed residential histories and information on many potential confounders, and examined associations between both short- (week long) and longer-term exposure periods (average over post-conception weeks 2−8) and cardiac birth defects (Stingone et al., 2014). In Stingone et al. (2014), median $PM_{2.5}$ levels assigned with monitors across the period of interest were 11.6 $\mu g/m^3$; $PM_{2.5}$ exposure was associated with increased odds of some cardiac defects (hypoplastic left heart syndrome, atrioventricular septal defect), decreased for others (atrial septal defects [ASD]), and null for many. This pattern of results is reflected in the general body of literature for cardiac defects, where several studies have shown either null associations or decreased odds of heart defects (including ASD) with $PM_{2.5}$ exposure (Vinikoor-Imler et al., 2015; Schembari et al., 2014; Agay-Shay et al., 2013; Padula et al., 2013c), while others have reported positive odds ratios (Girguis et al., 2016; Zhang et al., 2016; Salemi et al., 2015; Padula et al., 2013b). Studies of orofacial defects have similar issues, and report inconsistent results (Zhu et al., 2015; Padula et al., 2013a; Marshall et al., 2010). Studies of other types of birth defects have reported positive associations with limb defects (Vinikoor-Imler et al., 2013) and abdominal wall defects (Schembari et al., 2014), and negative associations with sperm disomy (Jurewicz et al., 2014). When examining weekly exposure, Stingone et al. (2014) observed increased odds of Tetralogy of Fallot and pulmonary valve stenosis at higher deciles of $PM_{2.5}$ exposure, and Zhu et al. (2015) observed increased odds of cleft lip with or without cleft palate with $PM_{2.5}$ exposure. In a further analysis of the population analyzed in Stingone et al. (2014), Warren et al. (2016) identified different gestational days as critical $PM_{2.5}$ exposure periods for Tetralogy of Fallot and pulmonary valve stenosis.

In summary, results for most birth defects are inconsistent across studies, or have a limited number of studies, hindering the ability to draw conclusions about this body of literature. Studies of birth defects and $PM_{2.5}$ are characterized in Supplemental Table S9-4 (U.S. EPA, 2018).

Toxicological Evidence for Birth Defects

No previous animal toxicology study addressed birth defects with $PM_{2.5}$ exposure. In a recent study, the effect of $PM_{2.5}$ on exacerbating congenital heart defects was evaluated in an animal model (Chen et al., 2016). Elevated homocysteine levels or hyperhomocysteinaemia during pregnancy, is a risk factor for pregnancy complications including congenital heart defects (Verkleij-Hagoort et al., 2006). $PM_{2.5}$ exposure potentiated the adverse fetal cardiovascular outcomes in rodent pups whose dams were hyperhomocysteinaemic during pregnancy (Chen et al., 2016). In this study, animals were exposed to

ambient $PM_{2.5}$ ($PM_{2.5}$, range 8−68 μg/m^3, mean 36 μg/m^3) in Fuzhou China or filtered air (FA) with particles removed (Chen et al., 2016). Pregnant dams were exposed to $PM_{2.5}$ during pregnancy and lactation and were made hyperhomocysteinaemic at the sensitive window for heart development (G8−G10). Various endpoints including morphological changes to the heart, apoptosis of the myocardium, cardiac progenitor transcriptional factor levels, and cytokine concentrations were studied in the offspring. $PM_{2.5}$ exposure potentiated the adverse morphological changes to the heart (atrial, ventral, or septal heart defects) that were induced by HCY. These morphological changes to the heart were accompanied by changes in myocardial apoptosis, expression of cardiac progenitors (GATA4 and Nkx2−5), and changes in cytokines (TNF-a and IL-1B).

9.1.2.6 Fetal and Infant Mortality

Fetal mortality is the intrauterine death of a fetus. Often these deaths are divided into those occurring before 20 weeks of gestation (spontaneous abortion) and those occurring after (miscarriage/stillbirth). In most areas, fetal deaths are only reported after 20 weeks of completed gestation; this may lead to potential bias, as the population at risk of fetal death is any conception but the actual measured population is only those fetuses reaching at least 20 weeks gestational age. Studies therefore tend to focus on the miscarriage/stillbirth fraction of fetal mortality. Infant mortality is a death occurring in the first year of life, and is divided into two periods: neonatal (i.e., death during the first 28 days), and post-neonatal (i.e., death after the first month of life and before the first birthday). The 2009 PM ISA (U.S. EPA, 2009) reported limited evidence for an association between PM_{10} and fetal mortality (measured as stillbirth) and consistent epidemiologic evidence for an association between PM_{10} exposure and infant mortality, especially due to respiratory causes during the post-neonatal period. A limited number of studies included in the 2009 PM ISA (U.S. EPA, 2009) evaluated the association between $PM_{2.5}$ exposure and infant mortality, and none considered infant mortality due to respiratory causes during the post-neonatal period.

In studies of fetal mortality occurring after 20 weeks of gestation, recent studies generally report positive associations, though timing of exposure varies across studies (Defranco et al., 2015; Green et al., 2015; Faiz et al., 2012). Defranco et al. (2015) reported positive associations with high $PM_{2.5}$ exposure (defined as above mean plus IQR) in entire pregnancy and third trimester, but not first or second trimesters. Green et al. (2015) observed positive associations with entire pregnancy exposures (OR 1.03, 95% CI: 0.99, 1.06), though these associations were attenuated after adjustment for NO_2 (OR 0.98, 95% CI: 0.93, 1.05), and stratification by California air basin resulted in associations with higher magnitudes (e.g., Sacramento Valley OR: 1.16, 95% CI: 1.00, 1.35; San Francisco Bay OR: 1.15, 95% CI: 0.97, 1.36). In a New Jersey study, Faiz et al. (2012) observed positive associations in all trimesters, though slightly stronger ones in the first and second trimesters. In a study of short-term exposures, Faiz et al. (2013) reported a positive association with stillbirth and $PM_{2.5}$ exposure averaged over the two previous days previous, though associations were attenuated to the null after copollutant adjustment (i.e., NO_2,

SO_2). Arroyo et al. (2016) also reported a positive association with short-term $PM_{2.5}$ exposure in gestational week 31 and late fetal death (less than 24 hours after birth). Studies of fetal mortality and $PM_{2.5}$ are characterized in Supplemental Table S9-5 (U.S. EPA, 2018).

The two studies of post-neonatal infant mortality reported positive associations for all-cause mortality, respiratory related mortality, and sudden infant death syndrome (SIDS) (Son et al., 2011b; Woodruff et al., 2008). In the U.S.-based study, the association for respiratory-related mortality (OR: 1.08, 95% CI: 0.97, 1.20) remained positive but was attenuated after adjusting for CO (OR: 1.04, 95% CI: 1.04, 0.92, 1.17), and other gaseous pollutants (i.e., SO_2, and O_3), while the association for SIDS moved away from the null after adjusting for CO in copollutant models Woodruff et al. (2008). In a case-crossover study, Yorifuji et al. (2016) report associations between same day $PM_{2.5}$ and post-neonatal death and all-cause deaths, as well as deaths related to respiratory, SIDS, and birth defects. Studies of infant mortality and $PM_{2.5}$ are characterized in Supplemental Table S9-5 (U.S. EPA, 2018).

9.1.3 Developmental Effects

Pregnancy and infancy are periods of rapid development and exposures occurring during these times may have long-lasting effects that do not manifest immediately (i.e., fetal origins or fetal programming hypothesis). Researchers have examined several health outcomes in associations with exposures during the periods of early development including: cancer (Chapter 8), growth (Chapter 9), infection (Chapter 5), eczema (Chapter 5), neurodevelopmental effects including autism (Chapter 8), cardiovascular effects (Chapter 7) and respiratory effects including asthma (Chapter 5). Of these, respiratory and neurodevelopmental outcomes are the most studied. In addition, these studies of early-life exposure provide evidence that long-term $PM_{2.5}$ exposure is associated with developmental effects (Table 9-7). The developmental studies are characterized in more detail in their respective sections elsewhere in the ISA and are presented here as summaries.

Table 9-7 Summary of developmental effects.

Developmental Effects	Summary of Evidence	Cross-link to Study Details	Causal Determination
Respiratory	Epidemiologic evidence: Studies provide evidence of decrements in lung function growth, asthma development, and respiratory infection.	Section 5.2.2.1 Section 5.2.3.1 Section 5.2.2	**Causal relationship is likely** to exist for long-term exposure to $PM_{2.5}$ and respiratory effects
	Toxicological evidence: Early life exposure to particulate matter has the potential to alter the growth or function of the respiratory system.		
Neurodevelopmental	Epidemiologic evidence: Limited body of evidence does not provide consistent evidence of positive associations with cognitive and behavioral effects or autism.	Section 8.2.7.2	**Causal relationship is likely** to exist for long-term exposure to $PM_{2.5}$ and nervous system effects
	Toxicological evidence: Neurodevelopment in laboratory animal toxicology studies is impacted by $PM_{2.5}$ exposure, including the structural change of ventriculomegaly, and brain inflammatory activation.	Section 8.2.7.2	
Cardiovascular	Epidemiologic evidence: $PM_{2.5}$ exposure was associated with increased odds of some cardiac defects, decreased for others, and null for many.	Section 6.2.5 Section 9.1.2.5	**Causal relationship** exists for long-term exposure to $PM_{2.5}$ and cardiovascular system effects
	Toxicological evidence: Early life exposure to PM in animal models has effects on the developing heart, inducing heart failure in adult animals after early life PM exposure.	Section 6.2.5.2 Section 9.1.2.5	

9.1.3.1 Respiratory Developmental Effects

Epidemiologic Evidence of Respiratory Development

Recent studies evaluate the relationship between $PM_{2.5}$ exposure during the prenatal period and/or the first year of life and respiratory health effects and generally observe positive associations. These studies are characterized in Chapter 5, and include studies of lung development (Section 5.2.2.1), lung function (Section 5.2.2.2.1), asthma development (Section 5.2.3.1) and respiratory infection (Section 5.2.6). Evidence from these studies inform and contribute to the conclusion that there is likely to be a causal relationship between long-term $PM_{2.5}$ exposure and respiratory effects. In addition, these studies of early life exposure provide evidence that long-term $PM_{2.5}$ exposure is associated with developmental effects (Table 9-7).

Toxicological Evidence for Respiratory Development

Early life exposure to particulate matter has the potential to alter the growth or function of the respiratory system. Multiple lines of evidence support that $PM_{2.5}$ or its soluble components can cross the placenta or the maternal fetal barrier to the fetal circulation with the potential to impact the developing fetus (Valentino et al., 2016; Veras et al., 2008). The existing evidence for the current ISA is summarized below in Table 9-7. The 2009 PM ISA (U.S. EPA, 2009) included a study of mice with impaired lung development and lung function after prenatal plus postnatal exposure to ambient $PM_{2.5}$ (Mauad et al., 2008); pulmonary pressure volume analysis demonstrated significant reductions in inspiratory and expiratory volumes and structural aberration included incomplete alveolarization of the lungs. In addition, Pires-Neto et al. (2006) found secretory changes in the nasal cavity of young mice exposed for 5 months to urban $PM_{2.5}$. These findings are discussed in Section 5.2.2.

In studies of DEP and asthma, prenatal DEP exposure increased susceptibility of animals to adult-induced allergic (ovalbumin [OVA]) asthma (significantly increased lung resistance and airway hyper-responsiveness, increased airway inflammation), shifted TH1 and TH2 responses and increased BAL cell counts all in an Aryl Hydrocarbon Receptor (AHR)-dependent mechanism (Manners et al., 2014). Another recent study showed diesel exhaust particulate exposure in utero and allergen exposure in utero conveyed protection from systemic and airway allergic (Aspergillus-induced) immune responses in adult offspring (Corson et al., 2010); adult offspring had a lower immune response when exposed in utero to DE or DE and Aspergillus fumigatus in combination versus allergen.

In another recent study, gestational and early prenatal exposure to Beijing $PM_{2.5}$ is associated with significant lung pathology (peribronchial and perivascular inflammation), increased oxidant production and a decreased antioxidant pool as well as significant changes to circadian clock gene expression (Song et al., 2017). More details on these studies can be found in Section 5.2.2.

9.1.3.2 Neurodevelopmental Effects

Epidemiologic Evidence of Neurodevelopment

Recent studies evaluate the relationship between $PM_{2.5}$ exposure during the prenatal period and/or the first year of life and neurodevelopmental effects and the limited body of evidence does not provide consistent evidence of positive associations. These studies are characterized in Chapter 8, and include studies of cognitive and behavioral effects (Section 8.2.7.1), and autism (Section 8.2.7.2). Evidence from these studies inform and contribute to the conclusion that there is likely to be a causal relationship between long-term $PM_{2.5}$ exposure and nervous system effects. In addition, these studies of early-life exposure provide evidence that long-term $PM_{2.5}$ exposure is associated with developmental effects (Table 9-7).

Toxicological Evidence of Neurodevelopment

The 2009 PM ISA U.S. EPA (2009) contained no studies on neurodevelopmental animal toxicology outcomes. The current ISA explores the effect of $PM_{2.5}$ exposure on behavioral outcomes that can be included in the autism spectrum or as an attention deficit or hyperactivity and structural changes in the brain that may accompany autism, ADHD or mental illness, e.g., ventricular enlargement. A recent study (Klocke et al., 2017) showed that prenatal exposure to CAPs was associated with ventriculomegaly in male and female offspring and increased numbers of activated microglia in the brain as well as multiple other brain structural changes. Females had significantly increased iron deposition in the CC with prenatal CAPs exposure; males had significantly decreased total number of microglia in the CC with a nonsignificant trend trended in this direction for females. Neurodevelopment in laboratory animal toxicology studies is impacted by $PM_{2.5}$ exposure, including the structural change of ventriculomegaly, and brain inflammatory activation. Key details from these studies is summarized in Table 9-7. These studies are discussed in more detail in CHAPTER 8.

9.1.3.3 Cardiovascular Effects

Since the 2009 PM ISA (U.S. EPA, 2009), new studies have evaluated developmental cardiovascular risk in animal models after PM exposure and are described below. The two new studies of cardiovascular effects found PM-dependent heart failure and exacerbation of existing congenital heart defects (birth defects section of the ISA, Section 9.3.1). This new study is summarized in Table 9-7.

Toxicological Evidence of Cardiodevelopment

Work by Gorr et al. (2014) showed prenatal and lactational $PM_{2.5}$ exposure induced heart failure in adult offspring with anatomy (dilated cardiomyopathy with ventricular volume changes, and ventricular wall thickening), functional measures (impaired pressure-volume loops and deficits in contraction length) and cellular manifestation (delayed calcium reuptake during relaxation and reduced response to B-adrenergic stimulation, increased cardiac collagen deposition) confirming heart failure. In work from the same lab, Tanwar et al. (2017) showed that prenatal exposure alone to ambient air PM was sufficient to produce heart failure in adulthood, looking at similar outcomes as Gorr et al. (2014) and mechanisms including acute inflammation in cardiac tissue at birth, and changes in cardiac epigenetic markers (sirtuins and DNA methyltransferases). Early life exposure to PM in animal models has effects on the developing heart, inducing heart failure in adult animals after early life PM exposure. For more details on these studies, see Chapter 6.

9.1.3.4 Postnatal Growth and Development

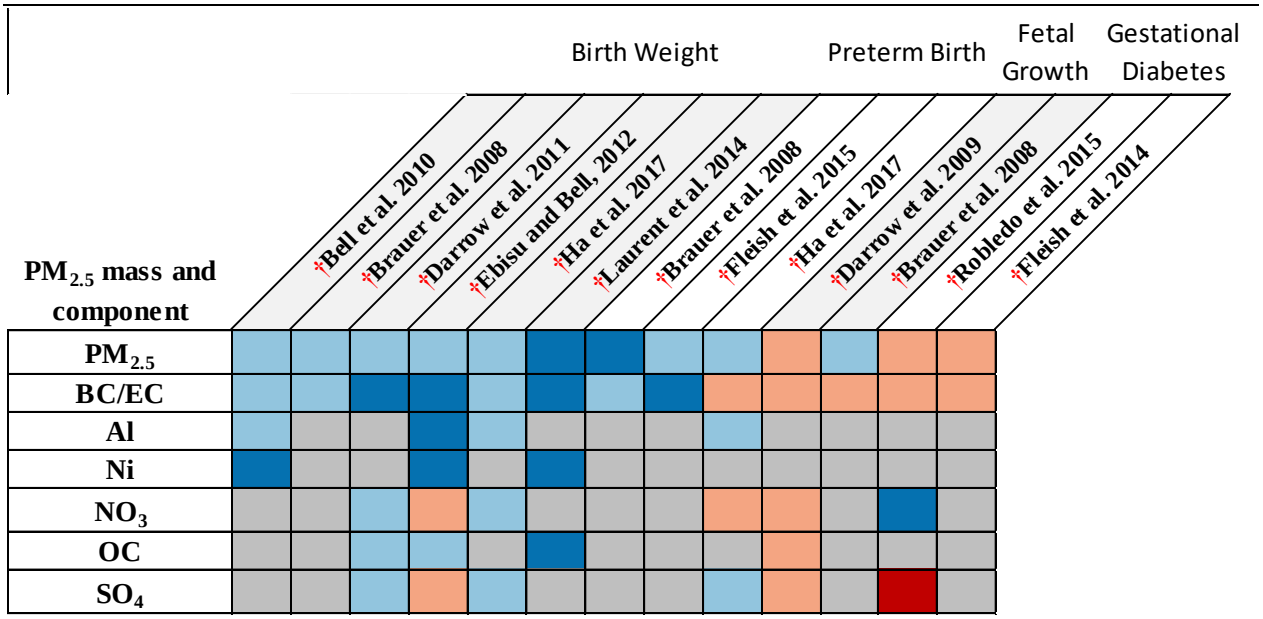
Growth of murine pups in the postnatal period was measured after prenatal exposure to Sterling Forest CAPs. Exposure to CAPs for 6 hours/day during any of the three trimesters of murine pregnancy or during the entire pregnancy was not associated with altered postnatal pup body weight gain in either male or female pups. (Blum et al., 2017).

9.1.4 Associations Between $PM_{2.5}$ Components and Sources and Reproductive and Developmental Effects

In general, few studies have examined associations between $PM_{2.5}$ components and birth outcomes. Elemental carbon (EC) is the component most studied across outcomes, and low birth weight (LBW) is the outcome most commonly evaluated. The evaluation of the association between $PM_{2.5}$ components and reproductive and developmental effects is complicated by the different methods applied across studies. As a result, the systematic standardization of results across studies (i.e., per 5 $\mu g/m^3$ increase), as is the convention throughout this ISA, is not possible when evaluating results for $PM_{2.5}$ components. Overall, the results for individual $PM_{2.5}$ components across studies are generally more imprecise than the results for $PM_{2.5}$ (i.e., much wider confidence intervals, often including the null value), which make the individual results, as well as results across studies, more difficult to interpret. As such, for the purposes of characterizing results with respect to $PM_{2.5}$ components a different convention is employed to evaluate the pattern of associations across studies. Specifically, risk estimates from studies are classified into four categories in Figure 9-3: (1) statistically significant positive associations; (2) positive associations, regardless of width of the confidence interval; (3) null or negative association; and (4) statistically significant negative association. Figure 9-3 demonstrates consistent positive associations for birth weight and preterm birth and exposure to $PM_{2.5}$, BC/EC, OC, and Al, with more studies evaluating $PM_{2.5}$ and BC/EC, and fewer studies examining other components. Based on the pattern of results across this limited number of studies, it is difficult to disentangle the independent effect of any of these components from the effect of $PM_{2.5}$ mass.

Among the studies that examine $PM_{2.5}$ components and LBW, all found positive associations with some components (Ha et al., 2017; Laurent et al., 2014; Ebisu and Bell, 2012; Darrow et al., 2011; Bell et al., 2010). In particular, EC was associated with decrements in birth weight or increased odds of LBW in all studies (Ha et al., 2017; Laurent et al., 2014; Ebisu and Bell, 2012; Darrow et al., 2011; Bell et al., 2010). A four-county cohort in Massachusetts and Connecticut using positive matric factorization to estimate concentrations averaged over the entire pregnancy observed associations with EC, silicon, aluminum, vanadium, and nickel (Bell et al., 2010). Another study included all counties in northeast and mid-Atlantic states with PM composition monitors, reporting positive association between EC, aluminum, calcium, nickel, silicon, titanium, and zinc and LBW or changes in birth weight (Ebisu and Bell, 2012). A study of the five-county Atlanta area reported null associations between $PM_{2.5}$ components and birth

weight in the first month of pregnancy, but both EC and water soluble metals (sum of chromium, copper, iron, manganese, nickel, and vanadium) concentrations were associated with changes in birth weight during the third trimester (Darrow et al., 2011). Laurent et al. (2014), used a spatio-temporal chemical transport model to examine components in Los Angeles county, and observed positive associations between EC, organic carbon, potassium, iron, chromium, nickel, and titanium associated and LBW.



Dark blue = study reported statistically significant positive association; Light blue = study reported a positive association regardless of width of confidence intervals; Light orange = study reported null or negative association; Red = study reported statistically significant negative association; Gray = study did not examine individual component. Only those $PM_{2.5}$ components that were examined in at least three studies are included in this figure.

†$PM_{2.5}$ component studies published since the 2009 PM ISA (U.S. EPA, 2009).

Figure 9-3 Heat map of associations observed between $PM_{2.5}$ and $PM_{2.5}$ components and birth outcomes and effects on pregnancy.

Additional studies have examined the relationship between PM component exposure and fetal growth (Fleisch et al., 2015; Brauer et al., 2008), and preterm birth (Darrow et al., 2009; Brauer et al., 2008). These studies generally report null associations for the components and fetal growth effects.

Among studies of pregnancy, a positive association between gestational diabetes and NO_3 was reported in a large U.S. cohort (Robledo et al., 2015). EC, organic carbon, and ammonium were not associated with gestational diabetes (Robledo et al., 2015; Fleisch et al., 2014).

In summary, there is no evidence than any component(s) is more strongly associated with any reproductive effects than $PM_{2.5}$.

9.1.5 Summary and Causality Determination

Overall, the evidence is suggestive of, but not sufficient to infer, a causal relationship between exposure to $PM_{2.5}$ and (1) male and female fertility and reproduction and (2) pregnancy and birth outcomes. Separate conclusions are made for these groups of reproductive and developmental effects because they are likely to have different etiologies and critical exposure windows over different lifestages. All available evidence examining the relationship between exposure to $PM_{2.5}$ and reproductive and developmental effects was evaluated using the framework described in the Preamble to the ISAs (U.S. EPA, 2015, HEROID). At the time of the 2009 PM ISA (U.S. EPA, 2009), evidence from the epidemiologic and toxicological studies had assessed the broader relationship between $PM_{2.5}$ exposure and reproductive and developmental effects. The 2009 ISA (U.S. EPA, 2009) concluded that the evidence was suggestive for a causal association between PM exposure and reproductive and developmental outcomes. The strongest evidence supporting the causality determination from the 2009 PM ISA (U.S. EPA, 2009) came from studies on low birth weight and developmental outcomes including infant mortality, especially due to respiratory causes during the post-neonatal period. This ISA continues to see strong supporting evidence from low birth weight. There is limited new evidence to inform the relationship between $PM_{2.5}$ and infant mortality from respiratory causes during the post-natal period; developmental outcomes are discussed in more detail in their specific organ system chapter. The developmental animal toxicological evidence has expanded greatly and is characterized elsewhere (respiratory, nervous system). The key evidence, as it relates to the causal framework, is summarized in Table 9-8. **Overall, the evidence is suggestive of, but not sufficient to infer, a causal relationship between $PM_{2.5}$ exposure and (1) Male and Female Reproduction and Fertility, (2) Pregnancy and Birth Outcomes.**

9.1.5.1 Male and Female Fertility and Reproduction

Overall the evidence is suggestive of, but not sufficient to infer a causal relationship between exposure to $PM_{2.5}$ and male and female fertility and reproduction. This is consistent with the 2009 PM ISA, which also concluded the evidence was suggestive of a causal relationship with reproductive and developmental effects. The key evidence supporting the causality determination is detailed below using the framework described in Table I of the Preamble to the ISAs (U.S. EPA, 2015, HERO ID) and is presented in Table 9-8. All available evidence examining the relationship between exposure to $PM_{2.5}$ and pregnancy and birth outcomes was thoroughly evaluated.

The relationship between $PM_{2.5}$ exposure and outcomes related to male and female fertility and reproduction are continuing to be evaluated in the literature, and thus, the number of studies for any one endpoint continues to grow. But questions remain surrounding uncertainties from lack of evaluation of copollutant confounding or multiple potential sensitive windows of exposure. Effects of $PM_{2.5}$ exposure on male reproduction have been studied in both the animal toxicology and the epidemiologic literature.

The strongest effects with $PM_{2.5}$ exposure come from studies on sperm motility (epidemiologic literature) and spermiation (animal toxicology literature). Other studies on sperm including the epidemiologic literature on sperm morphology have inconsistent results. Studies of female reproduction in association with $PM_{2.5}$ exposure also have mixed results. In rodents, ovulation and estrus are affected by PM exposure. In the epidemiologic literature, results on human fertility and fecundity in association with $PM_{2.5}$ exposure is limited, with evidence from IVF showing a modest association of $PM_{2.5}$ concentrations with decreased odds of becoming pregnant. Animal toxicological studies show inconsistent results from $PM_{2.5}$ exposure and its effects on reproduction. Biological plausibility for outcomes on Male and Female Fertility and Reproduction come from laboratory animal studies shown genetic and epigenetic changes to germ cells with $PM_{2.5}$ exposure (Section 9.1.1.1). **Collectively, the evidence is suggestive of, but not sufficient to infer, a causal relationship between $PM_{2.5}$ exposure and male and female reproduction and fertility.**

Table 9-8 Summary of evidence that is suggestive of, but not sufficient to infer, a causal relationship between $PM_{2.5}$ exposure and male and female reproduction and fertility.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{2.5}$ Concentrations Associated with Effects[c]
Limited evidence from multiple epidemiologic studies on sperm quality, fertility and is generally supportive but not entirely consistent	Limited evidence for decreases in sperm motility	Section 9.1.1.2 Hammoud et al. (2009) Radwan et al. (2015)	~15 µg/m^3 34.5 µg/m^3
	Limited evidence for decreased IVF success	Section 9.1.1.3 Legro et al. (2010)	14.08 µg/m^3
	Limited evidence of decreases in fecundability	Section 9.1.1.3 Slama et al. (2013)	34.0 µg/m^3
Limited number of supportive toxicological evidence for effects on male and female fertility and reproduction	Limited evidence for effects on spermatogenesis and spermiation with prenatal or early postnatal exposure	Pires et al. (2011)	16.61 µg/m^3
	Limited evidence of effects on estrous cycle (prolonged cycle), and number of ova (decreased number of antral follicles)	Veras et al. (2009)	27.5 µg/m^3
	Inconsistent evidence of decreased litter size	Veras et al. (2009) (Klocke et al., 2017)	27.5 µg/m^3 92.7 µg/m^3

Table 9-8 (Continued): Summary of evidence that is suggestive of, but not sufficient to infer, a causal relationship between $PM_{2.5}$ exposure and male and female reproduction and fertility.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{2.5}$ Concentrations Associated with Effects[c]
Uncertainty regarding epidemiologic evidence from copollutant models to support an independent $PM_{2.5}$ association	$PM_{2.5}$ effect estimates robust in limited analyses of copollutant models, but generally evaluation of potential copollutant confounding is limited	Radwan et al. (2015)	
Uncertainty due to limited biological plausibility from studies of pregnancy and birth outcomes	Some evidence for initial events that could lead to subsequent effects on sperm, ovulation and the estrous cycle	Section 9.1.1.1 Figure 9-1 Table 9-1	

$PM_{2.5}$ = particulate matter with a nominal aerodynamic diameter less than or equal to 2.5 μm; $PM_{10-2.5}$ = particulate matter with a nominal aerodynamic diameter less than or equal to 10 μm and greater than a nominal diameter of 2.5 μm.

[c]Describes the $PM_{10-2.5}$ concentrations with which the evidence is substantiated.

9.1.5.2 Pregnancy and Birth Outcomes

Overall the evidence is suggestive of, but not sufficient to infer a causal relationship between exposure to $PM_{2.5}$ and pregnancy and birth outcomes. This is consistent with the 2009 PM ISA, which also concluded the evidence was suggestive of a causal relationship with reproductive and developmental effects. All available evidence examining the relationship between exposure to $PM_{2.5}$ and pregnancy and birth outcomes was evaluated using the framework described in the Preamble to the ISAs (U.S. EPA, 2015b). The key evidence as it relates to the causal framework is summarized in Table 9-9. There are several well-designed, well-conducted studies that indicate an association between $PM_{2.5}$ and poorer birth outcomes, particularly low birth weight and preterm birth. Albeit, the collective evidence for many of the pregnancy and birth outcomes studies examined is not entirely consistent. There is also evidence for congenital heart defects of different types, as well as biological plausibility to support this outcome from the animal toxicology literature. For preterm birth, the timing of exposure was highly variable from study to study and limited assessment of potential copollutant confounding. The epidemiologic and toxicological literature generally show positive associations of $PM_{2.5}$ exposure with reduced fetal growth and reduced birth weight. Most of the epidemiologic studies do not control for copollutant confounding and do not have a specific sensitive window of exposure, but there is biological plausibility from the

animal toxicological literature in support of these outcomes as well as support for multiple sensitive windows for $PM_{2.5}$ exposure associated outcomes. Various pregnancy related pathologies including gestational hypertension, pre-eclampsia and gestational diabetes show inconsistent results in association with $PM_{2.5}$ exposure. Looking at gestational exposure during the second trimester for gestational diabetes, there are generally positive associations with $PM_{2.5}$ exposure.

There is some information on potential biological plausibility for effects of $PM_{2.5}$ on pregnancy and birth outcomes at relevant exposure levels for this ISA. $PM_{2.5}$ exposure in laboratory rodents induced impaired implantation, induced vascular endothelial dysfunction, and in humans was associated with epigenetic changes to the placenta, and impaired fetal thyroid function (Section 9.1.2.1). All of these pathways have the potential to contribute to the biological plausibility of $PM_{2.5}$ affecting pregnancy and birth outcomes. **In summary, the evidence is suggestive of, but not sufficient to infer, a causal relationship between exposure to $PM_{2.5}$ and pregnancy and birth outcomes.**

Table 9-9 Summary of evidence that is suggestive of, but not sufficient to infer, a causal relationship between $PM_{2.5}$ exposure and pregnancy and birth outcomes.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{2.5}$ Concentrations Associated with Effects[c]
Evidence from multiple epidemiologic studies of fetal growth and birth weight is generally consistent, but uncertainties remain	Positive associations from many studies, but variability in timing of exposure and limited assessment of copollutant confounding	Section 9.1.2 Table 9-6 Table 9-4	Mean concentrations across studies: 4.0−17.5 µg/m^3
Limited toxicological evidence for an effect of $PM_{2.5}$ on fetal growth and birth weight	Limited evidence that $PM_{2.5}$ exposure results in decreased birth weight of pups or decreased body length at birth	Section 9.1.2.3 Table 9-7	
Evidence from multiple epidemiologic studies of preterm birth is generally consistent, but uncertainties remain	Positive associations from many studies, but variability in timing of exposure and limited copollutant models to evaluate potential copollutant confounding	Section 9.1.2.4 Table 9-8 Table 9-4	Mean concentrations across studies: 1.8−22.1 µg/m^3

[c]Describes the $PM_{2.5}$ concentrations with which the evidence is substantiated.

9.1.5.3 Developmental Outcomes

Developmental outcomes with exposure to $PM_{2.5}$ are summarized in this chapter. Developmental evidence from the 2009 PM ISA (U.S. EPA, 2009) reported $PM_{2.5}$ associated with infant postnatal mortality, with effects stronger in those with respiratory illness. There is recent evidence from both epidemiologic and toxicological studies supporting a relationship between prenatal and childhood $PM_{2.5}$ exposure and effects on postnatal development, including effects on the respiratory, nervous, and cardiovascular systems (Table 9-7). These outcomes, while relevant to the broader reproductive and developmental category, are included in more depth in the specific organ systems of interest where causality determinations are made.

9.2 $PM_{10-2.5}$ Exposure and Reproductive and Developmental Effects

The evidence for effects of $PM_{10-2.5}$ on reproductive and developmental outcomes is characterized below. Infant respiratory mortality and decreased birth weight have the strongest evidence, reporting positive associations. Increased infant respiratory mortality was reported with increasing $PM_{10-2.5}$ exposure. Birth weight is associated with $PM_{10-2.5}$ exposure with reports of decreased birth weight with $PM_{10-2.5}$ exposure and increased odds of having a low birth weight baby with $PM_{10-2.5}$ exposure. Pre-term birth is associated with increasing $PM_{10-2.5}$ exposure as is infertility. Inconsistent evidence is seen with studies of birth defects and studies of pre-term birth with the literature being comprised of studies with positive associations as well as studies with null findings. Male and female reproduction and fertility studies show increased infertility and lower birth rates in epidemiologic studies of $PM_{10-2.5}$. No new studies on effects of $PM_{10-2.5}$ exposure on male and female reproduction and fertility have been reported in the animal toxicology literature. The 2009 PM ISA (U.S. EPA, 2009) contained studies of toxicological effects of $PM_{10-2.5}$ exposure with reproductive effects, but are not within the scope for this ISA. More detailed information on these studies is included in the sections that follow.

9.2.1 Male and Female Reproduction and Fertility

9.2.1.1 Biological Plausibility

There is a paucity of evidence for biological plausibility of health effects following exposure to $PM_{10-2.5}$ due to a dearth of information published in the literature. Thus, a biological plausibility figure

was not constructed for this size fraction. There have been a limited number of studies of reproductive health outcomes focused on $PM_{10–2.5}$ exposure; of these, few examine the same outcome. The studies are reported below as outcomes related to male and female reproduction and fertility.

9.2.1.2 Male and Female Reproduction and Fertility

$PM_{10–2.5}$ exposure has been studied in association with male and female reproduction and fertility in epidemiologic studies and details are reported herein. In examinations of the Nurses' Health Study, authors observed increased incident infertility and reduced endometriosis associated with increased $PM_{10–2.5}$ concentrations from a spatio-temporal model (Mahalingaiah et al., 2016; Mahalingaiah et al., 2014). In a cross-sectional study in Barcelona, Spain Nieuwenhuijsen et al. (2014) reported lower birth rates with increases in $PM_{10–2.5}$ from a land-use regression model.

No new studies on effects of $PM_{10–2.5}$ exposure on male and female reproductive effects and fertility have been reported in the literature. The 2009 PM ISA (U.S. EPA, 2009) contained studies of toxicological effects of $PM_{10–2.5}$ exposure with reproductive effects, but are not within the scope for this ISA.

In conclusion, increased infertility and lower birth rates were reported in epidemiologic studies of $PM_{10–2.5}$. No recent studies of laboratory animals studies on $PM_{10–2.5}$ are reported in this ISA. Overall, there are a limited number of studies which provide inconsistent evidence for an association between $PM_{10–2.5}$ exposure and a variety of reproductive effects. The results of these studies are summarized in Table 9-10.

9.2.2 Pregnancy and Birth Outcomes

9.2.2.1 Biological Plausibility

There is a paucity of evidence for biological plausibility of health effects following exposure to $PM_{10–2.5}$ due to a dearth of information published in the literature. Thus, a biological plausibility figure was not constructed for this size fraction. There have been a limited number of studies of pregnancy and birth outcomes focused on $PM_{10–2.5}$ exposure; of these, few examine the same outcome. The studies are reported below.

9.2.2.2 Pregnancy and Birth Outcomes

Pregnancy and birth outcomes from the epidemiologic literature have been reported in association with $PM_{10-2.5}$exposure and a summary of these studies follows. A Barcelona cohort found positive associations with preeclampsia (Dadvand et al., 2013a). In studies of preterm birth, time-series studies have reported null associations (Darrow et al., 2009) or elevated odds ratios (Salihu et al., 2012). Null effects were observed for PTB in pooled cohort study (ESCAPE) (Giorgis-Allemand et al., 2017). Salihu et al. (2012) observed elevated ORs for low birth weight, and Ebisu et al. (2016) observed small decreases in birth weight with increases in $PM_{10-2.5}$, including with adjustment for $PM_{2.5}$. A study of birth defects found both positive and negative associations with coarse PM exposure (Schembari et al., 2014).

In conclusion, a Barcelona cohort reported positive associations with pre-eclampsia rates, null effects were reported for preterm birth, elevated OR were reported for low birth weight and small decreases in birth weight were all reported in association with increasing $PM_{10-2.5}$. No recent studies of laboratory animals studies on pregnancy and birth outcomes with $PM_{10-2.5}$ exposure are reported in this ISA. Overall, there are a limited number of studies which provide inconsistent evidence for an association between $PM_{10-2.5}$ exposure and a variety of reproductive effects. The results of these studies are summarized in Table 9-10.

9.2.3 Developmental Outcomes

Studies of developmental outcomes have been reported from the epidemiologic literature in association with $PM_{10–2.5}$ exposure. Both a study in Seoul, South Korea and a study in Tokyo, Japan found increased infant mortality due to respiratory causes using coarse PM exposure from monitors (Son et al., 2011b) (Yorifuji et al., 2016). For exposures during the postnatal period, Peel et al. (2011) observed no associations between coarse PM and infant apnea and bradycardia.

9.2.4 Summary and Causality Determination

9.2.4.1 Male and Female Fertility and Pregnancy

Overall, the evidence is inadequate to infer the presence or absence of a causal relationship between $PM_{10–2.5}$ exposure and male and female fertility and reproduction. Developmental outcomes are briefly summarized here with causality determination made in the outcome specific chapter (respiratory effects). Separate conclusions are made for the two groups of reproductive and developmental effects because they are likely to have different etiologies and critical exposure patterns over different lifestages. At the time of the 2009 PM ISA (U.S. EPA, 2009), evidence from the epidemiologic and toxicological studies had assessed the broader relationship between PM exposure and reproductive and developmental outcomes. The paucity of evidence for $PM_{10–2.5}$ in the 2009 PM ISA (U.S. EPA, 2009) remains. While there are more recent studies in this ISA, there continue to be fewer studies contributing to this size fraction than to other size groups. Developmental outcomes for the literature are discussed in more detail in the respiratory section of the ISA with infant respiratory mortality having the strongest evidence, reporting positive associations from multiple studies. In the developmental literature increased infant respiratory mortality was reported with increasing $PM_{10–2.5}$ exposure.

Evidence for male and female reproduction and fertility includes work from the Nurses' Health Study which observed increased incident infertility and reduced endometriosis associated with increased $PM_{10–2.5}$ concentrations and cross-sectional work from a Spanish cohort reporting lower birth rates with increases in $PM_{10–2.5}$. There is a dearth of evidence detailing biological plausibility between $PM_{10–2.5}$ and Male and Female Reproduction and Fertility. **Overall, the evidence is inadequate to infer the presence or absence of a causal relationship between $PM_{10–2.5}$ exposure and male and female reproduction and fertility (Table 9-11).**

9.2.4.2 Pregnancy and Birth Outcomes

Overall, the evidence is inadequate to infer the presence or absence of a causal relationship between $PM_{10-2.5}$ exposure and pregnancy and birth outcomes. At the time of the 2009 PM ISA (U.S. EPA, 2009), evidence from the epidemiologic and toxicological studies had assessed the broader relationship between PM exposure and reproductive and developmental outcomes. The paucity of evidence for $PM_{10-2.5}$ in the 2009 PM ISA (U.S. EPA, 2009) remains.

Evidence for pregnancy and birth outcomes in association with $PM_{10-2.5}$ follows. Decreased birth weight is associated with $PM_{10-2.5}$ exposure including increased odds of having a low birth weight baby with $PM_{10-2.5}$ exposure. Preterm birth is associated with increasing $PM_{10-2.5}$ exposure. Inconsistent evidence is seen with studies of birth defects and studies of preterm birth with the literature being comprised of studies with positive associations as well as studies with null findings. A paucity of information exists in support of potential biological plausibility for $PM_{10-2.5}$ exposure and Pregnancy and Birth Outcomes. **Overall, the evidence is inadequate to infer the presence or absence of a causal relationship between $PM_{10-2.5}$ exposure and pregnancy and birth outcomes (Table 9-12).**

9.3 UFP Exposure and Reproductive and Developmental Effects

The evidence for effects of UFP on reproductive and developmental outcomes is characterized below. Toxicological studies of male reproductive function show increased testosterone, increased testicular cholesterol, and increased activation of biomarkers on testicular cholesterol biosynthesis pathway with UFP exposure in male rodents. The epidemiologic literature for pregnancy and birth outcomes shows positive associations of UFP with preterm birth and low birth weight. In the UFP toxicological literature, neurodevelopmental outcomes are well studied and report neurological associations from multiple studies evaluating outcomes including increased impulsivity, ventriculomegaly, glial activation, and neurotransmitter changes with UFP exposure. More detailed information on these studies is included in the sections that follow.

9.3.1 Male and Female Reproduction and Fertility

9.3.1.1 Biological Plausibility

This section describes biological pathways that potentially underlie reproductive and developmental health effects of male and female reproduction and fertility, and pregnancy, birth weight and birth outcomes resulting from exposure to UFP PM. Figure 9-4 graphically depicts the proposed pathways as a continuum of upstream events, connected by arrows, that may lead to downstream events observed in epidemiologic studies. This discussion of "how" exposure to UFP may lead to reproductive and developmental health effects contributes to an understanding of the biological plausibility of epidemiologic results evaluated later in Section 9.3.

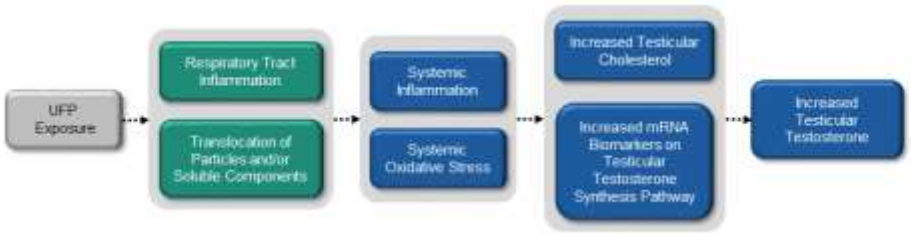

Figure 9-4 Potential biological pathways for male and female reproduction and fertility effects following UFP exposure.

[a] Note: The boxes above represent the effects for which there is experimental or epidemiologic evidence, and the dotted arrows indicate a proposed relationship between those effects. Shading around multiple boxes denotes relationships between groups of upstream and downstream effects. Progression of effects is depicted from left to right and color coded (grey, exposure; green, initial event; blue, intermediate event; orange, apical event). Here, apical events generally reflect results of epidemiologic studies, which often observe effects at the population level. Epidemiologic evidence may also contribute to upstream boxes. When there are gaps in the evidence, there are complementary gaps in the figure and the accompanying text below.

The evidence that exists in support of biological plausibility of UFP inhalation for effect on male and female reproduction and fertility and pregnancy, birth weight and birth outcomes follows in Figure 9-4. Initial events begin when particles are translocated/solubilized to the lung or the olfactory bulb with the potential for inflammation and oxidative stress. UFP and its soluble components may translocate into the systemic circulation and contribute to inflammatory or other processes in extrapulmonary compartments. A fraction of UFP may deposit on the olfactory epithelium. UFP and its soluble components may be transported via the olfactory nerve to the olfactory bulb of the brain. The extent to which translocation into the systemic circulation or transport to the olfactory bulb occurs is currently uncertain. For further discussion of translocation and olfactory transport, see Chapter 4. UFP inhalation by adult male laboratory animals manifests with increased testicular testosterone and its precursor testicular cholesterol (Li et al., 2012). Prenatal exposure of laboratory animals to UFP CAPS results in offspring with decreased kidney weight (Li et al., 2009). The epidemiologic evidence for biological plausibility shows that UFP exposure is associated with low birth weight (Laurent et al., 2014) and preterm birth (Laurent et al., 2016). The biological plausibility for reproductive and developmental outcomes including effects on reproduction and fertility; and pregnancy, birth weight and birth outcomes is emerging. As future studies evaluate the effects of UFP inhalation, more data may become available to elucidate biological plausibility of reproductive and developmental effects.

Inhalation of UFP could lead to effects on male and female reproduction and developmental health effects as well as pregnancy, birth outcomes and birth weight following multiple pathways that are currently sparsely populated. Potential pathways involve, particle translocation/solubility, inflammation and oxidative stress, that may lead to changes in the offspring inducing, altered male reproductive hormone levels, decreased growth and development (e.g., low birth weight), or preterm birth. Evidence from laboratory animals and from epidemiologic studies show that there is potential for growth in the understanding of how the biological plausibility of inhaled UFP affect reproductive and developmental apical events. These limited data provide biological plausibility for epidemiologic results of reproductive and developmental health effects and will be used to inform a causality determination, which is discussed later in the chapter (Section 9.3.4).

9.3.1.2 Male Reproductive Function

The 2009 PM ISA (U.S. EPA, 2009) did not contain studies of UFP in association with male reproductive function. In more recent studies (Table 9-13), UFP exposure has been examined for its effects on male reproductive hormones and sperm production. In these studies, UFP size ranged from 1−100 nm with peak size concentration occurring at 20−30 nm (Li et al., 2009). A couple of studies of DE with adult or prenatal exposures have explored these effects in rodents (Li et al., 2012; Li et al., 2009). Adult male mice were exposed to low dose-DE (LD-DE), high dose-DE (HD-DE), filtered-DE (F-DE) or control clean air for 8 weeks (Li et al., 2012). The HD-DE male mice had significantly higher serum testosterone ($p < 0.05$) than the control or the F-DE; LD-DE showed a nonsignificant trend of

increased testosterone production. Most hormones were refractory to DE exposure (FSH, LH, and progesterone) with 8 weeks of exposure (Li et al., 2012). Epididymal sperm count and morphology were refractory to PM exposure (Li et al., 2012). Cholesterol is an essential substrate for testosterone production; testicular cholesterol biosynthesis pathways (HMG-CoA reductase, HMG-CoA synthase, LDLR) were significantly upregulated ($p < 0.05$) with HD-DE exposure compared to F-DE and control (Li et al., 2012). Other endpoints essential to testosterone biosynthesis were also significantly upregulated with HD-DE exposure v. control or F-DE exposure (SR-B1, PBR, StAR, P450scc, 3B-HSD, P45017a, 17B-HSD, $p < 0.05$) (Li et al., 2012). In a separate study, the same laboratory also explored prenatal effects of DE on young male offspring, exploring many of the same hormone pathways and looking at male reproductive tract histology (Li et al., 2009). Pregnant dams were exposed to DE, F-DE or control clean air over GD1−19. Immature male offspring were evaluated on PND28. Message levels (mRNA) of FSH receptor and serum concentrations of corticosterone were significantly increased with DE exposure compared to F-DE and control ($p < 0.01$). In these younger mice, other hormone and histology endpoints changed with DE exposure, but they also changed with F-DE exposure compared to control (Li et al., 2009), indicating a gaseous contribution to the DE effect not a PM-specific effect. There were sensitive windows of exposure to UFP PM; exposure of adult males to UFP PM from DE was associated with significantly elevated testosterone but prenatal exposure was not sufficient to induce similar changes in younger male animals. In summary, UFP exposure did not affect rodent sperm count or morphology. Inhalation of UFP in adult animals was associated with changes in concentrations of contributors to the testicular cholesterol biosynthesis pathways including testicular cholesterol, SR-B1, PBR, StAR, P450scc, 3B-HSD, P45017a, and 17B-HSD that likely contributed to the UFP dependent elevated serum testosterone.

9.3.1.3 Female Reproduction and Fertility

No studies on female reproduction and fertility were in the 2009 PM ISA (U.S. EPA, 2009) and no recent studies exist for these health outcomes.

Table 9-13 Key animal toxicological studies UFP and male and female reproduction.

Study	Population N, Sex; Age (mean ± SD)	Exposure Details (Concentration; Duration)	Endpoints Examined
(Li et al., 2009)	Pregnant and lactating F344 rats and their offspring	Pregnant F344 rats were exposed to DEP (148.86 g/m^3, 1.83 × 106 particles/cm^3, 3.40 ppm CO, 1.46 ppm NO_X), filtered-DE (F-DE; 3.10 g/m^3, 2.66 particles/cm^3, 3.30 ppm CO, 1.41 ppm NO_X), or clean air (as a control) from gestation days 1 to 19. UFP size ranged from 1−100 nm with peak size concentration occurring at 20−30 nm.	Male offspring were examined on postnatal Day 28 for endpoints including reproductive organ weight, and hormone concentrations (testosterone, LH, FSH, STAR protein, and 17B-OH dehydrogenase).
(Li et al., 2012)	Adult male C57BL/Jcl mice	Male C57BL/Jcl mice were exposed to clean air, low-dose NR-DE (Low NR-DE), high-dose NR-DE (High NR-DE), or filtered diesel exhaust (F-DE) for 8 weeks at respective PM concentrations of 0.78±0.25, 41.73±0.58, 152.01±1.18, or 0.69±0.36 µg/m^3. UFP size ranged from 1−100 nm with most particles of 20−30 nm in size.	After 8 weeks exposure to DE, F-DE or clean air, isolated testicular interstitial cells from exposed animals were challenged with HCG to understand testicular testosterone production and the role of its precursors (cholesterol, HMG-COA, LDL-R, SR-B1, 17BHSD)

9.3.2 Pregnancy and Birth Outcomes

9.3.2.1 Biological Plausibility

There is a paucity of evidence for biological plausibility of health effects following exposure to UFP due to a dearth of information published in the literature. Thus, a biological plausibility figure was not constructed for this UFP pregnancy and birth outcomes. There have been a limited number of studies of pregnancy and birth outcomes focused on UFP exposure; of these, few examine the same outcome. The studies are reported below.

9.3.2.2 Pregnancy and Birth Outcomes

Limited epidemiologic evidence exists for UFP exposure and pregnancy and birth outcomes. Evidence for effects on birth outcomes includes the results of two, California-based studies using the University of California Davis/CIT_Primary (UCD_*P*) chemical transport model to estimate concentrations. The first, a cohort study of births in Los Angeles county, found increased odds of low birth weight with IQR increases in $PM_{0.1}$ (Laurent et al., 2014). The second, a case-control study of births across the state, found increased odds of preterm birth with increases in $PM_{0.1}$ (Laurent et al., 2016).

Animal toxicology studies routinely measure birth outcomes including birth weight and crown to rump length, measures which have the potential to be affected by UFP PM exposure (Table 9-15). Dams were exposed to control clean air, UFP diesel exhaust (UFP DE), sized 100 nm or less with the majority of the particles of 20−30 nm in size, or F-DE during pregnancy (GD1−19, 5 hours/day) and litter parameters were reported at birth (Li et al., 2013). No markers of maternal endocrine function (dam body weight gain, liver weight, serum maternal LH and corticosterone, corpus luteum 450SSC, 3β-hydroxysteroid dehydrogenase, 17B-estradiol and LH receptor mRNA) were altered with F-DE or DE exposure in pregnant female rats. Both DE and F-DE pups had significantly increased birth weights and significantly decreased crown to rump length at birth versus clean air, indicating that the PM portion of exposure is likely not contributing to the deficit. Also, sex ratio or the ratio of males to females per litter was not altered between treatment groups and neither was anogenital distance, a marker of androgenization. In summary, from this study the UFP PM portion of DE was not responsible for changes in birth weight, crown to rump length, sex ratio, or anogenital distance with prenatal PM exposure.

Table 9-14 Animal toxicological study of pregnancy and birth outcomes.

Study	Population N, Sex; Age (mean ± SD)	Exposure Details (Concentration; Duration)	Endpoints Examined
(Li et al., 2013)	Pregnant female Fischer rats (F344/DuCrlCrli)	Pregnant rats were exposed to DE, F-DE or clean air for the entire pregnancy. Particle size: the average diameter of UFP ranged from 22 to 27 nm. Concentration: DE (148.86 μg/m^3, 1.83 × 106 particles/cm^3), F-DE (3.10 μg/m^3, 2.66 particles/cm^3). Inhalation for 5 h/day GD 1 to GD19. UFP size ranged from 1−100 nm with peak size concentration occurring at 20−30 nm.	At birth, maternal outcomes (liver weight, spleen weight, hormone concentrations) were assessed and birth outcomes (birth weight, crown to rump length) were followed in pups.

9.3.3 Developmental Effects

Prenatal or early neonatal exposures have the potential to affect developing organs. Multiple studies characterized in the neurodevelopment section and briefly below show the effects of UFP PM on the nervous system after early life exposure of laboratory rodents to UFP PM, the section that provides the bulk of the new research in the UFP PM Developmental Effects section. These studies find that early life UFP PM exposure to laboratory rodents induces neurobehavioral changes like inattention and depression. Also, brain structures are changed in ways that are similar to the diseases autism or schizophrenia with ventricular enlargement or ventriculomegaly. Also, stress axes like the sympathetic nervous system were differentially activated with UFP PM exposure. These neurological outcomes differ by the sex of the animal tested and by the developmental exposure window (prenatal versus neonatal). Also noted, prenatal UFP PM exposure is associated with decreased kidney size in young male animals; the kidneys of the young male offspring (PND28) prenatally exposed to UFP (DE) were significantly smaller than control clean air exposed animals or F-DE exposed animals ($p < 0.01$) (Li et al., 2009). Dams were exposed to UFP PM DE, F-DE or control clean air 5 hours/day GD1−19. The neuro-developmental studies are characterized below in Section 9.3.3.1 and in Table 9-16.

9.3.3.1 Neurodevelopmental Outcomes

9.3.3.1.1 Neurobehavioral Outcomes, Animal Toxicology

A series of studies evaluated behavioral and neurotoxicological endpoints in adult mice previously exposed to Rochester, NY concentrated ambient ultrafine particles (CAPs) (<100 nm) during the first two weeks of life (Allen et al., 2014b; Allen et al., 2014c; Allen et al., 2014a; Allen et al., 2013). These studies are covered in greater detail in the nervous system section of the ISA (Chapter 8) with brief summaries here. Allen et al. (2013) showed early postnatal CAPs exposure produced mice with preference for immediate with serum corticosterone and some brain region-specific neurotransmitters correlated with measures of impulsivity-linked behavior in male mice. In a second study with similar study design using early life (postnatal) CAPs exposure, Allen et al. (2014c) showed indices of learning/memory were affected by PM. Davis et al. (2013) saw that PM exposure affected internalizing behavior in offspring of dams that were exposed to UFP (prior to conception, mated with unexposed males and then exposed to UFP during gestation). In summary, learning and memory were significantly impaired with UFP exposure, with novel object recognition affected in males (postnatal UFP exposure) and changes in time to approach novel objects affected in females (postnatal UFP exposure). UFP exposure both prenatally and postnatally induced depression like behavior; prenatal exposure's effects were limited to male offspring. UFP exposure did not contribute to anxiety.

9.3.3.1.2 Changes in Brain Structure, Animal Toxicology

Allen et al. (2014a) and Allen et al. (2015) examined changes in the brains of weanling mouse pups exposed postnatally to UFP. Ventriculomegaly was seen in young and adult male, but not female mice. Ventriculomegaly can be associated with increased risk of adverse neurodevelopmental outcomes including schizophrenia ADHD or autism spectrum disorders, some of which tend to have a higher incidence in males. In addition, there was a UFP-dependent decrease in size (PND14, both sexes) and myelination (PND14, males only) of the corpus callosum. Findings of ventriculomegaly, reductions in corpus callosum size, and hypomyelination, especially in males, are consistent with morphologic changes associated with neurodevelopmental disorders such as autism spectrum disorder in humans. There were also sex-specific and region specific alterations in neurotransmitters and hormones (concentration of glutamate, dopamine, norepinephrine, GABA, HVA and corticosterone as well as dopamine turnover (Allen et al., 2014c). Multiday exposure of weaning mice to UFP induced early (astrocyte and microglial) and persistent (microglial) activation, especially in males (Allen et al., 2014a) (Allen et al., 2015).

Table 9-15 Summary of UFP: Developmental outcomes.

Developmental Effects	Summary of Evidence	Cross-link to Study Details	Causality Determination
Neurodevelopment	Toxicological evidence: Early postnatal UFP exposure, Behavioral testing for impulsivity; Early postnatal and adult UFP exposure, measurements of potential brain ventriculomegaly, neurochemical disruption, and glial activation. Sex-dependent measurements; Susceptibility to induction of the Parkinson's disease phenotype (PDP) in adulthood following neonatal CAPS exposure, locomotion activity, and striatal GABA inhibitory function; Measurement of meso-corticolimbic monoamines/glutamate, brain glial activation, and brain histopathology; cerebral cortex primary neuronal cultures; locomotor activity and anxiety-related parameters by open field and elevated plus-maze; depression-like responses by tail-suspension tests.	Section 8.6.6	A Causal relationship is likely to exist for long-term exposure to UFP and nervous system effects
Renal	Toxicological evidence: Kidney development in male offspring, kidney weight. is impacted by $PM_{2.5}$ exposure.	Section 9.3.3	

9.3.4 Summary and Causality Determination

Overall, the evidence is inadequate to infer the presence or absence of a causal relationship between UFP exposure and male and female reproduction and fertility. Causality determinations are made for developmental outcomes in the specific chapters associated with the developmental outcome (i.e., nervous system). This causality determination is consistent with the 2009 PM ISA, which also reported limited evidence for reproductive and developmental effects in association with UFP exposure. The key evidence supporting the causality determination is detailed below using the framework described in Table I of the Preamble to the ISAs (U.S. EPA, 2015)and is presented in Table 9-16. All available evidence examining the relationship between exposure to UFP male and female reproduction and fertility as well as pregnancy and birth outcomes was thoroughly evaluated.

9.3.4.1 Male and Female Reproduction and Fertility

At the time of the 2009 PM ISA (U.S. EPA, 2009), there were not a lot of studies on UFP. The paucity of evidence for UFP in the 2009 PM ISA (U.S. EPA, 2009) remains, however there has been an expansion of studies in neurodevelopment in the laboratory animal toxicology literature. Limited evidence for effects on male reproductive function is provided by the animal toxicology literature which shows increased testosterone, increased testicular cholesterol, and increased activation of biomarkers related to testicular cholesterol biosynthesis with UFP exposure. The evidence for these determinations is contained below in Table 9-16.

Overall, many uncertainties remain when evaluating the evidence for these health endpoints; therefore, **the evidence is inadequate to infer the presence or absence of a causal relationship between UFP exposure and male and female reproduction and fertility.**

Table 9-16 Summary of evidence that is inadequate to infer the presence or absence of a causal relationship between UFP exposure and male and female reproduction and fertility.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	UFP Concentrations Associated with Effects[c]
Reproduction and Fertility: Limited and supportive toxicological evidence of effects on male reproductive endpoints	Adult UFP exposure induced increased testosterone and increased testicular cholesterol, increased activation of biomarkers on testicular cholesterol biosynthesis pathway	(Li et al., 2012)	149 µg/m^3

Table 9-16 (Continued): Summary of evidence that is inadequate to infer the presence or absence of a causal relationship between UFP exposure and male and female reproduction and fertility.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	UFP Concentrations Associated with Effects[c]
Limited evidence for biological plausibility.	Adult UFP impaired testicular T synthesis and biomarkers along the pathway.	(Li et al., 2012)	
Uncertainty regarding exposure measurement error	Chemical transport model to predict UFP concentrations with a 4-km spatial resolution		
Uncertainty regarding epidemiologic evidence from copollutant models to support and independent UFP association	No studies examine potential confounding of UFP associations by copollutants	Section 9.3.1.1	
Uncertainty due to limited biological plausibility from studies of male and female reproduction and fertility; pregnancy and birth outcomes	Dearth of evidence for biological plausibility related to (1) male and female reproduction and fertility.	Sections 9.3.1.1	

$PM_{2.5}$ = particulate matter with a nominal aerodynamic diameter less than or equal to 2.5 μm; $PM_{10-2.5}$ = particulate matter with a nominal aerodynamic diameter less than or equal to 10 μm and greater than a nominal diameter of 2.5 μm.

[a]Based on aspects considered in judgments of causality and weight of evidence in causal framework in Tables I and II of the Preamble.

[b]Describes the key evidence and references contributing most heavily to causality determination and, where applicable, to uncertainties or inconsistencies. References to earlier sections indicate where the full body of evidence is described.

[c]Describes the $PM_{10-2.5}$ concentrations with which the evidence is substantiated.

9.3.4.2 Pregnancy and Birth Outcomes

Overall, the evidence is inadequate to infer the presence or absence of a causal relationship between UFP exposure and pregnancy and birth outcomes. This causality determination is consistent with the 2009 PM ISA, which also reported limited evidence for reproductive and developmental effects in association with UFP exposure. The key evidence supporting the causality determination is detailed below using the framework described in Table I of the Preamble to the ISAs (U.S. EPA, 2015, HERO ID) and is presented in Table 9-17. All available evidence examining the relationship between exposure to UFP and pregnancy and birth outcomes was thoroughly evaluated.

At the time of the 2009 PM ISA (U.S. EPA, 2009), there were not a lot of studies on UFP. The paucity of evidence for UFP in the 2009 PM ISA (U.S. EPA, 2009) remains. Pregnancy and birth

outcomes show positive associations of UFP with preterm birth and low birth weight. There is limited evidence for biological plausibility in support of the reproductive and developmental outcomes. The evidence for these determinations is contained below in Table 9-17.

Overall, many uncertainties remain when evaluating the evidence for these health endpoints; therefore, **the evidence is inadequate to infer the presence or absence of a causal relationship between UFP exposure and pregnancy and birth outcomes.**

Table 9-17 Summary of evidence that is inadequate to infer the presence or absence of a causal relationship between UFP exposure and pregnancy and birth outcomes.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	UFP Concentrations Associated with Effects[c]
Pregnancy and birth outcomes: Limited epidemiologic evidence for associations with pregnancy and birth outcomes	Two studies utilize exposure model for $PM_{0.1}$ to examine associations with birth weight and preterm birth	Section 9.3.2.2 Laurent et al. (2014) Laurent et al. (2016)	1.13 µg/m^3
Uncertainty regarding exposure measurement error	Chemical transport model to predict UFP concentrations with a 4-km spatial resolution		
Uncertainty regarding epidemiologic evidence from copollutant models to support and independent UFP association	No studies examine potential confounding of UFP associations by copollutants	Section 9.3.2	
Uncertainty due to limited biological plausibility from studies pregnancy and birth outcomes	Dearth of evidence for biological plausibility related to pregnancy and birth outcomes.	Section 9.3.2.1	

$PM_{2.5}$ = particulate matter with a nominal aerodynamic diameter less than or equal to 2.5 µm; $PM_{10-2.5}$ = particulate matter with a nominal aerodynamic diameter less than or equal to 10 µm and greater than a nominal diameter of 2.5 µm.

[a]Based on aspects considered in judgments of causality and weight of evidence in causal framework in Tables I and II of the Preamble.

[b]Describes the key evidence and references contributing most heavily to causality determination and, where applicable, to uncertainties or inconsistencies. References to earlier sections indicate where the full body of evidence is described.

[c]Describes the $PM_{10-2.5}$ concentrations with which the evidence is substantiated.

CHAPTER 10 CANCER

Summary of Causality Determinations for Long-Term Particulate Matter (PM) Exposure and Cancer

This chapter characterizes the scientific evidence that supports causality determinations for long-term PM exposure and cancer. The types of studies evaluated within this chapter are consistent with the overall scope of the ISA as detailed in the Preface (Section P 3.1). In assessing the overall evidence, strengths and limitations of individual studies were evaluated based on scientific considerations detailed in the Appendix. More details on the causal framework used to reach these conclusions are included in the Preamble to the ISA (U.S. EPA, 2015).

Size Fraction	Causality Determination
$PM_{2.5}$	Likely to be Causal
$PM_{10-2.5}$	Suggestive of, but not sufficient to infer
UFP	Inadequate

10.1 Introduction

10.1.1 Evaluation of the Relationship Between Long-term PM Exposure and Cancer

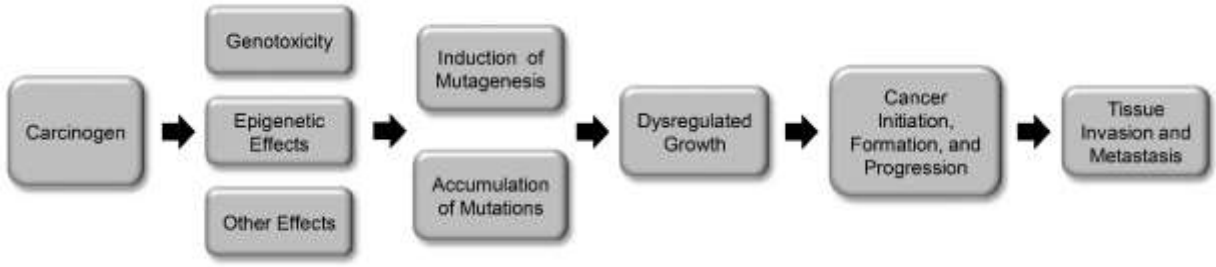
The 2009 Particulate Matter Integrated Science Assessment (2009 PM ISA) evaluated the relationship between long-term PM exposure and cancer, with an emphasis on specific PM size fractions ($PM_{2.5}$, $PM_{10-2.5}$, and UFPs) (U.S. EPA, 2009), with most studies focused on $PM_{2.5}$ exposure. This body of evidence was supported by decades of research on whole PM exposures (i.e., no defined size fraction), including diesel exhaust, gasoline exhaust, and wood smoke.

Since completion of the 2009 PM ISA, the International Agency for Research on Cancer (IARC) classified outdoor air pollution, including PM, as a Group 1 carcinogen (carcinogenic to humans) (IARC, 2016). IARC conducted a weight-of-evidence assessment for hazard identification that involved evaluating epidemiologic, animal toxicological, and mechanistic studies associated with outdoor air pollution. Studies evaluated in the IARC assessment consisted of those that examined inhalation as well as other routes of exposure, PM concentrations higher than 1−2 orders of magnitude above ambient, and individual PM components and specific PM size fractions. The conclusion of the IARC assessment was based primarily on epidemiology studies of ambient $PM_{2.5}$ exposures and lung cancer incidence and

mortality, on inhalation studies of promotion-initiation in mice exposed to ambient air PM_{10}, and on evidence from mechanistic studies using PM of various size fractions. In contrast, this ISA is tasked with evaluating only inhalation exposures of specific PM size fractions at relevant ambient concentrations (i.e., up to one to two orders of magnitude above ambient). The evaluation of the relationship between long-term exposure to $PM_{2.5}$, as well as other PM size fractions, and cancer is guided by the overall scope of the ISA as detailed in the Particulate Matter Integrated Review Plan (U.S. EPA, 2016) and summarized briefly in the Preface (Section 3.1).

10.1.2 Carcinogens and the Development of Cancer

Development of cancer is a complex, multistep disease process (Figure 10-1). Evidence collected over decades of scientific research suggests that dysregulation of cellular pathways controlling cell growth, survival, and genetic stability results in aberrant, unregulated cell division and is central to disease initiation and progression. The most widely accepted pathway to unregulated growth is accumulation of mutations in critical genes. However, more recently, epigenetic mechanisms, such as gene silencing through promotor methylation, or receptor-mediated cell proliferation have been proposed to be important to disease development (Smith et al., 2016).



Note: This scheme depicts important steps in the development of cancer and is adapted from Goodson et al. (2015) and Smart et al. (2008).

Figure 10-1 Key steps in the development of cancer.

Hanahan and Weinberg (2000) and Hanahan and Weinberg (2011) have proposed several hallmarks of cancer that describe the phenotype of cancer cells and developed tumors. These hallmarks organize the dysregulated pathways identified in cancer cells in terms of biological properties that are acquired during tumor development in humans (Hanahan and Weinberg, 2011). They include sustained proliferative signaling, evasion of growth suppressors, resistance of cell death, enabling of replicative immortality, induction of angiogenesis, activation of invasion and metastasis, reprogramming of energy

metabolism, and evasion of immune destruction. Few studies of exposure to PM size fractions have specifically examined dysregulated pathways associated with cancer cells and developed tumors. However, as described below, some studies of exposure to PM size fractions demonstrate perturbation of pathways related to the hallmarks of cancer, such as methylation of a tumor suppressor gene, which is relevant to evasion of growth suppressors.

Smith et al. (2016) has proposed ten characteristics of carcinogens as important to the etiology and progression of cancer. These characteristics are related to the mechanisms through which it is currently thought carcinogenic agents act. These characteristics include the ability to (1) be electrophilic either directly or after metabolic activation, (2) be genotoxic, (3) alter DNA repair or cause genomic instability, (4) induce epigenetic alterations, (5) induce oxidative stress, (6) induce chronic inflammation, (7) be immunosuppressive, (8) modulate receptor-mediated effects, (9) cause immortalization, and (10) alter cell proliferation, cell death, or nutrient supply. Numerous studies published prior to the 2009 PM ISA showed that PM of various size fractions exhibit many of these characteristics, especially the first six (IARC, 2016). Studies published since the 2009 PM ISA provide evidence that the PM size fractions of interest in this ISA, (i.e., $PM_{2.5}$, $PM_{10–2.5}$, and UFP) exhibit several of the key characteristics of carcinogens. New findings describe the capability of these PM size fractions to induce oxidative stress and to damage DNA, which can be processed by the cell into gene and chromosomal mutations. Furthermore, studies link PM size fractions to the expression of genes that are relevant to metabolic activation or biotransformation and to epigenetic alterations.

In addition to consideration of the hallmarks of cancer (Hanahan and Weinberg, 2000); (Hanahan and Weinberg, 2011) and the characteristics of carcinogens (Smith et al., 2016), studies examining the effects of exposure to PM size fractions provide information on other cancer-related biomarkers. Some studies detail the presence of mutagenic compounds in PM size fractions collected from ambient air, while others measure the formation of DNA adducts and carcinogenic potential.

10.2 $PM_{2.5}$ Exposure and Cancer

The 2009 PM ISA concluded that the overall body of evidence was "suggestive of a causal relationship between relevant $PM_{2.5}$ exposures and cancer" (U.S. EPA, 2009).[76] This conclusion was based primarily on positive associations observed in epidemiologic studies of lung cancer mortality. Epidemiologic studies evaluating $PM_{2.5}$ and lung cancer incidence or cancers of other organs and systems generally did not show evidence of an association. Toxicological studies did not focus on exposures to specific PM size fractions, but rather investigated the effects of exposures to total ambient PM, or other source-based PM such as wood smoke. Collectively, results of in vitro studies were consistent with the

[76] As detailed in the Preface, risk estimates are for a 5 $\mu g/m^3$ increase in annual $PM_{2.5}$ concentrations unless otherwise noted.

larger body of evidence demonstrating that ambient PM and PM from specific combustion sources are mutagenic and genotoxic. However, animal inhalation studies found no evidence of tumor formation in response to chronic exposures, except for one study demonstrating enhanced formation of urethane-induced tumors. In addition, a small number of studies provided preliminary evidence that PM exposure can lead to changes in methylation of DNA, which may also contribute to biological events related to cancer.

Recent studies expand upon the evidence for long-term $PM_{2.5}$ exposure and cancer detailed in the 2009 PM ISA. Although previous studies tended to focus more broadly on PM exposures, recent studies address a number of uncertainties and limitations with respect to the role of $PM_{2.5}$ exposure in the development of cancer. Evidence from experimental and epidemiologic studies demonstrate that $PM_{2.5}$ exposure can lead to a range of effects indicative of mutagenicity, genotoxicity, and carcinogenicity, as well as epigenetic effects. These cellular and molecular changes are supported by epidemiologic evidence demonstrating consistent positive associations between long-term $PM_{2.5}$ exposure and lung cancer mortality and incidence.

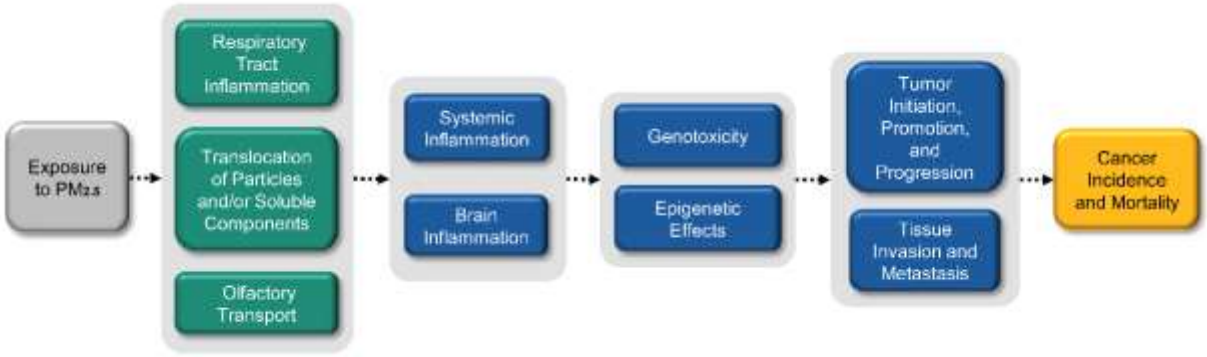
The following sections evaluate studies published since completion of the 2009 PM ISA. Although the ISA is tasked with reviewing new evidence describing the mutagenicity, genotoxicity, and carcinogenicity for each PM size fraction, it is recognized that there exists a large body of historical evidence demonstrating these effects resulting from exposure to total PM. Throughout this section recent studies are evaluated in the context of this larger collective body of evidence.

10.2.1 Biological Plausibility

This section describes biological pathways that potentially underlie the development of cancer resulting from exposure to $PM_{2.5}$. Figure 10-2 graphically depicts the proposed pathways as a continuum of upstream events, connected by arrows, that may lead to downstream events observed in epidemiologic studies. This discussion of "how" exposure to $PM_{2.5}$ may lead to the development of cancer contributes to an understanding of the biological plausibility of epidemiologic results evaluated later in Section 10.2.

Once $PM_{2.5}$ deposits in the respiratory tract, it may be retained, cleared, or solubilized (see Chapter 4). $PM_{2.5}$ and its soluble components may interact with cells in the respiratory tract, such as epithelial cells, inflammatory cells, and sensory nerve cells. One way in which this may occur is through reduction-oxidative (redox) reactions. As discussed in Section 2.3.3, PM may generate reactive oxygen species (ROS) and this capacity is termed "oxidative potential". Furthermore, cells in the respiratory tract may respond to the presence of PM by generating ROS. Further discussion of these redox reactions, which may contribute to oxidative stress, is found in Section 5.1.1 of the 2009 PM ISA (U.S. EPA, 2009). In addition, poorly soluble particles may translocate to the interstitial space beneath the respiratory epithelium and accumulate in the lymph nodes (see CHAPTER 4). Immune system responses due to the presence of particles in the interstitial space may contribute to chronic health effects. Inflammatory

mediators may diffuse from the respiratory tract into the systemic circulation and lead to inflammation in extrapulmonary compartments (see Chapter 6). Soluble components of $PM_{2.5}$ and poorly soluble particles that are part of the $PM_{2.5}$ fraction and smaller than approximately 200 nm may translocate into the systemic circulation and contribute to inflammatory or other processes in extrapulmonary compartments. A fraction of $PM_{2.5}$ may deposit on the olfactory epithelium. Soluble components of $PM_{2.5}$ and poorly soluble particles that are part of the $PM_{2.5}$ fraction and smaller than approximately 200 nm may be transported via the olfactory nerve to the olfactory bulb of the brain. The extent to which translocation into the systemic circulation or transport to the olfactory bulb occurs is currently uncertain. For further discussion of translocation and olfactory transport, see Chapter 4. The potential contribution of olfactory transport to brain inflammation or to upregulation of gene expression in the brain is discussed in Chapter 8.



Note: The boxes above represent the effects for which there is experimental or epidemiologic evidence, and the dotted arrows indicate a proposed relationship between those effects. Shading around multiple boxes denotes relationships between groups of upstream and downstream effects. Progression of effects is depicted from left to right and color-coded (gray, exposure; green, initial event; blue, intermediate event; orange, apical event). Here, apical events generally reflect results of epidemiologic studies, which often observe effects at the population level. Epidemiologic evidence may also contribute to upstream boxes. When there are gaps in the evidence, there are complementary gaps in the figure and the accompanying text below.

Figure 10-2 Potential biological pathways for the development of cancer following exposure to $PM_{2.5}$.

Evidence is accumulating that exposure to $PM_{2.5}$ may lead to carcinogenesis by two pathways. The first pathway involves genotoxicity, where electrophilic compounds induce DNA damage, such as DNA strand breaks or DNA adducts (where a compound is bound covalently to DNA), and such damage is then processed by the cell to result in a change in DNA sequence—i.e., a mutation. The second pathway involves epigenetic effects that alter gene expression, further altering cell growth, regulation, and other processes. Carcinogenesis is essentially dysregulated growth; one or the other or a combination of both pathways above can lead to cancer. A general scheme for cancer induction involves initiation, promotion, and progression, leading eventually to tissue invasion and metastasis. Although most of

epidemiologic evidence links $PM_{2.5}$ exposure to lung cancer, a plausible link to other kinds of cancer may exist. Evidence for these pathways and cancer-related biomarkers is described below. A discussion of the hallmarks of cancer (Hanahan and Weinberg, 2000); (Hanahan and Weinberg, 2011) and the characteristics of carcinogens (Smith et al., 2016), as they relate to $PM_{2.5}$, follows.

Genotoxicity

Genotoxicity is a term that refers to DNA damage, mutations, or both (Shaughnessy and DeMarini, 2009). DNA damage consists of alterations to DNA such as a DNA strand break (breakage of the phosphodiester bonds) or a DNA adduct (the covalent binding of a chemical to DNA). The DNA damage itself generally does not alter the sequence or number of the four bases/nucleotides in DNA, whose order form the basis of the genetic code. DNA damage can be caused by spontaneous errors of nucleic acid metabolism or by endogenous or exogenous mutagens. In contrast, mutations are changes in DNA sequence (i.e., in the order or number of the bases/nucleotides), and they occur when the cell processes DNA damage incorrectly, such as by failing to repair the damage or by trying to perform DNA replication past the unrepaired damage. Thus, mutagenesis is a cellular process, usually involving DNA replication and DNA repair. There are three classes of mutations: gene, chromosomal, and genomic. Mutations within a single gene are called gene or point mutations, such as base substitutions. Mutations involving more than one gene are called chromosomal mutations, such as chromosomal aberrations involving multigenetic deletions, inversions, duplications, or translocations. The gain or loss of a whole chromosome (aneuploidy) is an example of genomic mutation. As detailed below, $PM_{2.5}$ exposure is associated with mutagenicity, DNA adducts and other DNA damage, oxidative stress, biotransformation, and chromosomal (or cytogenetic) effects.

Mutations are considered biomarkers of early biological effect (Demetriou et al., 2012). The Ames *Salmonella*/mammalian-microsome mutagenicity assay is a bacterial assay and the most widely used assay of any kind for detecting the mutagenic activity of an agent (Claxton et al., 2010). In the absence of metabolic activation, it detects agents that are called direct-acting mutagens; in the presence of metabolic activation, it detects agents that are indirect-acting mutagens, i.e., those requiring metabolism to electrophilic forms. The somatic mutation theory of cancer is the most widely accepted theory of cancer etiology, and it postulates that cancer occurs at a minimum from the accumulation of mutations in critical genes. The presence of mutagens within PM and the mutagenicity of organic extracts of PM provide biological plausibility for observations made in epidemiologic studies of cancer incidence. Although the Ames assay has several technical limitations and is criticized due to its use of bacteria as a model species, more than four decades of published results evaluating 10,000 compounds have clearly demonstrated the validity of this assay for evaluating the mutagenicity of PM collected from ambient air (Claxton et al., 2010; U.S. EPA, 2009). New studies published since the 2009 PM ISA provide evidence to support mutagenicity resulting from $PM_{2.5}$ exposure (Section 10.2.2.1).

DNA adducts are a type of DNA damage and serve as a biological marker of exposure (Demetriou et al., 2012). They form via a covalent bond between DNA and a carcinogen or a metabolite of a carcinogen. Repair proteins may remove DNA adducts. However, persistent adducts may result in mutations when the DNA polymerase tries to replicate past the adduct, resulting in nucleotide (base) substitutions, deletions, duplications, and chromosome rearrangements. An in vitro toxicological study described in the 2009 PM ISA provides evidence for the formation of DNA adducts following exposure to $PM_{2.5}$ (De Kok et al., 2005). In this study, rat liver S9 metabolism was found to increase DNA reactivity (i.e., the induction of DNA adducts). Supporting evidence is provided by recent epidemiologic studies showing benzo[a]pyrene (B[a]P) -like DNA adducts in association with $PM_{2.5}$ exposure (Li et al., 2014; Rossner et al., 2013b). Other types of DNA damage involve the formation of oxidized bases or nucleotides, as well as the induction of single- or double-strand breaks, all of which can be determined by the comet assay (Demarini, 2013). Evidence for such DNA damage following $PM_{2.5}$ exposure is provided by several in vitro studies using the comet assay and by a study measuring phosphorylated H2AX, which measures double-strand breaks (Section 10.2.2.2). A single epidemiologic study provides supportive evidence for DNA damage, as assessed by the comet assay, in association with $PM_{2.5}$ concentrations (Chu et al., 2015).

Some of the studies examining DNA damage identified oxidized bases, suggesting a role for oxidative stress in the development of the DNA lesions (Section 10.2.2.2). These oxidized DNA nucleobases are considered a biomarker of exposure (Demetriou et al., 2012). Exposure to PM can result in oxidative stress either through the direct generation of ROS, or indirectly through the induction of inflammation. Treatment with an antioxidant blocked strand breaks due to $PM_{2.5}$ exposure (Oh et al., 2011). Other in vitro studies showed that exposure to $PM_{2.5}$ increased the production of reactive oxygen species (ROS) in vitro. The in vitro results are supported by both animal toxicological and controlled human exposure studies. An inhalation study involving $PM_{2.5}$ in male mice found oxidized DNA bases in lung tissue (Soberanes et al., 2012). A study in human subjects found increased lipid peroxidation products in urine (Liu et al., 2015). The presence of oxidative stress-mediated DNA lesions, including adducts, can lead to the introduction of fixed mutations into the genome after incorrect repair of the damaged base or replication past the base by low fidelity DNA polymerases. The potential for oxidative stress to result in mutagenesis is underscored by the DNA repair mechanisms that have evolved to protect the genome from mutagenesis caused by these lesions.

Some components of PM, especially organic compounds, may undergo metabolism in a variety of cell types, resulting in electrophilic compounds that may bind to DNA, RNA, or proteins. Evidence that genes participating in polycyclic aromatic hydrocarbon (PAH) biotransformation are upregulated as a result of $PM_{2.5}$ exposure is provided by in vitro studies Borgie et al. (2015b) and Gualtieri et al. (2011). Biotransformation via Cyp1A1 may result in the production of PAH metabolites capable of reacting with DNA to form bulky DNA adducts. As in the case of oxidative-stress mediated DNA adducts, when DNA repair of bulky adducts is absent or ineffective, mutational events may occur.

Cytogenetic effects, such as micronuclei formation and chromosomal aberrations, are also biomarkers of genotoxicity (Demarini, 2013). Micronuclei are small nuclei formed either by chromosomal breakage or aneuploidy, which is the addition or deletion of a whole chromosome (Demetriou et al., 2012). $PM_{2.5}$ exposure increased micronuclei formation in vitro (Lemos et al., 2016; Oh et al., 2011). This effect was blocked by an antioxidant, suggesting that oxidative stress may play a role (Oh et al., 2011). The formation of micronuclei correlated with the amount of DNA damage detected by the comet assay in the same study. Epidemiologic studies provide supporting evidence of chromosomal aberrations in association with $PM_{2.5}$ exposure (Rossner et al., 2013a; Rossner et al., 2011).

Epigenetic Effects

Epigenetic mechanisms regulate the transcription of genes without altering the nucleotide sequence of DNA. Three sets of epigenetic effects were examined in studies of $PM_{2.5}$: methylation of tumor suppressor genes, global DNA methylation, and alteration in noncoding miRNA. Changes in DNA methylation patterns can affect gene expression and genomic instability (Demetriou et al., 2012). They are considered a biomarker of early exposure. In general, transcription repression is associated with DNA methylation in promoter regions of genes. Inhalation exposure to $PM_{2.5}$ increased methylation of the p16 promotor in the lung (Soberanes et al., 2012). The p16 protein is a tumor suppressor, suggesting an epigenetic mechanism for dysregulated growth. Methylation of repetitive elements, a surrogate of global DNA methylation, was correlated with $PM_{2.5}$ concentrations in blood and lung tissue of Wistar rats (Ding et al., 2016). Global DNA methylation is a measure of genomic instability which can contribute to the accumulation of mutations in critical genes involved in the development of cancer. In general, hypomethylation is associated with genomic instability. In an in vitro study, methylation of repetitive elements and methyltransferase gene expression were decreased due to $PM_{2.5}$ exposure (Miousse et al., 2015). Support for a relationship between $PM_{2.5}$ exposure and global DNA methylation is provided by several epidemiologic studies (Section 10.2.3). Alteration in a third type of epigenetic effect, specific noncoding miRNA, was also found as a result of $PM_{2.5}$ exposure (Borgie et al., 2015b). These effects may contribute to the accumulation of mutations or dysregulated growth.

Carcinogenic Potential

None of the toxicological studies involving $PM_{2.5}$ exposure provides direct evidence of carcinogenesis. However, an animal inhalation study found that $PM_{2.5}$ exposure led to tumor promotion in a model of urethane-induced tumor initiation (Cangerana Pereira et al., 2011). Furthermore, exposure to $PM_{2.5}$ in vitro increased cell invasion, a measure of metastatic potential, which correlated with PAH content (Yue et al., 2015). This effect was blocked by treatment with an antioxidant, suggesting a role for oxidative stress. Epidemiologic studies provide initial evidence that exposure to long-term $PM_{2.5}$ concentrations may contribute to reduced cancer survival (Section 10.2.5.3). This could involve an enhancement of tumor progression or metastasis/tissue invasion or some other mechanism.

Characteristics of Carcinogens and Hallmarks of Cancer

$PM_{2.5}$, as described in the studies evaluated in this chapter, exhibits several characteristics of carcinogens (Smith et al., 2016). Exposure to $PM_{2.5}$ results in genotoxic effects, epigenetic alterations, and oxidative stress. In addition, exposure to $PM_{2.5}$ induces expression of genes involved in PAH biotransformation, indicating that $PM_{2.5}$ contains electrophilic species. Additional studies provide evidence that $PM_{2.5}$ exposure may lead to perturbations of pathways related to the hallmarks of cancer (Hanahan and Weinberg, 2000); (Hanahan and Weinberg, 2011). Findings of enhanced tumor formation may indicate the sustaining of proliferative signaling; increased cell invasion may indicate the activating of invasion and metastasis; methylation of a tumor suppression gene may indicate the evading of growth suppressors; and increased telomerase activity may indicate the enabling of replicative immortality.

Summary of Biological Plausibility

As described here, there are two proposed pathways by which exposure to $PM_{2.5}$ could lead to the development of cancer. The first pathway involves genotoxicity, including DNA damage that could lead to mutational events, such as gene mutation and cytogenetic effects. The second pathway involves epigenetic effects, including methylation of a tumor suppressor gene. Although experimental studies in animals and humans contribute most of the evidence of upstream events, epidemiologic studies report associations between exposure to $PM_{2.5}$ and DNA damage (including DNA adducts), chromosomal mutation (chromosomal aberrations), and epigenetic changes (altered global DNA methylation). Evidence of tumor promotion, a measure of carcinogenic potential, was found in an animal toxicological study. Together, these proposed pathways provide biological plausibility for the epidemiologic results of lung cancer incidence and mortality and will be used to inform a causality determination, which is discussed later in the chapter (Section 10.2.5).

10.2.2 Genotoxicity

In the 2009 PM ISA, there were many toxicological studies that examined mutagenicity, DNA damage, and other endpoints related to genotoxicity. The presence of mutagens in PM extracts collected from ambient air was first demonstrated by Pitts et al. (1975). In agreement with that work and many similar subsequent findings published over the past 40 years, results from studies evaluated in the 2009 PM ISA confirmed that PM and/or PM extracts collected from both ambient air and multiple combustion sources can induce DNA mutations in various strains of *Salmonella* developed by Bruce Ames and others. PM exposure in other in vitro assay systems resulted in changes in molecular and cellular markers that have been associated with genotoxicity. In addition, an in vivo study by Sato et al. (2003) reported increased DNA adducts in lung, liver, and nasal mucosal tissues after inhalation exposure to urban roadside air. Because this study evaluated effects of exposure to a mixture of PM and gases, it does not inform the current ISA, which identifies the hazard for effects after exposures to only the PM component

of complex mixtures. Furthermore, a small number of epidemiologic studies evaluated in the 2009 PM ISA examined molecular and cellular markers that have often been linked with genotoxicity. Many of these studies focused only on PM_{10} exposures or individual components of PM. As a result, these epidemiologic studies did not thoroughly examine the relationship between $PM_{2.5}$ exposure and genotoxicity.

As noted in the 2009 PM ISA, there was a paucity of available studies that investigated the effects of exposures to specific PM size fractions. There were no new studies that evaluated in vivo effects of exposures to $PM_{2.5}$ present in ambient air. Although new in vitro studies were reviewed that confirmed previous reports demonstrating induction of mutagenesis, DNA strand breaks, micronuclei, and oxidative stress after $PM_{2.5}$ and/or $PM_{2.5}$ extract exposures, the relationships between observations from in vitro assays and in vivo endpoints and complex biological disease processes such as carcinogenesis remained uncertain. Moreover, the diversity of in vitro assay protocols and measured endpoints limited the ability to draw more than general conclusions regarding the carcinogenic potential of $PM_{2.5}$.

Since the 2009 PM ISA, new studies continue to investigate mutagenicity, genotoxicity, and carcinogenicity of PM, including many studies that, as in the past, evaluate the effects of total particulate matter (TPM), PM_{10}, and total PM collected from specific combustion sources including diesel and gasoline exhaust and woodsmoke. In addition, recent studies also investigate cancer-related effects following inhalation of $PM_{2.5}$ CAPs, ambient air, and emissions from specific combustion sources. The findings from these studies are supportive of findings from previous studies. However, as discussed in the Preface , the focus of the PM ISA is on the evaluation of the health effects due to exposures to specific PM size fractions (i.e., $PM_{2.5}$, $PM_{10–2.5}$, and UFPs). As a result, in the evaluation of long-term $PM_{2.5}$ exposure and cancer, in the assessment of the experimental evidence for mutagenicity, genotoxicity, and other endpoints associated with carcinogenesis and cancer, the focus is on exposures to $PM_{2.5}$.

10.2.2.1 Mutagenicity

Evidence for mutagenicity is provided by toxicological studies. The Ames *Salmonella*/mammalian-microsome mutagenicity assay has been used for more than 40 years to identify the presence of chemical mutagens (Claxton et al., 2010; Ames, 1971). Developed to screen single chemicals for their potential to induce mutagenesis, the assay was first extended to investigate the mutagenicity of extracted organic material (EOM) from PM collected from air in Los Angeles (Pitts et al., 1975). The *Salmonella* test provided a simple, fast, and inexpensive method for detecting the presence of mutagens within the complex mixture of chemical species that can be present in ambient air.

Assay results over the past 40 years have provided meaningful information regarding the mutagenicity of airborne compounds. The *Salmonella* test, however, is not without technical limitations. For example, it is difficult to draw detailed conclusions based upon direct comparisons between study results because of assay sensitivity to differences in methods. Many studies examine only the organic

matter adsorbed onto collected particles and extraction protocols including solvent and extraction method selection have been shown to affect the amount and class of compounds recovered (Claxton et al., 2004). In addition, several strains of *Salmonella* and variations in assay protocols have been developed. One advantage of the assay is that various strains selectively respond to specific chemical classes, such as nitroarenes, PAHs, or aromatic amines, providing the ability to infer some of the chemical classes responsible for the mutagenicity. However, differences in strains and protocols can modify the reproducibility of results and/or the sensitivity of the assay to certain classes of mutagens (Claxton et al., 2004; Gatehouse et al., 1994). Moreover, studies have revealed that mutagenicity fluctuates seasonally (Claxton et al., 2004). Together, these factors can affect the number of revertant colonies observed and thus limit direct comparisons between disparate studies.

Analyses using various data bases have been performed to see how well the *Salmonella* mutagenicity assay predicts rodent carcinogenicity. The values that have been calculated for both the sensitivity (the percentage of known carcinogens to elicit a positive response in *Salmonella*) and specificity (the percentage of known noncarcinogens to elicit a negative response in *Salmonella*) are 45−80 and 67−100% for sensitivity and specificity, respectively (Kirkland et al., 2005; Zeiger, 1998; Zeiger et al., 1990; Tennant et al., 1987; Kier et al., 1986). Thus, agents that are not carcinogenic in rodents can also be mutagenic in the assay, and some chemical classes of rodent carcinogens are not mutagenic in the *Salmonella* assay (Zeiger et al., 1990). Considering also that PM is a heterogeneous and dynamic mixture with many unknown chemical species, *Salmonella* assay results are accordingly accompanied by uncertainty.

As discussed above, most studies of PM with the *Salmonella* mutagenicity assay evaluated only the EOM adsorbed onto particles. Because extraction results in an enriched preparation of organic compounds, the concentration applied in the assay may not reflect the administered dose delivered to the lung via inhalation of ambient air, nor accurately represent the mixture present on PM as species such as metals and volatile organic compounds (VOCs) will not be responsive to organic extraction. Further, the bioavailability of extracted compounds may not be comparable to the bioavailability of those adsorbed onto particles.

As with many bioassay, the *Salmonella* strains used in the Ames assay have been engineered to improve their ability to detect mutagens. Thus, there is a mutation in a gene coding for a component of the cell wall that makes the cells more permeable to large molecules. This permits PM components such as PAHs to enter the cell and get to the DNA. Likewise, there are various DNA repair deficiencies, such as the elimination of nucleotide excision repair or the addition of error-prone DNA repair, that also enhance the sensitivity of the strains to mutagens. Several different mutations in the histidine genes are present in the strains, permitting the detection of all six types of base substitutions, a 2-base frameshift mutation, as well as some small deletions. One of the most important developments that has made the strains especially useful for complex mixtures is the development of strains with various metabolic capabilities, permitting the inference of specific chemical classes in a complex mixture as being

responsible for some of the mutagenicity of that mixture. Thus, some strains express excess nitroreductase, which activates nitroarenes, and others express acetyltransferase, which can help activate aromatic amines.

Although many new studies using the *Salmonella*/mammalian-microsome assays have been published, only a fraction evaluated the mutagenic activity of $PM_{2.5}$. Of these, all were conducted outside of the U.S. in Brazil, Japan, India, and Italy. In general, the findings support previously published results that organic extracts from collected PM (various size fractions) contain compounds capable of inducing mutagenesis in the *Salmonella* assay. Specifically, results from these studies demonstrate that organic extracts of $PM_{2.5}$ collected from diverse sampling locations exhibit mutagenic activity. The induction of mutations in both the absence and presence of mammalian S9 fractions indicate the presence of compounds that are capable of interacting with DNA without biotransformation as well as those that require metabolic activation to generate ultimate carcinogens (Lemos et al., 2016; Traversi et al., 2014; de Rainho et al., 2013; Rainho et al., 2013; Lemos et al., 2012; Singla et al., 2012; Traversi et al., 2011; Kawanaka et al., 2008; Traversi et al., 2008). In addition to these general findings, several studies also identified the presence of certain compound classes, seasonal variation in mutagenic activity, and the tendency for $PM_{2.5}$ to elicit a greater increase in mutagenicity compared to PM_{10} (Lemos et al., 2016; Traversi et al., 2014; de Rainho et al., 2013; Rainho et al., 2013; Lemos et al., 2012; Singla et al., 2012; Traversi et al., 2011; Kawanaka et al., 2008; Traversi et al., 2008).

As has been documented by past studies, use of plasmid-modified strains sensitive to nitro-PAH species in new studies confirmed the presence of those compounds in airborne particulate matter from sites in Brazil and Italy. Sites included low traffic areas identified as urban background or residential locations (Lemos et al., 2016; de Rainho et al., 2013; Rainho et al., 2013; Lemos et al., 2012; Traversi et al., 2011). For example, Traversi et al. (2011) used three isogenic strains with varying nitroreductase activity to qualitatively demonstrate the contribution of nitroaromatic compounds to the overall mutagenicity observed. $PM_{2.5}$ was most mutagenic in strains with elevated nitroreductase activity, suggesting the presence of nitroaromatic compounds in the extracts evaluated. The knowledge that these compounds are present in PM emissions and that they can induce mutagenesis in the *Salmonella* assay is well established (NTP, 2014; Claxton et al., 2004; Purohit and Basu, 2000; Rosenkranz and Mermelstein, 1983).

Kawanaka et al. (2008) investigated the mutagenicity of EOM from $PM_{2.5}$ collected roadside in Saitama City, Japan. Using a cascade impactor, 12 fractions of varying aerodynamic diameters were collected including fine fractions (<0.12, 0.12−0.20, 0.20−0.30, 0.30−0.50, 0.70−1.2, 1.2−2.1, 2.1−3.5, 3.5−5.2, 5.2−7.8, 7.8−11, >11 μm). The authors used the *Salmonella* assay to determine the mutagenic potency of each fraction and GC/NCI/MS/MS to determine the mass contribution of select nitroaromatic compounds to the total PM mass collected. They used known quantities of those compounds to estimate the contribution of those species to total mutagenicity. Using this approach, the authors reported that the quantity of nitro-PAHs per unit mass in the ultrafine fraction (<0.12) was greater than in that of $PM_{2.5}$ or

$PM_{10-2.5}$. In addition, the authors determined that mutagenicity per unit mass of $PM_{2.5}$ was less than that of UFP in both strains. Moreover, of the six nitroaromatic compounds evaluated, the contribution to mutagenic activity calculated was greatest for 1,8-dinitropyrene in all three fractions of PM extracts evaluated. Due to biological variability of the *Salmonella* assay as well as incomplete details regarding the statistical analysis of the data collected, it is difficult to calculate definitive values for these contributions.

Several studies evaluated seasonal variation in mutagenesis using the *Salmonella* assay (Lemos et al., 2016; Traversi et al., 2011; Traversi et al., 2008). Each observed greater mutagenic activity in extracts from PM collected during the autumn and winter seasons compared to that from PM collected during the spring and summer seasons. These findings agree with previous studies that have also demonstrated the inverse correlation between temperature and mutagenic activity (IARC, 2016; Claxton et al., 2004). Singla et al. (2012) also compared seasonal variation in mutagenic activity. Although the authors did not provide a statistical analysis of the variation in values, they did report a consistent trend in which the mutagenicity of extracts from PM collected during the winter season was greater than the mutagenicity of those from PM collected during the monsoon season. In this study, they suggested that this divergence may be due not only to the increase in temperature, but also to the increase in rainfall.

Singla et al. (2012) and Traversi et al. (2011) analyzed the mutagenic activity of $PM_{2.5}$ and PM_{10} collected during the same timeframes. In experiments using the frameshift strain TA98 without the addition of S9, which especially detects nitroarenes (Singla et al., 2012), the authors reported that the organic extracts collected from $PM_{2.5}$ had higher mutagenic potencies that those from PM_{10}. However, this same effect was not observed in experiments using TA100, which detects primarily PAHs. Likewise in the study by Traversi et al. (2011), the mutagenic potency of the organics extracted from $PM_{2.5}$ was 6.5-fold greater than that from PM_{10} in strain TA98. Further, the authors reported greater mutagenicity for the organic extracts from $PM_{2.5}$ collected in the winter season compared to that from PM_{10} when using the nitro-PAH sensitive YG1021 strain (5.75-fold increase). A third study carried out a similar analysis. Lemos et al. (2012) compared the mutagenic activity of organic extracts from $PM_{2.5}$ and total suspended particles (TSP). The authors reported that the mutagenic potencies of the organic extracts from $PM_{2.5}$ were generally greater than those from TSP; however, a statistical analysis was not provided. Lemos et al. (2012) showed that an aqueous extract generated sequentially after the organic extraction was not mutagenic, showing that all the measured mutagenic activity was in the organic extract.

In summary, while the Ames *Salmonella*/mammalian-microsome mutagenicity assay has several technical limitations and is criticized due to its use of bacteria as a model species, four decades of published results from this assay have clearly demonstrated the presence of mutagenic agents in PM of various size fractions collected from ambient air (IARC, 2016; U.S. EPA, 2009). New studies involving $PM_{2.5}$ exposure published since the 2009 PM ISA also provide evidence of the presence of mutagenic agents (Lemos et al., 2016; Traversi et al., 2014; de Rainho et al., 2013; Rainho et al., 2013; Lemos et al., 2012; Singla et al., 2012; Traversi et al., 2011; Kawanaka et al., 2008; Traversi et al., 2008).

10.2.2.2 DNA Damage

10.2.2.2.1 Toxicological Evidence

In addition to *Salmonella* studies that evaluated mutagenicity, new reports that measured other effects relevant to genotoxicity and carcinogenicity as a result of $PM_{2.5}$ exposures have been published. Many of these studies used a variety of in vitro assays including cell-free and cell culture systems that are designed to identify specific cellular endpoints. For example, the comet assay measures DNA single- and double-strand breaks and can be adapted to identify the presence of apurinic and apyrimidinic (together noted as AP) sites by the introduction of alkaline conditions, and certain types of damaged bases, including oxidized bases, through the additional use of lesion-specific endonucleases (Collins et al., 2008). Several other assays to identify the presence of oxidative stress after $PM_{2.5}$ exposures have also been used in new studies. The relevance of data generated in the comet assay is supported by the fact that oxidative stress is one of the key characteristics of carcinogens (Smith et al., 2016).

The presence of reactive oxygen species (ROS) in a cell is a consequence of normal physiological processes, however oxidative stress, which is the imbalance between the generation of ROS and the protective mechanisms by which ROS are detoxified or ROS-induced damage is repaired, has been associated with the development of several health effects including cancer. ROS and ROS-induced lipid peroxidation products interact with DNA to form DNA lesions such as 7,8-dihydro-8-oxoguanine (8-oxoG), thymine glycol, 2,6-diamino-4-hydroxy-5-formamidopyrimidine (FaPy), etheno-DNA adducts, and malondialdehyde DNA adducts (Smart et al., 2008). The presence of these lesions can lead to the introduction of fixed mutations into the genome after incorrect repair of the damaged base or replication past the base by low fidelity DNA polymerases. The potential for oxidative stress to result in mutagenesis is underscored by the DNA repair mechanisms that have evolved to protect the genome from mutagenesis caused by these lesions. Increased 8-oxoG levels, one of the most widely studied lesions, has been demonstrated to result in spontaneous tumorigenesis in MTH1-deficient mice (Tsuzuki et al., 2001).

Since the 2009 PM ISA, several new studies have been published to identify the potential for oxidative stress resulting from exposure to $PM_{2.5}$. They have focused primarily on evaluating the oxidative potential of PM in acellular in vitro assays, as well as the capability of PM to induce oxidative stress in cultured cells. Because an important source of oxidative stress is inflammation, one new study measured in vitro inflammatory responses to $PM_{2.5}$ exposure. Evidence for inflammation at the organ and system level resulting from $PM_{2.5}$ exposure is described in Chapters 4 and 5.

Collectively, results from the in vitro studies demonstrate that damage to DNA bases and DNA strands can occur due to exposure to $PM_{2.5}$ in these systems and that production of ROS may contribute to that damage. As with *Salmonella* assay results, the findings are limited by the well understood caveats that apply to many in vitro model systems, including uncertainty regarding the relationship between measures of molecular markers and in vivo outcomes. As with the *Salmonella* assay, PM processing after

collection and use of extracted material in many studies may result in PM that is not representative of that in ambient air and/or alter its toxicity. For example, Turner et al. (2015) investigated how the use of EOM from collected particles may affect results for a suite of in vitro toxicity tests. The authors reported that the use of EOM from diesel exhaust particles (DEP) induced greater biological responses than intact DEP in suspension. They also evaluated the effect of cell type and observed that, in general, human premacrophage monocyte (GDM-1) cells were more sensitive than A549 cells.

Several studies measured DNA damage after exposure to ambient $PM_{2.5}$ (Lemos et al., 2016; Danielsen et al., 2011; Oh et al., 2011; Bonetta et al., 2009) and DEP (Dumax-Vorzet et al., 2015; Jalava et al., 2015; Gualtieri et al., 2011) using the comet assay. Although the variety of PM preparation and comet assay methods make direct comparisons difficult, the results suggest that exposure of cultured cells in vitro to $PM_{2.5}$ extracted material and/or suspensions can result in DNA damage. Oh et al. (2011) collected $PM_{2.5}$ from a traffic area in Suwon City, South Korea that was located approximately 20 miles south of Seoul and exposed human bronchial epithelial (BEAS-2B) cells to the organic crude extracted (CE) fraction as well as fractions of the CE that were separated by acid-base partitioning. Using the alkaline comet assay, the authors identified increased damage compared to control in the CE as well as the aliphatic, aromatic, and slightly polar fractions ($p < 0.01$). Repetition of the same assay with the addition of several different oxidant modulators rescued the damage to some extent in all cases, suggesting that the observed damage was, in part, the result of oxidative stress. Further, the authors also assessed the presence of specific lesions through the addition of formamidopyrimidine DNA glycosylase (FPG) and endonuclease III which can detect the presence of oxidized bases and some alkylation damage. For these experiments, increased damage was observed compared with controls in the CE as well as the fractions noted above ($p < 0.01$), providing support for the hypothesis that $PM_{2.5}$-induced oxidative stress can result in DNA damage.

These findings are supported by others (Danielsen et al., 2011; Gualtieri et al., 2011). Danielsen et al. (2011) detected DNA damage in A549 and human monocyte (THP-1) cells after exposure to PM (collection efficiency of 60−80% between 0.2 and 0.8 μm; upper cut point of 2.3 μm) suspension collected from two sites near Slagslunde, North Zealand, Denmark and confirmed the capability of the collected PM to generate ROS in other acellular and cell culture-based assays. Throughout their results, however, statistically significant increases ($p < 0.05$) were frequently observed only after exposure to suspension concentrations of greatest magnitude. In the study by Gualtieri et al. (2011), exposure to $PM_{2.5}$ suspension from PM collected near Milan, Italy resulted in an increase in DNA damage ($p < 0.05$) in BEAS-2B cells compared to controls.

In contrast to the findings by Danielsen et al. (2011) and Gualtieri et al. (2011), Jalava et al. (2015) did not observe DNA damage after exposure to fine PM suspensions. In this study, the authors exposed mouse macrophages (RAW 264.7) to $PM_{10–2.5}$, $PM_{2.5–1}$, $PM_{1–0.2}$, and $PM_{0.2}$ suspensions collected at Nanjing University in China and measured DNA damage using the alkaline comet assay. Although the

authors noted an increase in damage following some exposures to PM of other size fractions, there was no change in the damage measured in suspensions of $PM_{2.5-1}$ or $PM_{1-0.2}$ compared to controls.

Bonetta et al. (2009) also demonstrated the capability of PM extract exposure to result in DNA damage in the comet assay and observed that the amount of damage measured can vary with sampling location, which is consistent with similar findings in *Salmonella* assay studies. Using aqueous and organic extracts from $PM_{2.5}$ collected at urban, highway, and industrial sites near Alessandria, Italy, DNA damage was measured in human lung epithelial (A549) cells with the comet assay. The authors reported that exposure to organic extracts from $PM_{2.5}$ collected from all three sites resulted in an increase in damage using the alkaline comet assay compared to controls ($p < 0.001$). The increase was greatest for exposure to the highway site $PM_{2.5}$ organic extracts (*p*-value not provided). Exposure to aqueous extracts resulted in an increase in damage compared to control ($p < 0.001$) using the FPG-modified alkaline comet assay for $PM_{2.5}$ collected from the industrial site only.

Wessels et al. (2010) demonstrated that DNA damage after exposure to subfractions of $PM_{2.5}$ can vary with sampling location. To represent and compare diverse PM mixture profiles, the authors collected PM from four locations including a rural location at a beach on the west coast of Ireland and three urban locations in Birmingham, U.K. that varied in the extent to which vehicle traffic would contribute to the PM mixture sampled. Five size fractions were collected. $PM_{2.5}$ was collected in four fractions of particles with aerodynamic diameters of <0.5, 0.5−0.95, 0.95−1.5, and 1.5−3 μm. The fifth fraction comprised particles with diameters in the range of 3−7 μm. To evaluate the genotoxicity of aqueous PM suspensions, cultured A549 cells were used in the FPG-modified comet assay. The authors generally observed greater amounts of DNA damage after exposure to urban roadside PM suspensions compared to exposure to PM of equal mass collected from the rural site ($p < 0.1$) for size fractions with aerodynamic diameters of <0.5, 0.95−1.5, and 1.5−3 μm. This contrasts with the 3−7 μm fraction for which there was not a significant difference in the amount of damage induced after exposure to PM collected from any of the urban locations compared to that collected from the rural location. The variation in damage between size fractions was also examined. After adjusting for sampling site, the amount of DNA damage induced by extracts of PM from different particle size fractions was similar.

Borgie et al. (2015b) compared the effects of exposure to intact ambient $PM_{2.5}$ with aerodynamic diameters between 0.3 and 2.5 μm (described as $PM_{2.5-0.3}$) collected from an urban site in Beirut, Lebanon to that collected from a rural site in Byblos, Lebanon which is located 35 km from Beirut. The authors measured phosphorylated H2AX (γ-H2AX), a marker of DNA double strand breaks (DSB), in cultured BEAS-2B cells. Exposure to$PM_{2.5}$ collected from the urban location increased double-strand breaks at both low and high concentrations (3 and 12 $\mu g/cm^2$). In contrast, exposure to $PM_{2.5}$ collected from the rural location induced breaks only at the high concentration (12 $\mu g/cm^2$) only ($p < 0.05$), indicating that the $PM_{2.5}$ collected from the urban location had greater DNA damaging potency than that collected from the rural location.

The induction of oxidative stress after exposure to ambient $PM_{2.5}$ and DEP extracts and suspensions in cell culture demonstrated by comet assay results has been supported by studies that have used other in vitro methods to measure oxidative stress (Dumax-Vorzet et al., 2015; Miousse et al., 2015; Mirowsky et al., 2015; Gordon et al., 2013). Mirowsky et al. (2015) collected $PM_{2.5}$ as well as $PM_{10–2.5}$ from two rural and three urban sites in California and generated aqueous suspensions of both soluble and insoluble material. Using cultured human pulmonary microvasculature endothelial (HPMEC-ST11.6R) cells, they measured ROS with 2′,7′-dichlorofluorescein diacetate (DCFH-DA). DCFH-DA, after removal of the acetate groups by cellular esterases, can be oxidized to highly fluorescent DCF that can then be used to quantify the amount of intracellular ROS. The results identified two variables. That is, both the size fraction and location at which the PM was collected can affect the amount of intracellular ROS generated after exposure to aqueous PM suspension. Suspensions of $PM_{2.5}$ collected at urban sites were characterized by less ROS activity than those of $PM_{10–2.5}$ ($p < 0.001$). The same outcome was not observed, however, after exposure to $PM_{2.5}$ and $PM_{10–2.5}$ suspensions from the rural sites because the ROS activity generated by both was similar. When comparing the same size fractions between urban and rural sites, no differences were reported between sites for the $PM_{2.5}$ suspensions, whereas greater ROS activity was observed in experiments with $PM_{10–2.5}$ from the urban sites than $PM_{10–2.5}$ collected at the rural sites (*p*-value not provided).

Additional studies were identified that also used the DCFA-FA assay to assess intracellular ROS after exposure to PM (Dumax-Vorzet et al., 2015; Gordon et al., 2013). Gordon et al. (2013) exposed BEAS-2B and HBEpC cells to suspensions of size-fractionated PM from ambient air collected from five diverse sampling locations across the U.S. The PM size fractions collected were described as $PM_{2.5–0.2}$, $PM_{10–2.5}$, and $PM_{0.2}$. Like several other findings already highlighted, the authors reported variation in ROS production because of sampling site, season, and particle size. The report also noted that exposure to the $PM_{2.5}$ resulted in ROS production that was less than that of either $PM_{10–2.5}$ or UFP on an equal mass exposure when sampling locations were combined. Dumax-Vorzet et al. (2015) used cultured mouse embryonic fibroblasts (MEFs) in the DCFA-DA assay in addition to an acellular plasmid scission assay to estimate ROS after exposure to DEP suspension. The authors noted a dose-dependent increase in ROS (*p*-value not provided) using both methods.

Studies that used in vitro methods other than DCFA-FA to evaluate ROS or measured other endpoints that are relevant to oxidative stress have also been published. A change in superoxide was not detected in a study by Miousse et al. (2015) using dihydroethidium oxidation after exposure to aqueous extracts from $PM_{2.5}$ collected at an underground parking deck, but an increase in catalase expression ($p < 0.01$) was noted by the authors. Mirowsky et al. (2015) evaluated infiltrating polymorphonuclear cells (PMNs) as inflammation and ROS generated by PMNs in response to PM exposure has also been proposed as a pathway that may result in genotoxicity. The authors compared the effect of exposure on the percent of PMNs in lavage fluid for the various sampling locations and PM size fractions using oropharyngeal aspiration of aqueous PM suspension exposure in mice (FVB/N). Except for one rural location, the increase in percentage of PMNs after exposure to $PM_{2.5}$ suspensions were less than that after

exposure to $PM_{10–2.5}$ ($p < 0.001$). Upregulation of genes involved in antioxidant defense, i.e., the Phase 2 enzymes, were also observed in different in in vitro systems after $PM_{2.5}$ exposure. Borgie et al. (2015b), as described above, found increased gene expression of NQO1 in BEAS-2B cells.

In addition to in vitro studies, one in vivo study examined DNA damage. Exposure of male C57BL/6 mice to concentrated ambient $PM_{2.5}$ ($PM_{2.5}$ CAPs) in Chicago, IL resulted in an increase in 8-oxoG positive nuclei in lung tissue ($p < 0.01$) (Soberanes et al., 2012). This finding provides evidence of oxidative DNA damage in lungs following $PM_{2.5}$ exposure.

In summary, numerous in vitro studies conducted in cultured cells provide evidence of DNA damage, measured as single- and double-strand breaks, following exposure to suspended $PM_{2.5}$ or $PM_{2.5}$ extracts. Increased ROS production was also found in cellular assays. These results indicate that exposure to $PM_{2.5}$ induces oxidative stress, one of the identified characteristics of a carcinogen (Smith et al., 2016). Additionally, there is evidence of a direct relationship between oxidative stress and DNA damage. In an in vivo study, $PM_{2.5}$ CAPs inhalation resulted in oxidative DNA damage in lungs.

10.2.2.2.2 Evidence from Controlled Human Exposure Studies

Controlled human exposure studies have evaluated various markers relevant to DNA damage. Hemmingsen et al. (2015) reported mostly negative findings for DNA damage and oxidative stress from a controlled, cross-over, repeated measures human exposure study carried out in central Copenhagen, Denmark. In this study, overweight, older adults were exposed for 5 hours in chambers with and without high efficiency particulate adsorption filters. Peripheral blood mononuclear cells collected immediately before and after the exposure were negative for change from controls for several endpoints evaluated. These include ROS production, DNA strand breaks, oxidized DNA bases, and mRNA expression of CCL2, IL8, TNF, HMOX1, and OGG1. The only positive association identified was between FPG sensitive sites and exposure to urban air although it failed to reach statistical significance.

Another controlled human exposure study by Liu et al. (2015) measured malondialdehyde (MDA) in blood and urine and 8-oxo-dG in urine. The former is a lipid peroxidation product capable of reacting with DNA bases, whereas the latter is excreted after oxidized dGTP molecules in cellular dNTP pools used for nuclear and mitochondrial DNA replication throughout the cell are acted upon by MTH1 followed by 8-oxo-dGMPase in the process of dNTP pool sanitization. In this single-blind randomized crossover study, nonsmoking adults were exposed for 130 minutes to $PM_{10–2.5}$, $PM_{2.5}$, and UFP CAPs drawn from a downtown street in Toronto, Canada. Participant blood and urine were collected before exposure and after exposure at two-time points (1-hour, 21 hours). Positive associations between urinary MDA concentrations and $PM_{2.5}$ CAPs were reported for both time points (1-hour post-exposure: $p < 0.05$; 21 hours post-exposure $p < 0.1$). Urinary creatinine was used to normalize biomarker concentrations. No association was observed between blood MDA concentration and concentration of $PM_{2.5}$.

10.2.2.2.3 Epidemiologic Evidence

Several recent studies have examined a variety of molecular and cellular markers often associated with DNA damage. Study characteristics including $PM_{2.5}$ concentrations, study population, and exposure assignment approach for the studies that examined long-term $PM_{2.5}$ exposure and DNA damage are detailed in Table 10-1.

Table 10-1 Study specific details and $PM_{2.5}$ concentrations from recent studies that examined DNA damage.

[a]Median concentration.

†Studies published since the 2009 PM ISA.

Rossner et al. (2013b) examined bulky B[a]P-like DNA adducts in study populations in two Czech Republic cities, Prague and a more polluted city (i.e., higher concentrations of not only PM but other pollutants as well), Ostrava. Whereas the study population in Prague consisted of only nonsmoking policeman, the study population in Ostrava was comprised of policeman, office workers, and volunteers.

This resulted in two different types of study populations where one consisted of individuals that may have smoked. Smoking status was not specifically adjusted for in the statistical models, but measures of cotinine in the blood, a proxy for tobacco smoke exposure was included as a covariate. This study found a higher number of B[a]P-like adducts in people that resided in Ostrava in association with $PM_{2.5}$ concentrations (β = 0.002 [95% CI: 0.002, 0.003]). These results are consistent with Li et al. (2014) in a study conducted in Shanghai, China that examined B[a]P-like adducts in a population of nonsmoking men that were traffic policemen or office workers. Using $PM_{2.5}$ concentrations collected through personal monitoring the 24-hours preceding biological sample collection, the authors observed an overall increase in BPDE-DNA adducts (0.8% [95% CI: 0.4, 1.2]), which was driven by the exposure group (1.2% [95% CI: 0.6, 1.5]) consisting of traffic policeman with limited evidence of an increase (0.1% [95% CI: 0.02, 0.23]) in the control group (i.e., office workers).

A study conducted in a cohort from three Chinese cities (Zhuhai, Wuhan, and Tianjin) broadly examined $PM_{2.5}$-modulated DNA damage by focusing on tail DNA and whether specific genetic polymorphisms modify the effect (Chu et al., 2015). Using $PM_{2.5}$ data from a personal monitoring campaign, Chu et al. (2015) reported evidence of a weak positive association between $PM_{2.5}$ concentrations and percentage of tail DNA from peripheral blood samples (β = 0.001 [95% CI: 0.000, 0.002]). These results are consistent with some of the results from Ma et al. (2015) in a study of DNA damage conducted in Shenyang consisting of traffic and nonfield traffic policemen. The authors graded the extent of DNA damage on a scale of 1 to 3, where 1 and 2 represented DNA damage <40% and 3 >40% damage. For DNA damage graded 1 and 2, Ma et al. (2015) did not observe a difference in the level of DNA damage between policemen exposed to high and low $PM_{2.5}$ concentrations. However, when examining Grade 3, there was a much larger percent of DNA damage in the traffic policemen compared to the nonfield policemen.

10.2.2.2.4 Summary

In summary, several lines of evidence provide support for a relationship between exposure to $PM_{2.5}$ and DNA damage. in vitro toxicological studies demonstrate that damage to DNA bases and DNA strands can occur after exposure to $PM_{2.5}$ in these systems and that production of ROS may contribute to that damage. An animal inhalation study (Soberanes et al., 2012) and a controlled human exposure study (Liu et al., 2015) also provide evidence of oxidative DNA damage. These findings are supported by epidemiologic studies that demonstrate DNA damage in association with $PM_{2.5}$ concentrations (Chu et al., 2015; Ma et al., 2015). In addition, epidemiologic studies indicated a larger percentage of B[a]P-like DNA adducts in people exposed to higher $PM_{2.5}$ concentrations (Li et al., 2014; Rossner et al., 2013b).

10.2.2.3 Cytogenetic Endpoints

10.2.2.3.1 Toxicological Evidence

New in vitro studies also demonstrated the presence of chromosomal abnormalities using the cytokinesis block micronucleus assay (CBMN) after exposure to $PM_{2.5}$ (Lemos et al., 2016; Oh et al., 2011). The CBMN assay detects acentric chromosome fragment loss and whole chromosome loss resulting from clastogenic and aneugenic agents, respectively (Kirsch-Volders et al., 2003). Lemos et al. (2016) exposed Chinese hamster lung fibroblasts (V79) to EOM material from $PM_{2.5}$ collected near a petrochemical complex in Triunfo, Brazil. In total, 23 results were reported comprising exposures to two concentrations of samples collected in two locations over several different seasons. Of those 23 results, increases over controls were noted for only three ($p < 0.05$). The remaining 20 results were negative for increases. Oh et al. (2011) also measured micronuclei and reported results consistent with comet assay results reported in the same study (see Section 10.2.2.2). That is, increases in micronuclei in the aliphatic, aromatic, and slightly polar fractions as well as the highest doses of CE compared to controls ($p < 0.01$) were observed in organic extracts from $PM_{2.5}$ collected near Seoul, Korea and this damage was prevented by the addition of ROS scavengers, as was the case for the comet assay results.

10.2.2.3.2 Epidemiologic Evidence

Recent studies have examined cytogenetic endpoints such as chromosomal aberrations and micronuclei. Study characteristics including $PM_{2.5}$ concentrations, study population, and approaches to exposure assignment are detailed in Table 10-2.

Table 10-2 Study specific details and $PM_{2.5}$ concentrations from recent studies that examined cytogenetic endpoints.

[a]Range of mean concentrations across days of biological sampling, same day and 1−3 weeks prior to biological sampling.

[b]Median concentration.

†Studies published since the 2009 PM ISA.

Recent studies conducted in the Czech Republic that examined the relationship between $PM_{2.5}$ exposure and cytogenetic effects did not report clear evidence of associations. Rossner et al. (2011), in a study of nonsmoking policemen working more than 8 hours outdoors per day in Prague, reported no association between $PM_{2.5}$ concentrations measured by ambient monitors in the 2-days prior to personal sampling and the genomic frequency of translocations, percentage of aberrant cells, or the number of acentric fragments. However, when examining different time windows by extending out to longer lags, there was evidence of a positive association between $PM_{2.5}$ concentrations in the 15−28 days prior to personal sampling and the number of acentric fragments (β = 0.64 [95% CI: 0.05, 1.24]). This initial study by Rossner et al. (2011) that focused on Prague was expanded upon to include participants that were defined as living in a more polluted city, Ostrava (Rossner et al., 2013a). As detailed in Section 10.2.2.2, the study populations between Prague and Ostrava differed in that individuals in Ostrava may have smoked. Similar to Rossner et al. (2013b), smoking status was not specifically adjusted for in Rossner et al. (2013a), but measures of cotinine in the blood, a proxy for tobacco smoke exposure was included as a covariate. Rossner et al. (2013a) examined the same markers of chromosomal aberration as Rossner et al. (2011), but also examined the number of micronuclei. When comparing the stable chromosomal aberrations (i.e., genomic frequency of translocations, percentage of aberrant cells, or the number of acentric fragments), the authors observed relatively similar results in both study locations in the 2-days prior to personal sampling even though the $PM_{2.5}$ concentrations were much higher in Ostrava. However, when examining longer lags of exposure (i.e., 1−14 days prior to sampling) there was evidence of a positive association between $PM_{2.5}$ concentrations and the percentage of aberrant cells in Prague (OR = 2.43 [95% CI: 1.26, 4.68], increment not specific). An examination of the frequency of micronuclei found a lower percentage in Ostrava (β = −0.032 [95% CI: −0.042, −0.022]) than Prague (β = −0.074 [95% CI: −0.114, −0.034]).

Additional studies conducted in Italy and Greece examined associations between $PM_{2.5}$ and cytogenetic endpoints with a focus on micronuclei frequency. Ceretti et al. (2014) as part of the RESPIRA study, examined cytogenetic endpoints in exfoliated buccal cells of children residing in Brescia, Italy. The study focused on air pollution concentrations during the winter months because that period of the year has higher concentrations of pollutants, including $PM_{2.5}$. The authors reported no evidence of a positive association between $PM_{2.5}$ concentrations assessed on the same day or during the 1, 2, or 3 weeks prior to biological sample collection and micronuclei frequency. However, there was some evidence of increases in the frequency of nuclear buds, binucleated cells, basal cells, and condensed chromatin cells with $PM_{2.5}$ concentrations in the 1 week prior to biological sample collection. O'Callaghan-Gordo et al. (2015) took a different approach to examining micronuclei frequency in children by focusing on whether a higher micronuclei frequency in pregnant women attributed to air pollution exposure led to higher micronuclei frequencies in children at the time of birth. As part of the Rhea mother-child cohort, O'Callaghan-Gordo et al. (2015) reported positive associations between $PM_{2.5}$ concentrations over the entire pregnancy and micronuclei frequency in maternal (RR = 1.5 [95% CI: 1.0, 2.3]), but not cord, blood (RR = 0.97 [95% CI: 0.63, 1.50]). However, when stratifying by smoking status, an association larger in magnitude was observed in smoking mothers (RR = 1.7 [95% CI: 0.95, 3.1]) compared to nonsmokers (RR = 1.4 [95%

CI: 0.80, 2.5]), but 95% confidence intervals crossed the null for both. Additionally, the association between $PM_{2.5}$ and micronuclei frequency was found to be increased among women with a lower intake of vitamin C during pregnancy (i.e., <85 ng/day).

10.2.2.3.3 Summary

In summary, there is some support for a relationship between exposure to $PM_{2.5}$ and cytogenetic effects. Toxicological studies demonstrate chromosomal abnormalities and micronuclei formation after exposure to $PM_{2.5}$ in in vitro systems and suggest that production of ROS may contribute to the damage (Oh et al., 2011). Epidemiologic studies provide weaker evidence of cytogenetic effects in association with exposure to $PM_{2.5}$; however, there is initial evidence that micronuclei frequency may be correlated with the intake of an antioxidant nutrient (O'Callaghan-Gordo et al., 2015).

10.2.2.4 Other Markers

10.2.2.4.1 Toxicological Evidence

Studies have also evaluated several other molecular and cellular endpoints that are relevant to carcinogenesis. Many of these studies describe events important to the DNA damage response and gene expression that may be relevant to cancer initiation and progression. Expression of genes that participate in PAH biotransformation have been commonly measured in new studies and include AhR, AhRR, ARNT, Cyp1A1 and Cyp1B1 (Yoshizaki et al., 2016; Borgie et al., 2015b; Gualtieri et al., 2011; Oh et al., 2011). Biotransformation may result in the production of PAH metabolites capable of reacting with DNA to form DNA adducts. When DNA repair is absent or ineffective, the formation of DNA adducts may be processed by the cell to mutations.

Borgie et al. (2015b) compared the effects of exposure to intact ambient $PM_{2.5}$ with aerodynamic diameters between 0.3 and 2.5 μm (described as $PM_{2.5–0.3}$) collected from an urban site in Beirut, Lebanon to that collected from a rural site in Byblos, Lebanon which is located 35 km from Beirut. The authors measured AhR, ARNT, AhRR, CYP1A1, and CYP1B1 gene expression in cultured BEAS-2B cells. A general pattern was observed for measurements of CYP1A1 and AhRR expression. That is, after exposure to $PM_{2.5}$ collected from the urban location, increases in expression were observed compared to controls after exposure to both low and high concentrations (3 and 12 $\mu g/cm^2$). In contrast, $PM_{2.5}$ collected from the rural location resulted in an increase compared to control for the high concentration exposure (12 $\mu g/cm^2$) only ($p < 0.05$), indicating that the $PM_{2.5}$ collected from the urban location may possess greater potency than that collected from the rural location. Some increases were also observed for CYP1B1 expression, whereas results were generally negative for AhR and ARNT expression. The finding of increased CYP1A1 expression was confirmed by Oh et al. (2011), discussed above. They estimated

CYP1A1 activity using the ethoxyresorufin-O-deethylase (EROD) assay and reported an increase compared with controls in the total extract as well as the aromatic fraction ($p < 0.01$). Gualtieri et al. (2011) also measured gene expression. They too noted an increase in Cyp1A1 ($p < 0.0001$), Cyp1B1 (p-value not provided) and AhRR (p-value not provided) expression, similar to both Borgie et al. (2015b) and Oh et al. (2011). AhR (p-value not provided) and ARNT (p-value not provided) expression decreased after exposure of BEAS-2B cells to $PM_{2.5}$. Dumax-Vorzet et al. (2015) also measured Cyp1A1 expression; however, the authors did not observe evidence of an increase in Cyp1A1 mRNA after exposure to DEP particle suspension. Because the authors did observe an increase in ROS in the same study, they concluded that Cyp1A1 activity was not the source of the increased ROS.

mRNA expression of some of the same genes detailed in the previous paragraph were measured in an animal study by Yoshizaki et al. (2016). In this study, mRNA from nasal epithelium was quantified for AhR, Cyp1A1, Cyp1A2, Cyp1B1, Erβ-1, and Erβ-2 in male and female BALB/c mice exposed to $PM_{2.5}$ CAPs in São Paulo, Brazil. After exposure, only two changes were reported. Cyp1B1 mRNA expression was increased in exposed female ($p = 0.01$), but not male mice compared with animals exposed to ambient air, and Erβ-2 mRNA expression was decreased in exposed female ($p = 0.007$), but not male mice compared with animals exposed to ambient air. There was not an increase in mRNA for the other four genes evaluated in male or female mice. The authors also measured AhR- and Erβ-positive nuclei in nasal epithelium cells. They observed an increase in the percent of AhR-positive nuclei in $PM_{2.5}$-exposed female ($p = 0.044$) but not male mice compared with controls, and a decrease in the percent of Erβ-positive nuclei in female, but not male mice compared with mice exposed to ambient air.

In addition, one study evaluated the effect of $PM_{2.5}$ exposure on telomerase. Telomerase is a protein that adds telomere repeat sequences to the ends of chromosomes. This is one way in which cells avoid senescence and arrested cell division. Telomerase can play a role in cancer development by conferring cellular immortality. Borgie et al. (2015b) reported increased telomerase activity in cultured BEAS-2B cells exposed to $PM_{2.5}$.

10.2.2.4.2 Evidence from Controlled Human Exposure Studies

Hemmingsen et al. (2015) reported negative findings for mRNA expression of CCL2, IL8, TNF, HMOX1, and OGG1 in a controlled, cross-over, repeated measures human exposure study carried out in central Copenhagen, Denmark. In this study, overweight, older adults were exposed in chambers with and without high efficiency particulate adsorption filters. Peripheral blood mononuclear cells collected immediately before and after the exposure were negative for change from controls for several endpoints evaluated.

10.2.2.4.3 Epidemiologic Evidence

In addition to examining specific changes in the genome that could lead to cancer, an additional study focused on whether $PM_{2.5}$ exposure resulted in differential expression of genes related to a specific health outcome, such as cancer (Chu et al., 2016). Within the TrIPS study, a panel of 63 nonsmoking white men were selected to examine the relationship between gene expression and long-term traffic-related pollution exposure (i.e., $PM_{2.5}$, EC, and OC). Long-term $PM_{2.5}$ exposure was defined as the exposure during the first and last work shift within a week. To focus the analysis on a collection of genes that may influence a health outcome, the authors applied Gene Set Enrichment Analysis (GSEA) to examine gene specific networks. The GSEA analysis identified 44 genes that were previously related to various cellular and biological processes. Chu et al. (2016) then used GeneMANIA network analysis to examine the inter-relationship among this core set of 44 genes. The authors found evidence that long-term exposure to traffic-related pollutants, including $PM_{2.5}$, increased the expression of five genes (ACP1, HSP90AA1, LEF1, MLH1, and RBM5) that are common in cancer pathogenesis.

10.2.2.4.4 Summary

Studies in cultured cells in vitro and in an animal model have demonstrated the upregulation of genes involved in PAH biotransformation following exposure to suspended $PM_{2.5}$ or $PM_{2.5}$ extracts. These results indicate that $PM_{2.5}$ contains electrophilic species, one of the identified characteristics of a carcinogen (Smith et al., 2016). $PM_{2.5}$ exposure also increased telomerase activity in vitro. This result indicates that $PM_{2.5}$ may promote cellular immortalization, another of the characteristics of a carcinogen. Epidemiologic studies link exposure to $PM_{2.5}$ with the upregulation of several genes that may be involved in cancer pathogenesis.

10.2.2.5 Summary of Genotoxicity

Studies published since the completion of the 2009 PM ISA (U.S. EPA, 2009) provide a broader evaluation of the relationship between $PM_{2.5}$ exposure and mutagenicity, DNA damage, cytogenetic effects, and other markers of genotoxicity. The importance of *Salmonella* assay results is that positive results demonstrate the presence of species capable of inducing mutations. It can identify the presence of species that can result in mutations as the result of direct interactions with DNA as well as those that require metabolic activation. Because the most widely accepted theory of cancer etiology is the accumulation of mutations in critical genes, the presence of mutagens within $PM_{2.5}$ and the mutagenicity of organic extracts of $PM_{2.5}$ provide biological plausibility for observations made in epidemiologic studies. Further, results can suggest the presence of certain species such as nitro-polycyclic aromatic compounds (nitro-PAHs). The *Salmonella* assay, however, does not capture the complex biological in vivo activity of human cells, tissues, and other processes or systems of increasing biological

organization. Therefore, although exposure to mutagens present in $PM_{2.5}$ clearly could result in the introduction of mutations that could lead to initiated cells in vivo, strictly interpreted, the results from *Salmonella* only provide evidence for the presence of species capable of inducing mutagenesis. Thus, it is also necessary to consider results from in vitro assays that use mammalian cell lines and in vivo animal studies to completely characterize the effects of PM exposure in humans.

Toxicological studies conducted in mammalian cell lines demonstrated damage to DNA bases, DNA strand breaks, oxidative stress, micronuclei formation, and chromosomal aberrations in response to $PM_{2.5}$ exposure. Upregulation of enzymes involved in antioxidant defense or biotransformation was also found. Dampening oxidative stress using inhibitors decreased DNA damage and micronuclei formation, supporting a role for oxidative stress in mediating genotoxicity (Oh et al., 2011). Although limited in number, some in vivo studies also examined DNA damage following $PM_{2.5}$ exposure. One study, using $PM_{2.5}$ CAPs collected in Chicago, found evidence of oxidative DNA damage in lung tissue (Soberanes et al., 2012). Controlled human exposure studies, including a study using $PM_{2.5}$ CAPs, also demonstrated oxidative DNA damage. A limitation of the collective body of in vitro evidence is that $PM_{2.5}$ was mainly collected overseas in locations with high pollution levels. A limitation of the in vivo evidence is that there are only a few studies. However, one of these found both evidence of oxidative DNA damage and methylation of the promotor region of a tumor suppressor gene in the lung (see also Section 10.2.3.1).

Epidemiologic studies examined a variety of biomarkers and collectively did not provide clear evidence of a relationship between any specific marker and $PM_{2.5}$ exposure. Although there was some evidence indicating a larger percentage of B[a]P-like DNA adducts in people exposed to higher $PM_{2.5}$ concentrations (Li et al., 2014; Rossner et al., 2013b), clear associations between $PM_{2.5}$ and various cytogenetic parameters were not observed in recent studies in the Czech Republic (Rossner et al., 2013b; Rossner et al., 2011). Only one study examined the association between $PM_{2.5}$ and micronuclei frequency in maternal blood and reported evidence of increased micronuclei frequency, specifically in women with low intake of vitamin C during pregnancy (O'Callaghan-Gordo et al., 2015). Those studies that examined DNA damage, by focusing on tail DNA, reported weak positive associations between personal $PM_{2.5}$ concentrations and percentage of tail DNA (Chu et al., 2015; Ma et al., 2015). Additionally, there is preliminary evidence that long-term $PM_{2.5}$ exposure may result in the differential expression of genes linked with cancer pathogenesis.

10.2.3 Epigenetic Effects

Epigenetic mechanisms regulate the transcription of genes without altering the nucleotide sequence of DNA. These mechanisms generally involve DNA methylation, histone modifications, chromatin remodeling, and changes in noncoding mRNA and nuclear organization and lead to alterations that may have long-term consequences or are heritable (Keverne and Curley, 2008; Jones and Baylin, 2007). DNA methylation and histone modifications, which include methylation, acetylation,

phosphorylation, ubiquitylation, and sumoylation, are known to be linked (Hitchler and Domann, 2007; Jones and Baylin, 2007). Numerous studies have identified epigenetic processes in the control of cancer (Foley et al., 2009; Gopalakrishnan et al., 2008; Jones and Baylin, 2007; Valinluck et al., 2004), embryonic development (Foley et al., 2009; Gopalakrishnan et al., 2008; Keverne and Curley, 2008), and inflammation and other immune system functions (Adcock et al., 2007).

Epigenetic modifications resulting in decreased expression of tumor suppressor genes and increased expression of transforming genes have been observed in human tumors (Valinluck et al., 2004). In general, transcription repression is associated with DNA methylation in promoter regions of genes. Cytosine methylation in CpG dinucleotides has emerged as an important, heritable epigenetic modification that can result in chromatin remodeling and decreased gene expression. Global changes in DNA methylation are also seen in cancer and hypomethylation is associated with genomic instability (Gopalakrishnan et al., 2008).

Growing evidence demonstrates the epigenetic effects of PM exposure, which is associated primarily with alterations in DNA methylation. In the 2009 PM ISA, there were a small number of epidemiologic studies that examined epigenetic effects, specifically methylation. DNA methylation is an epigenetic mechanism that regulates the proper expression of genetic information in a tissue-, cell-, and sex-dependent manner and controls the expression of tumor promotor and suppressor genes and of repetitive elements. Repetitive elements comprise up to ⅔ of mammalian genomes and are heavily methylated to prevent their aberrant transcription. Thus, repetitive element methylation levels have been used as surrogate biomarkers of global DNA methylation, which is linked to genomic instability and thus may contribute to the accumulation of mutations. A large subset of studies has evaluated the effect of PM exposure on this marker. In particular, research has focused on retrotransposons LINE-1 and Alu (SINE in mouse) and satellite DNA. Studies evaluated in the 2009 PM ISA found inconsistent evidence of an association between PM exposure and methylation of Alu and long interspersed nuclear element-1 (LINE-1) sequences, two sequences linked previously with global genomic DNA methylation. Recent epidemiologic studies further evaluated DNA methylation, and provide evidence for both hyper- and hypomethylation in response to $PM_{2.5}$ exposure. Both DNA hyper- and hypomethylation have been observed in malignant cells. Recent animal toxicological studies investigated epigenetic effects resulting from $PM_{2.5}$ exposure and provide evidence for methylation of a tumor promotor gene and alteration in noncoding mRNA.

10.2.3.1 Methylation of Tumor Suppressor Genes

Evidence that exposure to $PM_{2.5}$ results in the methylation of tumor promoter genes is provided by animal toxicological studies. Soberanes et al. (2012) measured molecular markers that have been associated with an increased risk of cancer in a high-risk smoking cohort. Using male C57BL/6 mice, the authors reported increased promotor methylation of p16 (CDNK2A), a tumor suppressor, and of matrix

metalloproteinase-2 (MMP-2) compared to controls ($p < .001$) in whole lung genomic DNA following inhalational exposure to $PM_{2.5}$ CAPs in Chicago, IL. The authors also reported an increase in DNA methyltransferase 1 (DNMT1) mRNA and protein ($p < 0.01$), but not DNMT3a or DNMT3b expression. Finally, they also noted an increase in 8-oxoG positive nuclei in lung tissue ($p < 0.01$), supporting the presence of ROS following $PM_{2.5}$ exposure. Alveolar epithelial cells exposed to the same $PM_{2.5}$ CAPs exhibited increased DNMT1 transcription and methylation of the p16 promotor; these effects were inhibited by treatment with an antioxidant targeted to mitochondria and by an inhibitor of JNK.

Another study using Wistar rats measured changes in p16CDNK2A (CDNK2A) and APC promoter methylation following $PM_{2.5}$ exposures of 4 hours to 28 days (Ding et al., 2016). Animals were exposed to ambient air at three sites in Zhejiang, China. Exposed rats were housed in cages roadside of a traffic tunnel and busy intersection; control rats were housed in cages at a university greenspace 0.5 mile from the nearest road. Although the authors made separate measurements for spring and autumn seasons, the DNA methylation was not different between the seasons, so seasonal data were analyzed together. The authors reported β-values and 95% confidence intervals for methylation of p16CDNK2A and APC promoters in peripheral blood and lung tissue after exposures of 4 hours and 7 days. The authors did not observe an association between $PM_{2.5}$ mass over exposures of these durations and p16CDNK2A promoter methylation in blood or lung tissue. An association was calculated for APC promoter methylation for only the 7-day exposure in lung tissue (0.009 [0.001, 0.019], $p = 0.046$). The study also reported associations after 14−28 days of exposure and note a positive exposure between $PM_{2.5}$ mass and p16CDNK2A promoter methylation in blood (0.037 [0.017, 0.057], $p = 0.001$) and lung tissue (0.011 [0.003, 0.019], $p = 0.011$), as well as APC promoter methylation in lung tissue (0.008 [0.002, 0.015], $p = 0.046$). The authors noted that methylation changes generally returned to levels comparable to controls after the longer 28-day exposures. The appreciable difference in environment between the exposure sites and plausible introduction of other stressors into the environment of the experimental animals elevates the uncertainty in the reported results.

10.2.3.2 Methylation of Repetitive Line Elements

10.2.3.2.1 Toxicological Evidence

In the experimental animal study discussed above using Wistar rats, Ding et al. (2016) also characterized global epigenetic changes represented by LINE-1 and Alu methylation after exposure to $PM_{2.5}$. Animals were exposed to low, medium, and high levels of traffic-related air pollution in Zhejiang, China. The authors reported β-values and 95% confidence intervals for methylation of LINE-1 in peripheral blood and lung tissue. They observed associations with 4-hour $PM_{2.5}$ exposure and decreased LINE-1 methylation in blood (−0.027 [−0.041, −0.013], $p = 0.003$) and lung (−0.041 [−0.049, −0.032], $p < 0.001$) tissues as well as with exposure for 7 days (blood: −0.064 [−0.104, −0.023], $p = 0.003$; lung:

−0.033 [−0.058, −0.008], p = 0.012). After 14 and 28 days, decreased LINE−1 methylation was associated with $PM_{2.5}$ exposure in the lung (−0.015 [−0.028, −0.002], p = 0.024). No associations were observed with Alu methylation. The authors do note that methylation changes generally returned to levels comparable to controls after the longer 28-day exposures.

Montrose et al. (2015) also investigated global DNA methylation in peripheral blood in a study of sled dogs residing in kennels in and near Fairbanks, AK. During Alaskan winters, severe temperature inversions result in elevated $PM_{2.5}$ concentrations in Fairbanks. Sled dogs housed at three kennels were recruited to participate. Average $PM_{2.5}$ mass was 90 μg/m^3 at Kennel A, 48 μg/m^3 at Kennel B, and 16 μg/m^3 at Kennel C. The authors did not identify any differences in the levels of global DNA methylation or percentage of methylated cytosine bases between the dogs from three kennels, and thus did not find an association between $PM_{2.5}$ mass and global DNA methylation.

Epigenetic effects following PM exposure have also been investigated using in vitro methods. Miousse et al. (2015) measured epigenetic changes at repetitive sequences and changes in methyltransferase gene expression in cultured murine macrophages (RAW264.7) after exposure to aqueous extracts of PM (number median aerodynamic diameter of 0.42 μm) collected from the lowest level of a multilevel underground parking deck at the University of Arkansas in Little Rock. Measurements of DNMT1 and DNMT3b mRNA transcripts following PM extract (50 μg/mL) exposure revealed a decrease after 24 hours compared to control ($p < 0.05$ and $p < 0.001$, respectively). No change was observed in the amount of DNMT3a mRNA measured at 24 hours, however, an increase was noted at 72 hours ($p < 0.001$). When the authors measured methyltransferase enzymatic activity, however, no change was observed after exposure to PM extracts. Several repetitive elements were studied to identify their methylation status and expression level after PM extract exposure. Weak hypomethylation of SINE B1/B2 was observed at the 24-hour time point control ($p < 0.01$ and $p < 0.05$, respectively). After 72 hours, methylation levels of SINE B1 returned to levels similar to that of the control; however, SINE B2 remained weakly hypomethylated ($p < 0.05$). Analysis of SINE B1/B2 expression did not reveal any differences between exposed and control cells at either time point. No change in methylation or expression of the other transposable element evaluated, L1, was observed.

In the same report, Miousse et al. (2015) also measured the change in methylation of major and minor satellites after 24 and 72 hours of exposure to aqueous extracts of PM. Only one change from the controls was observed. After 72 hours of exposure to 50 μg/mL PM extract, hypomethylation of the major satellites was reported. The authors again also measured the corresponding mRNA levels. No change in expression of either the major or minor satellites at either time point was observed.

10.2.3.2.2 Epidemiologic Evidence

Recent epidemiologic studies have expanded upon the examination of the relationship between $PM_{2.5}$ exposure and DNA methylation. These studies encompass both the examination of the methylation

of specific parts of the genome that may play an important role in carcinogenesis as well as an overall assessment of DNA methylation. Study characteristics, including $PM_{2.5}$ concentrations, study population, and approach to assigning $PM_{2.5}$ exposure, are detailed in Table 10-3.

Table 10-3 Study specific details and $PM_{2.5}$ concentrations from recent studies that examined DNA methylation.

†Studies published since the 2009 PM ISA.

Those studies that examined overall global methylation provide an assessment as to whether exposure to $PM_{2.5}$ can result in either hyper- or hypomethylation of DNA. De Prins et al. (2013) in a study conducted in Flanders, Belgium examined global DNA methylation (percentage 5-methyl-2´-deoxycytidine, %5 mdC) in 48 nonsmoking adults. The authors examined methylation at two-time periods, once in the summer and once in the winter, and whether any changes in methylation were associated with cumulative $PM_{2.5}$ exposures that were either short or long in duration (i.e., <1 week or up to a few months). In analyses combining the two sampling periods, De Prins et al. (2013) reported evidence indicating a reduction in overall DNA methylation across the lags examined with the magnitude of the reduction increasing over time, with the most pronounced reductions occurring at a 30-day lag (−0.14 [95% CI: −0.28, 0.00] for an IQR increase in $PM_{2.5}$ concentrations of 14.2 µg/m³) and 60-day lag (−0.18 [95% CI: −0.37, 0.01] for an IQR increase in $PM_{2.5}$ concentrations of 11.4 µg/m³). In seasonal analyses, there was also evidence of a reduction in methylation, but mostly in the summer and at shorter lags (i.e., 2-day and 3-day). In a subsequent genome-wide meta-analysis of DNA methylation in the Normative Aging Study (NAS) as well as the German KORA F3 and F4 studies, associations between $PM_{2.5}$ (trailing 2-day average), $PM_{2.5}$ (trailing 7-day average), and $PM_{2.5}$ (trailing 28-day average) was found to result in 1, 1, and 10 CpG sites that had changes in methylation, respectively (Panni et al., 2016). At the 10 CpG sites identified using 28-day average $PM_{2.5}$ exposure, 7 sites had higher methylation and 3 lower methylation. In a sensitivity analysis, the authors reported associations with $PM_{2.5}$ (trailing 28-day average) that were generally similar after adjustment for annual average $PM_{2.5}$ (trailing 1-year average). Although De Prins et al. (2013) and Panni et al. (2016) examined global DNA methylation across the entire genome, Madrigano et al. (2011) examined global methylation by focusing on specific portions of the genome, i.e., the LINE-1 and Alu repetitive elements. Within the NAS cohort, the authors examined multiple exposure time windows, 28, 45, 60, 90, and 180 days prior to biological sampling. For analyses

focusing on $PM_{2.5}$ exposure, Madrigano et al. (2011) reported some evidence of a small decrease in methylation at 45- and 60-days for only LINE-1, but 95% confidence intervals were large.

Additional studies that examined DNA methylation at specific sites of the genome relied on an assessment of $PM_{2.5}$ exposure using personal monitors. Guo et al. (2014) examined associations between personal $PM_{2.5}$ concentrations and blood DNA methylation (percentage 5 methylcytosine, %5 mC) of the tandem repeats SATα, NBL2, and D4Z4 in 60 office workers and 60 truck drivers within the Beijing Truck Driver Air Pollution Study. Biological samples from participants were provided twice, 1−2 weeks apart. The authors reported an inverse association between $PM_{2.5}$ concentrations and SATα methylation ($\beta = -1.35$, SE = 0.54) in office workers and truck drivers combined, with the association stronger in truck drivers ($\beta = -2.34$, SE = 0.94). There was also evidence of an inverse association between $PM_{2.5}$ concentrations and NBL2 methylation, but only in truck drivers ($\beta = -0.88$, SE = 0.84). These results indicate that higher exposures to $PM_{2.5}$ may result in the differential methylation of some parts of the genome. Sanchez-Guerra et al. (2015) also examined the Beijing Truck Driver Air Pollution Study cohort to examine methylation of both 5mC and 5-hydroxymethylcytosine (5hmC). Most DNA methylation studies focus on 5mC because it is often considered a marker of suppressed gene expression; however, 5mC is oxidized to 5hmC which is a potential marker of gene expression (Sanchez-Guerra et al., 2015). The authors examined whether PM exposure increases the oxidation of 5mC to 5hmC and subsequently increases blood levels of 5hmC. Using the same personal $PM_{2.5}$ measurements as the Beijing Truck Driver Air Pollution studies described previously, the authors did not report any evidence of an increase in 5hmC in response to $PM_{2.5}$ exposure.

Although the previous studies evaluated focused on DNA methylation in adults, a study conducted in Belgium examined the relationship between maternal $PM_{2.5}$ exposure and placental DNA methylation. Janssen et al. (2013) within the ENVIRONAGE cohort, examined the association between global DNA methylation and $PM_{2.5}$ exposure during each trimester of gestation and the entire pregnancy. The authors reported evidence of an overall reduction in placental DNA methylation by 2.2% (95% CI: −3.7, −0.73) when examining $PM_{2.5}$ exposures over the entire pregnancy. Analyses of individual trimesters as well as a model that simultaneously included each trimester provide evidence of the greatest reduction in methylation occurring in the 1st trimester, −2.4 and −2.1%, respectively.

10.2.3.3 Noncoding mRNAs

In addition to DNA methylation, interest in how environmental exposures affect miRNA expression has also increased since the 2009 PM ISA. miRNAs are small, evolutionary conserved, noncoding RNAs involved in the regulation of gene expression. Recently, animal toxicological studies have reported that exposure to various environmental stressors, including PM, can lead to alterations in miRNA expression and subsequent alterations in the expression of genetic information.

Borgie et al. (2015b) compared the effects of exposure to intact ambient $PM_{2.5}$ with aerodynamic diameters between 0.3 and 2.5 μm (described as $PM_{2.5–0.3}$) collected from an urban site in Beirut, Lebanon to that collected from a rural site in Byblos, Lebanon, which is located 35 km from Beirut. The authors measured miR-21, miR-26b, and miR-27a expression in cultured BEAS-2B cells. After exposure to PM collected from the urban location, miR-21 expression was increased compared to controls after exposure to both low and high concentrations (3 and 12 $\mu g/cm^2$). In contrast, PM collected from the rural location resulted in an increase compared to control for the high concentration exposure (12 $\mu g/cm^2$) only ($p < 0.05$), indicating that the $PM_{2.5}$ collected from the urban location may possess greater potency than that collected from the rural location.

10.2.3.4 Summary of Epigenetic Effects

Studies published since the completion of the 2009 PM ISA provide a broader evaluation of the relationship between $PM_{2.5}$ exposure and epigenetic effects. An animal toxicological study involving inhalation of $PM_{2.5}$ CAPs (Chicago) found methylation of the tumor suppressor gene p16 and upregulation of methylation enzymes in lung tissue (Soberanes et al., 2012). An in vitro experiment found similar results in the same study, as well as evidence for oxidative stress contributing to the effects. Other evidence from animal toxicological studies includes methylation of p16 and the repetitive line element LINE-1 in blood and lung tissue in association with $PM_{2.5}$ concentrations in a field study conducted in China (Ding et al., 2016) and upregulation of noncoding mRNA in an in vitro study involving $PM_{2.5}$ collected in Lebanon (Borgie et al., 2015b).

Recent epidemiologic studies of ambient and personal $PM_{2.5}$ concentrations generally reported some evidence of a change in DNA methylation. In studies examining both global methylation as well as methylation of specific genomic sites (i.e., CpG sites, LINE-1, Alu, SATα, and NBL2), there was evidence indicating hypomethylation in response to $PM_{2.5}$ exposure (Panni et al., 2016); Guo et al. (2014); (De Prins et al., 2013; Madrigano et al., 2011). However, there was also evidence of hypermethylation in some instances (Panni et al., 2016). A recent study in a cohort of mother-child pairs in Belgium also noted associations with $PM_{2.5}$ concentrations and changes in global DNA methylation (Janssen et al., 2013). Collectively, studies of $PM_{2.5}$ exposure and DNA methylation provide some evidence of epigenetic effects, but the broad number of biomarkers and measures of DNA methylation examined complicate the overall interpretation of results across studies.

10.2.4 Carcinogenic Potential

In the 2009 PM ISA (U.S. EPA, 2009), there were a small number of in vivo toxicological studies that examined carcinogenic potential. No evidence of increased tumor formation was found after chronic inhalation of diesel exhaust (Reed et al., 2004) or hardwood smoke (Reed et al., 2006) in a cancer-prone

mouse model. However, urban air in Brazil enhanced the formation of tumors in mice that were pretreated with urethane to initiate tumor formation (i.e., a model of tumor promotion) (Cury et al., 2000; Reymao et al., 1997). Because these in vivo studies evaluated effects of exposure to mixtures of PM and gases, they do not directly inform the current ISA, which identifies the hazard for effects after exposures to only the PM component of complex mixtures. Studies published since the 2009 PM ISA include an in vivo study of tumor promotion and an in vitro study of cell invasion, which is an indicator of metastasis.

Cangerana Pereira et al. (2011) exposed female Swiss mice to ambient $PM_{2.5}$ in downtown São Paulo, Brazil, 20 m from the roadside. Some animals were pretreated with the tumor initiator urethane, while others received saline. Exposed animals were housed in exposure chambers fitted with a filter designed to trap large particles but not $PM_{2.5}$. Control group animals were housed in exposure chambers fitted with a series of three filters designed to trap all ambient particles. After 60 days of exposure to 4.54 μg/m^3 and 17.66 μg/m^3 $PM_{2.5}$ in the filtered and nonfiltered chambers respectively, the authors counted the number of urethane-induced nodules (classified as adenomas) present at the pleural surface. The number of nodules observed in urethane-pretreated mice exposed to $PM_{2.5}$ was 4.0 ± 3.0; the number of nodules observed in the urethane-pretreated control group was 2.0 ± 2.0 (p = 0.02). Of animals treated with saline rather than urethane, neither those exposed to $PM_{2.5}$ nor those exposed to filtered air developed tumors. The results of this study, together with previously published observations that investigated the effect of air pollution on urethane-exposed mice (Cury et al., 2000; Reymao et al., 1997), demonstrate that ambient PM may have a promoting effect in lung carcinogenesis. The mechanism by which exposure to $PM_{2.5}$ enhanced tumorigenesis in this study was not explored; however, activation of inflammatory pathways, suppression of DNA repair, and an enhancement of DNA replication errors are all possibilities.

Yue et al. (2015) collected $PM_{2.5}$ over spring, summer, autumn, and winter from a peri-urban residential area of Taiyuan, China. Using A549 cells and $PM_{2.5}$ suspensions in a cell invasion assay, the authors report that cell invasion was greatest after exposure to $PM_{2.5}$ collected in the winter (p values not provided). The concentrations of 18 PM-bound PAHs were also measured. The authors reported that the amounts of PAHs measured for each season roughly corresponded to the extent to which cell invasion was observed for the same season, i.e., the amount of PM-bound PAH was greatest for that collected in the winter season, and the number of invading cells was greatest after exposure to PM collected during the winter season as well. When the authors repeated the experiment with a range of winter $PM_{2.5}$ suspension concentrations, the increase in invasive cells compared to controls was observed at the greatest doses only (3 μg/mL: $p < 0.05$; 10 μg/mL: $p < 0.01$). The authors also measured changes in mRNA of proteins important to the suppression and promotion of cell migration and invasion and noted a decrease in E-cad and TIMP-2 and an increase in Fib and MMP-2. Lastly, the authors also demonstrated the generation of ROS after exposure to the winter $PM_{2.5}$ with the DCFH-DA assay and demonstrated attenuation of cell migration in the presence of the antioxidant N-acetyl-L-cysteine, providing support for the contribution of ROS to additional events relevant to carcinogenesis.

In summary, although neither of the toxicological studies involving $PM_{2.5}$ exposure provides direct evidence of carcinogenesis, both demonstrated increased carcinogenic potential. Chronic inhalation of $PM_{2.5}$ CAPs collected in Brazil resulted in tumor promotion in an animal model. Furthermore, exposure to $PM_{2.5}$ in vitro increased cell invasion, a measure of metastatic potential, which correlated with PAH content. This effect was blocked by treatment with an antioxidant, suggesting a role for oxidative stress in mediating cell invasion. Epidemiologic studies provide initial evidence that exposure to long-term $PM_{2.5}$ concentrations may contribute to reduced cancer survival (see Section 10.2.5.3). This could involve an enhancement of tumor progression or metastasis/tissue invasion or some other mechanism.

10.2.5 Cancer Incidence, Mortality, and Survival

At the completion of the 2009 PM ISA, epidemiologic studies that examined the association between long-term $PM_{2.5}$ exposure and cancer primarily focused on lung cancer mortality, with a more limited number of studies examining lung cancer incidence and other types of cancers. Although these studies tended to support a relationship between long-term $PM_{2.5}$ exposure and lung cancer mortality, the overall body of evidence was rather small and mostly limited to analyses and reanalyses of a few cohorts (i.e., American Cancer Society [ACS], Harvard Six Cities [HSC], Netherlands Cohort Study on Diet and Cancer [NLCS-Air], and Adventist Health and Smog Study [AHSMOG]). Since then, several new cohort studies and meta-analyses, as well as extensions and reanalyses of older cohorts, have examined $PM_{2.5}$ and both lung cancer incidence and mortality along with the potential relationship between long-term $PM_{2.5}$ exposure and cancers in other organs. Additionally, epidemiologic studies have examined the potential impact of $PM_{2.5}$ exposure on the survival of cancer patients. Overall, when evaluating recent epidemiologic studies, the strongest evidence demonstrating an association between long-term $PM_{2.5}$ exposure and cancer comes from studies that examine lung cancer incidence and mortality. This evidence is further supported by studies that examined associations in never smokers.

10.2.5.1 Lung Cancer

Epidemiologic studies that examine the relationship between long-term $PM_{2.5}$ exposure and lung cancer often focus on lung cancer mortality, which could be a reflection of the high case-fatality rate of lung cancer, resulting in measures of lung cancer mortality and incidence being comparable (Hamra et al., 2014). Recent studies of $PM_{2.5}$ and lung cancer have expanded upon the body of evidence for both lung cancer mortality and incidence. The following section focuses on those recent studies that adequately examine the relationship between long-term $PM_{2.5}$ exposure and lung cancer mortality and incidence using either modeled or monitored $PM_{2.5}$ concentrations. Many of the studies that examine lung cancer mortality are also evaluated in the long-term $PM_{2.5}$ exposure and mortality section (see Section 11.1.2). As a result, the focus of this section is specifically on issues inherent to the evaluation of the relationship between long-term $PM_{2.5}$ exposure and lung cancer mortality or incidence. Other studies with identified

limitations including, but not limited to, ecological study design, estimation of $PM_{2.5}$ concentrations for entire study duration from concentrations of other pollutants using conversion factors, and inadequate control for potential confounders are not the focus of this section. These studies are available at: https://hero.epa.gov/hero/particulate-matter.

Study characteristics including $PM_{2.5}$ concentrations, study population including number of deaths or cases, and exposure assignment approach for the large cohort studies that focused on national or regional analyses evaluated in the 2009 PM ISA, along with recent cohort studies that examine lung cancer mortality and incidence are detailed in Table 10-4. The results from these studies are highlighted in Figure 10-3, and provide evidence of generally consistent, positive associations across different exposure assignment approaches and study locations. Within the cohorts summarized in Table 10-4 and Figure 10-3, additional analyses were conducted to further examine the associations observed in the main analysis, which comprise the focus of the following sections.

Table 10-4 Study specific details and $PM_{2.5}$ concentrations from recent studies and studies evaluated in the 2009 PM ISA that examined lung cancer mortality and incidence.

Study	Cohort Location	Years Air Quality/Follow-up	Events/ Population	Mean Concentration µg/m^3	Exposure Assessment
Lung cancer mortality					
North America					
McDonnell et al. (2000)[a]	AHSMOG (California)	$PM_{2.5}$: 1973−1977 Follow-up: 1977−1992	Deaths: 13[e] Pop: 1,228[e]	31.9	Monthly average concentration for Airshed where participant resided
Laden et al. (2006)[b,c]	HSC Extension (Six U.S. cities)	$PM_{2.5}$: 1979−1987; 1985−1998[f] Follow-up: 1974−1998	Deaths: 226 Pop: 8,096	Across sites: 10.2−29.0 Overall mean: 16.4	One centrally located monitoring site in each city

Figure 10-3 Summary of associations reported in previous and recent cohort studies that examined long-term $PM_{2.5}$ exposure and lung cancer mortality and incidence.

10.2.5.1.1 Lung Cancer Mortality

Recent studies that examined the association between long-term $PM_{2.5}$ exposure and lung cancer mortality have attempted to account for the potential confounding effects of exposure to cigarette smoke

through detailed information on smoking status as well as exposure to second-hand smoke (SHS). These studies have assessed the role of smoking status on the relationship between long-term $PM_{2.5}$ exposure and lung cancer mortality through two approaches, either including smoking status as a covariate in the main statistical model or examining whether smoking status modifies the $PM_{2.5}$-lung cancer mortality association. The following section discusses both approaches, focusing first on those studies that had individual-level data on smoking status and then those studies that used proxy measures to account for smoking status within the study population.

Individual-Level Data on Smoking Status

The majority of studies that examined the $PM_{2.5}$-lung cancer mortality relationship focused on the ACS-CPS II cohort, building off the initial work presented in Pope et al. (1995) and then reanalyzed in subsequent studies (e.g., (Krewski et al., 2009)). These studies differed primarily in the years of $PM_{2.5}$ data examined, years of follow-up, exposure assignment approaches, and geographic extent of the cohort examined (i.e., national or specific location; Table 10-4). A summary of the results from studies that focused on the ACS-CPS II cohort that are evaluated in this section are detailed in Table 10-5.

Whereas the initial ACS-CPS II studies focused on assigning exposure using the average $PM_{2.5}$ concentrations across all monitors, Jerrett et al. (2013) conducted a more detailed exposure assessment using LUR in a subset of the full cohort limited to California. The authors reported a positive association with lung cancer mortality (HR = 1.06 [95% CI: 0.96, 1.17]). Although specific to California, the results of Jerrett et al. (2013) are consistent with those observed in the full cohort using cruder exposure assessment techniques, which includes Krewski et al. (2009) as well as a recent analysis by Thurston et al. (2013) that focused on mortality and long-term exposure to $PM_{2.5}$ components and sources. Using a similar exposure assignment approach as Krewski et al. (2009), Thurston et al. (2013) reported a HR = 1.03 (95% CI: 0.99, 1.08) for lung cancer mortality in a model adjusting for a range of individual- and ecological-level covariates including cigarette smoking history.

Table 10-5 Summary of results from studies that examined long-term $PM_{2.5}$ exposure and mortality in the American Cancer Society-Cancer Prevention Study II.

Study	ACS-CPS II Population	Location	Result[a]
Krewski et al. (2009)	Full cohort	National	1.05 (1.02, 1.09)
†Jerrett et al. (2013)	Full cohort	California	1.06 (0.96, 1.17)
†Thurston et al. (2013)	Full cohort	National	1.03 (0.99, 1.08)
†Turner et al. (2016)	Never smokers	National	1.04 (1.01, 1.08)
†Turner et al. (2011)	Full cohort	National	1979−1983: 1.07 (0.99, 1.16) 1999−2000: 1.13 (1.01, 1.25) 1979−1983; 1999−2000: 1.09 (0.98, 1.21)
†Turner et al. (2014)	Full cohort[b]	National	Never smoker (high vs. low): 1.26 (0.90, 1.77) Current smoker (high vs. low): 1.19 (1.03, 1.38)

[a]All results are for a 5 μg/m^3 increase in $PM_{2.5}$ concentrations except Turner et al. (2014) where results were based on comparing results between the 25th percentile (≤10.59 μg/m^3) and 75th percentile (>14.44 μg/m^3) of $PM_{2.5}$ concentrations.

[b]Study population that produced these results was smaller than the total population of the study detailed in Table 10-4, Never Smokers (Lung Cancer Deaths = 144, Population = 149,617); Current Smokers (Lung Cancer Deaths = 793, Population = 65,275).

†Studies published since the 2009 PM ISA.

Using a more refined exposure assignment approach in the full ACS-CPS II cohort, Turner et al. (2016) examined associations between both overall $PM_{2.5}$ concentrations using a national-level hybrid LUR Bayesian maximum entropy interpolation (LURBME) model as well as $PM_{2.5}$ concentrations decomposed into near-source (LUR) and regional (LURBME-LUR) components. The authors reported a positive association between overall $PM_{2.5}$ from the LURBME model and lung cancer mortality (HR = 1.04 [95% CI 1.01, 1.08]). Positive associations were also observed when examining both the near-source (HR = 1.08 [95% CI: 0.98, 1.18]) and regional (HR = 1.04 [95% CI: 1.00, 1.07]) components of ambient $PM_{2.5}$ concentrations. The results of Turner et al. (2016) provide evidence that within the ACS-CPS II, regardless of the exposure assignment approach used there is evidence of a consistent positive association between long-term $PM_{2.5}$ exposure and lung cancer mortality (see Figure 10-3).

As detailed above, traditionally ACS-CPS II studies have included covariates for smoking status or exposure to SHS in statistical models, but have not accounted for potential residual confounding by cigarette smoke. Often the examination of the association between long-term air pollution exposure, including $PM_{2.5}$, and lung cancer mortality in never smokers has been limited by the small number of lung cancer deaths (Turner et al., 2011). Within the ACS-CPS II cohort Turner et al. (2011) examined lung cancer mortality only in never smokers by using the three $PM_{2.5}$ exposure periods (i.e., 1979−1983,

1999−2000, and average of 1979−1983 and 1999−2000) initially detailed in Pope et al. (2002). Across the three different exposure periods and the three different statistical models examined, which varied by the degree of individual- and ecological covariates included, associations were consistently positive with HRs ranging from 1.07−1.14. In the fully adjusted model, which in addition to controlling for a number of individual-level covariates also controlled for county-level residential radon concentrations, Turner et al. (2011) found little evidence that radon confounded the $PM_{2.5}$-lung cancer mortality relationship, reporting a HR = 1.07 (95% CI: 0.99, 1.16) and HR = 1.13 (95% CI: 1.10, 1.25) for 1979−1983 and 1999−2000, respectively.

In Turner et al. (2011) the examination of the relationship between long-term $PM_{2.5}$ exposure and lung cancer mortality was on never smokers, while Turner et al. (2014) took this initial analysis one step further and focused on whether there is evidence of an interaction between long-term $PM_{2.5}$ exposure and smoking status. While the discussion of the interaction between smoking status and $PM_{2.5}$ is more informative in identifying populations potentially at increased risk of a PM-related health effect (see Chapter 12), analyses focusing solely on never smokers and current smokers in Turner et al. (2014) provide additional supporting evidence for a relationship between long-term $PM_{2.5}$ exposure and lung cancer mortality. In analyses comparing lung cancer mortality in never smokers exposed to low (≤25th percentile = 10.59 μg/m^3) and high (>75th percentile = 14.44 μg/m^3) $PM_{2.5}$ concentrations the authors reported a HR = 1.26 (95% CI: 0.90, 1.77) while for current smokers the authors reported a HR = 1.19 (95% CI: 1.03, 1.38). Although 95% confidence intervals are larger for the strata of never smokers due to the small number of cases, the results of Turner et al. (2014) support a relationship between long-term $PM_{2.5}$ exposure and lung cancer mortality, particularly in locations with higher $PM_{2.5}$ concentrations.

Similar to the ACS-CPS II cohort, the HSC cohort had detailed individual-level data on smoking status. Lepeule et al. (2012) extended the analysis of the original HSC cohort and reported a positive association between $PM_{2.5}$ concentrations in the 1−3 years prior to lung cancer death (or censoring; HR = 1.17 [95% CI: 1.03, 1.32]). This lag structure between $PM_{2.5}$ exposure and lung cancer mortality was also observed in the Canadian Community Health Survey (CCHS) cohort. In models controlling for smoking status using individual-level data, Pinault et al. (2016) reported a HR = 1.08 (95% CI: 0.99, 1.18) when examining $PM_{2.5}$ exposures over the 3 years prior to death.

In additional analyses stratifying by smoking status, Lepeule et al. (2012) reported that the association between $PM_{2.5}$ and lung cancer mortality persisted in never smokers, but the 95% confidence intervals were large (HR = 1.12 [95% CI: 0.73, 1.70]) due to only 26 out of the 350 lung cancer deaths occurring in never smokers. Overall, the association largest in magnitude for $PM_{2.5}$ and lung cancer mortality were observed for former smokers (HR = 1.40 [95% CI: 1.14, 1.73]). The results of Lepeule et al. (2012) indicating an association larger in magnitude for never smokers compared to the full cohort are consistent with the results of Carey et al. (2013) in a National English cohort. Carey et al. (2013) reported a HR = 1.22 (95% CI: 1.08, 1.41) in a model that included covariates for smoking and BMI. In models

including additional variables for education and income separately the lung cancer mortality association was attenuated, but remained positive (with income: HR = 1.05; with education HR = 1.11). When restricting the analysis to never smokers, the authors observed a rather large increase in the lung cancer mortality association (HR = 1.41 [95% CI: 1.22, 1.62]).

There was no evidence of an association between long-term $PM_{2.5}$ exposure and lung cancer mortality in two cohorts of women, the California Teachers Study (CTS) and the Canadian National Breast Screening Survey (CNBSS). In the CTS, 67% of participants were never smokers, and Lipsett et al. (2011) reported no evidence of an association between long-term $PM_{2.5}$ exposure and lung cancer mortality (HR = 0.97 [95% CI: 0.84, 1.13]). The results from the CTS cohort are consistent with the CNBSS cohort, which had a lower percentage of never smokers, 49.3% (HR = 0.98 [95% CI: 0.89, 1.09]) (Villeneuve et al., 2015). In the CTS cohort, the null $PM_{2.5}$-lung cancer mortality association persisted in several sensitivity analyses including, but not limited to, only post-menopausal women as well as women who did not relocate during follow-up. However, when focusing on only never smokers, Lipsett et al. (2011) reported that the association between long-term $PM_{2.5}$ exposure and lung cancer mortality was positive, but imprecise (HR = 1.27 [95% CI: 0.91, 1.78]) due to the small number of lung cancer deaths (i.e., 50) in this subset of the cohort, which is consistent with never smoker analyses in both Lepeule et al. (2012) and Carey et al. (2013). Villeneuve et al. (2015) in the CNBSS cohort only reported results by smoking status in analyses of all cancers, and did not observe a similar pattern of associations as the other cohorts when stratifying by smoking status (i.e., associations larger in magnitude for never smokers).

Across the lung cancer mortality studies, the magnitude of the association was generally consistent in areas where mean $PM_{2.5}$ concentrations were generally below 15 $\mu g/m^3$ (i.e., in the U.S. and Canadian cohorts), and below 30 $\mu g/m^3$ in all studies except Wong et al. (2016) (Table 10-4). Wong et al. (2016) in a study conducted in Hong Kong that examined long-term $PM_{2.5}$ exposure and all cancers, in a model controlling for smoking status, reported an association for lung cancer mortality similar in magnitude (HR = 1.07 [95% CI: 0.98, 1.17]) to that observed in the other cohort studies. Additionally, unlike the other studies evaluated in this section where the age of study participants was broader, the cohort was limited to those 65 years of age and older. The interpretation of these results is complicated when examining associations by smoking status. For men, 85% of the lung cancer mortality cases were in ever smokers, while for women 72% were in never smokers. However, when examining associations in each subset of the cohort, no evidence of an association was observed in women that were never smokers or ever smokers, while the strongest association was in ever smoker men (HR = 1.17 [95% CI: 1.02, 1.33]). There was evidence of a positive association for never smoker men, but the 95% confidence intervals were large due to the small number of cases (HR = 1.09 [95% CI: 0.72, 1.66]).

Proxy Measures of Smoking Status

In addition to the cohorts discussed above that controlled for smoking status or examined whether there was evidence of effect measure modification by smoking status, several cohorts examined the

association between long-term $PM_{2.5}$ exposure and lung cancer mortality without the ability to account for smoking status through detailed individual-level data. In an analysis of the Canadian Census Health and Environment Cohort (CanCHEC), Crouse et al. (2015) using a 7-year moving window of $PM_{2.5}$ concentrations for each year of follow-up reported a HR = 1.03 (95% CI: 1.01, 1.05). To adjust for smoking status and obesity, the authors used ancillary data on smoking and obesity to adjust for both risk factors not included in the original data set. Applying this method to account for smoking status and obesity resulted in a slightly larger HR = 1.08 (95% CI: 1.04, 1.09). A subsequent analysis of CanCHEC conducted by Weichenthal et al. (2016) limited to Ontario and focusing on $PM_{2.5}$ oxidative potential (see Section 10.2.5) also reported results for $PM_{2.5}$ and they were larger in magnitude (HR = 1.12 [95% CI: 1.00, 1.25]) compared to those observed in the full CanCHEC study (Crouse et al., 2015). The difference in results between the Ontario and national CanCHEC studies could be attributed to several factors (e.g., demographic differences), along with the exposure assignment approach employed in each study (see Table 10-4). Similar to Crouse et al. (2015), Weichenthal et al. (2016) indirectly adjusted for smoking status and obesity, by including a variable in the statistical model that accounted for both through examination of a secondary nationally representative data set (i.e., CCHS), and found the results were relatively similar to that observed in the main model (HR = 1.09 [95% CI: 0.97, 1.22]). Cesaroni et al. (2013) in the Rome Longitudinal Study (RoLS) also used proxy measures to account for smoking status, but relied on measures of neighborhood socioeconomic level and pre-existing comorbidities, which have been shown to be associated with smoking, to develop an indicator variable meant to control for smoking status. Using time-dependent annual $PM_{2.5}$ concentrations the authors reported a positive association (HR = 1.02 [95% CI: 1.00, 1.05]) between $PM_{2.5}$ exposure and lung cancer mortality.

While the previous studies detailed within this section focused specifically on ambient $PM_{2.5}$ exposure and lung cancer mortality in the general population, Hart et al. (2011) examined ambient air pollution exposures and cause-specific mortality, including lung cancer, in an occupational cohort from the Trucking Industry Particle Study (TrIPS). The TrIPS cohort consisted of men employed in the trucking industry, and similar to the CanCHEC and RoLS cohorts the authors did not have individual-level data to account for smoking status. However, unlike the CanCHEC and RoLS cohorts the authors did not attempt to indirectly adjust for smoking status. While most of the studies detailed in this section relied on multiple years of $PM_{2.5}$ data, only data from the year 2000 was available. In analyses focusing on the full cohort, the authors reported a positive association between $PM_{2.5}$ exposure and lung cancer mortality (HR = 1.03 [95% CI: 0.94, 1.12]). To further assess the association between $PM_{2.5}$ exposure and cause-specific mortality, Hart et al. (2011) conducted a sensitivity analysis that excluded long haul truckers, which potentially reduces exposure misclassification by focusing on those truckers that return home nightly due to $PM_{2.5}$ exposures being assigned at the residential address. In the subset analysis, the authors tended to observe associations larger in magnitude across mortality outcomes compared to the full cohort although confidence intervals were larger (lung cancer; HR = 1.08 [95% CI: 0.97, 1.21]).

Summary

In summary, results from recent epidemiologic studies that examined the association between long-term $PM_{2.5}$ exposure and lung cancer mortality are generally consistent with those studies evaluated in the 2009 PM ISA (Figure 10-3). Additional reanalyses of the ACS cohort using different years of $PM_{2.5}$ data and follow-up along with exposure assignment approaches and geographic extent of the cohort continue to provide evidence of consistent positive associations between long-term $PM_{2.5}$ exposure and lung cancer mortality. Additional epidemiologic studies that used individual-level data to control for smoking status conducted both within the U.S. and internationally, also provide evidence of generally consistent positive associations. The positive associations observed across studies are further supported by studies that conducted analyses focusing on never smokers that also reported positive associations, albeit with wide confidence intervals due to the small number of lung cancer mortality cases within the population of never smokers. There was no evidence of an association between long-term $PM_{2.5}$ exposure and lung cancer mortality in two cohorts of women (i.e., CTS and CNBSS cohorts). However, an analysis of never smokers in the CTS cohort reported evidence of a positive association that was consistent with the other studies evaluated within the section that conducted analyses of never smokers. The results across studies that had individual-level data on smoking status are supported by additional epidemiologic studies in cohorts that relied upon proxy measures to account for smoking status.

10.2.5.1.2 Lung Cancer Incidence

Although there is a high case-fatality rate for lung cancer, at the completion of the 2009 PM ISA (U.S. EPA, 2009), an uncertainty identified was the limited number of studies that examined lung cancer incidence. These studies did not provide evidence of an association between long-term $PM_{2.5}$ exposure and lung cancer incidence. Since the completion of the 2009 PM ISA, a larger number of studies have examined lung cancer incidence, but overall the total number of studies remains small compared to lung cancer mortality. Similar to some of the lung cancer mortality studies, the lung cancer incidence studies also conducted stratified analyses by smoking status, which can contribute to assessing whether a relationship exists between long-term $PM_{2.5}$ exposure and lung cancer by focusing on never smokers. A unique feature of lung cancer incidence studies that also allows for further assessment of the $PM_{2.5}$-lung cancer relationship is their ability to examine associations by the histological subtype of lung cancer. Specifically, an assessment of adenocarcinoma, the only subtype that develops in nonsmokers, can contribute to further accounting for residual confounding due to smoking (Hystad et al., 2013). The following lung cancer incidence studies examine both associations stratified by smoking status, and in most cases also histological subtype.

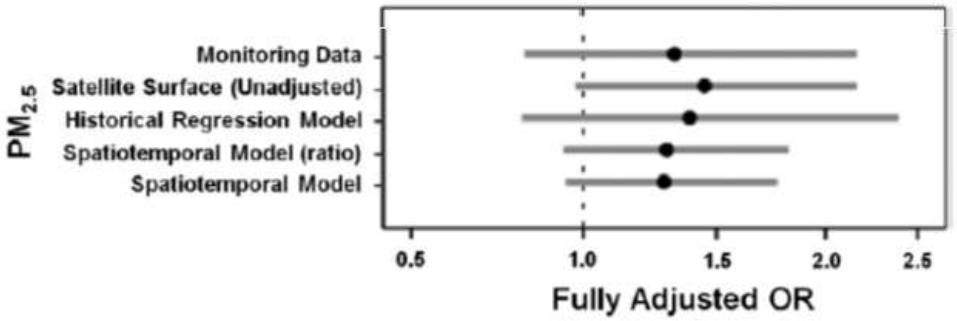
Within the U.S., the Nurses' Health Study (NHS) cohort (Puett et al., 2014) and the AHSMOG-2 cohort (Gharibvand et al., 2016) both examined the association between long-term $PM_{2.5}$ exposure and lung cancer incidence. In the NHS cohort, Puett et al. (2014) used 72-month average predicted $PM_{2.5}$ concentrations as the exposure metric, but due to the lack of $PM_{2.5}$ monitors prior to 1999, $PM_{2.5}$

concentrations for earlier time periods of the study were estimated from PM_{10}. The authors reported evidence of a small positive association with wide confidence interval for lung cancer incidence in the full cohort when adjusting for smoking status and SHS exposure (HR = 1.03 [95% CI: 0.95, 1.12] when examining 72-month average $PM_{2.5}$ concentrations). In a subset analysis of only never smokers the authors reported an association larger in magnitude (HR = 1.12 [95% CI: 0.87, 1.44]), which was also observed when combining never smokers and former smokers that had quit more than 10 years ago (HR = 1.17 [95% CI: 1.03, 1.33]). There was no evidence of an association when examining the combination of current smokers and former smokers that stopped smoking within the last 10 years. Lung cancer incidence was further evaluated through an examination of histological subtypes, specifically adenocarcinomas which comprise 44% of all lung cancer cases (Puett et al., 2014). Compared to the full cohort, when examining adenocarcinomas, the authors observed associations larger in magnitude for both the full cohort and the subset of never smokers and former smokers that had quit more than 10 years ago with HRs ranging from 1.15−1.29, but across categories confidence intervals were wide.

Gharibvand et al. (2016) within the AHSMOG-2 cohort examined mean monthly $PM_{2.5}$ concentrations over a 24-month period. In the cohort approximately 80% of the participants were never smokers, and they represented 46% of the lung cancer cases. In the full cohort, Gharibvand et al. (2016) reported evidence of a positive association when examining monthly average $PM_{2.5}$ concentrations (HR = 1.20 [95% CI: 1.02, 1.42]), which was similar in magnitude when examining both never (HR = 1.15 [95% CI: 0.95, 1.39]) and ever (HR = 1.22 [95% CI: 1.01, 1.48]) smokers. Overall, the lung cancer incidence associations in the AHSMOG-2 cohort are larger in magnitude than those observed in Puett et al. (2014), which could be attributed to the larger percentage of never smokers or long-term former smokers in the study population. On average, within the cohort, ever smokers quit smoking 24 years ago (Gharibvand et al., 2016). In an attempt to assess the influence of differences in time-activity on the observed associations, the authors examined average daily time spent outdoors and time lived at each residential location and found in both instances associations were similar in magnitude to the full cohort for those people that spent more than 1 hour per day outdoors and resided at their current address for more than 5 years. Of the lung cancer cases, approximately 66% were adenocarcinomas, which is a much larger percent than was observed in the NHS cohort, but the authors did not examine associations by histological subtype.

Additional national cohorts conducted in Canada, provide evidence of an association between long-term $PM_{2.5}$ exposure and lung cancer incidence that is similar in magnitude to that observed in AHSMOG-2 (Gharibvand et al., 2016). Hystad et al. (2013) used a case-control study with participants identified through the National Enhanced Cancer Surveillance System (NECSS) project. To reduce exposure misclassification and account for time-activity, the study was limited to cases and controls that had complete 20-year residential histories. In fully adjusted models that accounted for smoking status, the authors reported evidence of a positive association between annual $PM_{2.5}$ concentrations and lung cancer incidence (OR = 1.14 [95% CI: 0.97, 1.33]). Hystad et al. (2013) further assessed whether the exposure assignment approach used influenced the $PM_{2.5}$-lung cancer incidence association observed, and found

that across exposure assignment approaches which included using fixed-site monitoring data, satellite data, a historical regression model, and two different versions of a spatiotemporal model, the magnitude of associations was generally consistent (Figure 10-4). In additional analyses stratified by smoking status, the authors observed the strongest association among former smokers (OR = 1.20 [95% CI: 0.98, 1.48]), with no evidence of an association in never smokers (0.97 [95% CI: 0.62, 1.53]), which could be attributed to only 6% of all lung cancer cases in this population being never smokers. In histological subtype analyses, Hystad et al. (2013) did not observe a clear relationship between long-term $PM_{2.5}$ exposure and one subtype, which differs from the results of Puett et al. (2014), which indicated associations larger in magnitude for adenocarcinomas.



Source: Permission pending, Hystad et al. (2013).

Figure 10-4 $PM_{2.5}$—lung cancer incidence odds ratios (OR) for a 10 μg/m³ increase in $PM_{2.5}$ concentrations from sensitivity analyses using different exposure assignment approaches in the Canadian National Enhanced Cancer Surveillance System (NECSS) project.

The main results of Hystad et al. (2013) are consistent with those observed in another Canadian cohort (CNBSS) by Tomczak et al. (2016), which is the same cohort that was examined for lung cancer mortality by Villeneuve et al. (2015) detailed above. In a model controlling for smoking status and other SES-related variables, the authors observed evidence of an increase in lung cancer incidence in this cohort of women (HR = 1.16 [95% CI: 1.05, 1.28]). In analyses stratified by smoking status, no association was observed for never smokers, while the association for ever smokers was consistent with that observed in the full cohort, indicating that this subset of the cohort is responsible for the overall association (HR = 1.18 [95% CI: 1.06, 1.32]). Tomczak et al. (2016) also conducted histological subtype analyses and observed evidence of a positive association for small cell carcinoma and adenocarcinoma. Although the 95% confidence intervals for the histological subtype analyses in Hystad et al. (2013) were large resulting in the inability to clearly identify differences across subtypes, the central estimates were also largest in magnitude for small cell carcinoma and adenocarcinoma.

The examination of $PM_{2.5}$ and lung cancer incidence in the European Study of Cohorts for Air Pollution Effects (ESCAPE) study resulted in an association similar in magnitude to that observed in the AHSMOG-2, NECSS, and CNBSS cohorts discussed above (HR = 1.18 [95% CI: 0.96, 1.46]) (Raaschou-Nielsen et al., 2013). The results of Raaschou-Nielsen et al. (2013) are the same as those reported by Raaschou-Nielsen et al. (2016) as part of the European Study of Transport-related Air Pollution and Health Impacts-Integrated Methodologies for Assessing Particulate Matter (TRANSPHORM) project, which also used data from the ESCAPE study, but focused on associations between long-term $PM_{2.5}$ component exposures and lung cancer incidence. In additional analyses conducted by Raaschou-Nielsen et al. (2013) that attempted to reduce the impact of exposure misclassification by focusing on those residents who did not change residence during the follow-up period, the authors reported an association similar in magnitude to the full cohort (HR = 1.20 [95% CI: 0.96, 1.51]), which is consistent with the analysis focusing on people that resided at their residential location for over 5 years conducted by Gharibvand et al. (2016) in the AHSMOG-2 cohort. Analyses stratified by smoking status did not provide strong evidence for differences among never, former, and current smokers, but associations were largest in magnitude for never (HR = 1.21) and former (HR = 1.41) smokers although 95% confidence intervals were large. When examining histological subtypes, Raaschou-Nielsen et al. (2013) observed a positive association for only adenocarcinomas (HR = 1.51 [95% CI: 1.10, 2.08]).

In another study conducted in Europe, Hart et al. (2015), in a cohort in the Netherlands (NLCS-Air), also observed evidence of a positive association between long-term $PM_{2.5}$ exposure and lung cancer incidence in models that included a variable to adjust for smoking status (HR = 1.08 [95% CI: 0.96, 1.21] for 1987−1996). Within this study a case-cohort approach was used as detailed in the original NCLS-Air cohort (Brunekreef et al., 2009; Beelen et al., 2008a). Interestingly the results of Hart et al. (2015) differ from those observed in the original NCLS-Air cohort analysis where no evidence of an association was reported with lung cancer incidence (Figure 10-3). Although not explicitly detailed in Hart et al. (2015) there are differences with the original NLCS-Air studies that could contribute to the disparate results observed between the original and extended analyses, specifically (1) an additional 6 years of follow-up, (2) the transition of some individuals to being classified as cases, (3) the exclusion of individuals without exposure or smoking status information, and (4) the use of age in years as the timescale instead of time in study (Hart, 2017b). In addition to providing overall results, Hart et al. (2015) also attempted to adjust the observed association to account for exposure measurement error by using information from a validation study involving personal and near-home outdoor measurements of 47 nonsmokers from 2004−2005. After adjusting for exposure measurement error using a regression calibration analysis the $PM_{2.5}$-lung cancer incidence association increased in magnitude, but had larger confidence intervals (1.17 [95% CI: 0.93, 1.47]). The approach by Hart et al. (2015) along with those less computationally intensive approaches detailed in Raaschou-Nielsen et al. (2013) in the ESCAPE study and Gharibvand et al. (2016) in the AHSMOG-2 cohort consistently demonstrate that $PM_{2.5}$-lung cancer incidence associations are robust when trying to account for or reduce the potential impact of exposure measurement error. However, it should be noted that in Hart et al. (2015) residential address information was only available at baseline and the validation study was conducted after the follow-up period ended,

both of which contribute some level of uncertainty in adjusting the association to account for exposure measurement error. Hart et al. (2015) also conducted histological subtype analyses, and observed positive associations across all subtypes, but no clear difference in associations between subtypes existed.

Summary

Recent epidemiologic studies build upon the limited number of studies evaluated in the 2009 PM ISA that examined the association between long-term $PM_{2.5}$ exposure and lung cancer incidence, and provide evidence of consistent positive associations (Figure 10-3). Consistent with lung cancer mortality studies, studies that conducted analyses focusing on the subset of the cohort that were never smokers generally reported evidence of positive associations, albeit with wide confidence intervals due to the small number of never smokers within the cohorts. A subset of the studies focusing on lung cancer incidence also examined histological subtype, which provided some evidence of positive associations for adenocarcinomas, the only subtype of lung cancer observed in never smokers. However, in some studies the examination of associations by histological subtype were limited due to the small number of never smokers included within the cohort (e.g., NECSS cohort). In several studies, the $PM_{2.5}$-lung cancer incidence associations observed were further evaluated in sensitivity analyses that attempted to reduce exposure measurement error by accounting for length of time at residential address, examining different exposure assignment approaches, and conducting regression calibration to account for exposure measurement error. Across all approaches, associations between long-term $PM_{2.5}$ exposure and lung cancer incidence were found to remain relatively unchanged, but in some cases confidence intervals increased in width.

10.2.5.1.3 Copollutant Models

Across the epidemiologic studies that examined associations between long-term $PM_{2.5}$ exposure and lung cancer incidence and mortality, only a few examined potential copollutant confounding. Jerrett et al. (2013) in the ACS-CPS II cohort conducted copollutant analyses with NO_2 and O_3. Within the study, estimated O_3 concentrations at the residential address were derived from IDW, while the NO_2 concentrations were estimated using the same LUR model as $PM_{2.5}$. $PM_{2.5}$ was similarly correlated with both NO_2 and O_3 (r = 0.55). In a copollutant model with NO_2, the $PM_{2.5}$-lung cancer mortality association was attenuated and became null (HR = 0.99 [95% CI: 0.87, 1.11]), but remained relatively unchanged from the single-pollutant model result in a copollutant model with O_3 (HR = 1.10 [95% CI: 0.99, 1.22]). These results are consistent with those observed in Lipsett et al. (2011) in the CTS cohort. The authors reported that $PM_{2.5}$ was moderately to highly correlated with NO_X, CO, NO_2, and PM_{10} with correlations ranging from 0.52−0.91, but in copollutant models with O_3 the $PM_{2.5}$-lung cancer mortality association was relatively unchanged (HR = 1.04 [95% CI; 0.70, 1.53]) compared to the single-pollutant model result. The authors did not present results for copollutant models with the other pollutants examined.

Whereas the lung cancer mortality studies tended to report results for copollutant models with O_3, only Gharibvand et al. (2016) examined $PM_{2.5}$-lung cancer incidence associations in models with O_3. Within the AHSMOG-2 cohort, Gharibvand et al. (2016) observed that the $PM_{2.5}$-lung cancer incidence association was unchanged in copollutant models with O_3 (HR = 1.21 [95% CI: 1.02, 1.43]). Raaschou-Nielsen et al. (2013) within the ESCAPE study, also examined potential copollutant confounding of the $PM_{2.5}$-lung cancer incidence association, and did not find any evidence of confounding in models with NO_2 and $PM_{10–2.5}$ (quantitative results not presented).
