CONTENTS

INTEGRATED SCIENCE ASSESSMENT TEAM FOR PARTICULATE MATTER

Executive Direction

Dr. John Vandenberg (Director)—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Steven J. Dutton (Deputy Director)—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Reeder Sams (Deputy Director—Acting)—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Debra Walsh (Deputy Director—Retired)—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Tara Greaver (Branch Chief—Acting)—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Andrew Hotchkiss (Branch Chief—Acting)—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Alan Vette (Branch Chief—Acting) —Air and Energy Research Program, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Jennifer Richmond-Bryant (Branch Chief—Acting)—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Scientific Staff

Mr. Jason Sacks (Assessment Lead, Integrated Science Assessment for Particulate Matter)—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Barbara Buckley (Deputy Assessment Lead, Integrated Science Assessment for Particulate Matter)—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Michelle Angrish—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Renee Beardslee (Separated)—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. James Brown—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Mr. Evan Coffman—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Mr. Allen Davis—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Brooke Hemming—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Erin Hines—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Ellen Kirrane—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Dennis Kotchmar—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Meredith Lassiter—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Thomas Long—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Thomas Luben—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Stephen McDow—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Jennifer Nichols—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Molini M. Patel (Separated)—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Joseph P. Pinto (Retired) —National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Jennifer Richmond-Bryant—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Michael Stewart—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Dr. Christopher Weaver—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Technical Support Staff

Ms. Marieka Boyd—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Mr. Kenneth J. Breito (Separated)—Senior Environmental Employment Program, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Annamarie Cory—Oak Ridge Associated Universities, Inc., National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Charlene Finley (Separated)—Oak Ridge Institute for Science and Education, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Beth Gatling—Oak Ridge Institute for Science and Education, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Mr. William Griffin (Separated)—Oak Ridge Institute for Science and Education, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Hillary Hollinger—Oak Ridge Associated Universities, Inc., National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Mr. Saturo Ito (Separated)—Oak Ridge Institute for Science and Education, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Mr. Ryan Jones—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Emily Lau (Separated)—Oak Ridge Institute for Science and Education, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Connie Meacham (Retired)—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Danielle Moore—Senior Environmental Employment Program, National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Mr. Francis Polakiewicz—Oak Ridge Associated Universities, Inc., National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Mr. Samuel Thacker—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Ms. Erin Vining—Oak Ridge Associated Universities, Inc., National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

Mr. Richard N. Wilson—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

AUTHORS, CONTRIBUTORS, AND REVIEWERS

Authors

Mr. Jason Sacks (Assessment Lead, Integrated Science Assessment for Particulate Matter)—National Center for Environmental Assessment, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC

PREFACE

The Preface to the Integrated Science Assessment for Particulate Matter (PM ISA) outlines the legislative requirements of a National Ambient Air Quality Standard (NAAQS) review and the history of the PM NAAQS. This information provides an understanding of the function of the ISA, and in terms of providing a starting point for this PM ISA, presents the basis for the decisions that supported the previous PM NAAQS review. In addition, the Preface details the purpose of the ISA as well as specific issues pertinent to the evaluation of the scientific evidence that takes place within this ISA, including the scope of the ISA and discipline specific decisions that governed parts of the review.

P.1 Legislative Requirements for the Review of the National Ambient Air Quality Standards

Two sections of the Clean Air Act (CAA) govern the establishment, review, and revision of the National Ambient Air Quality Standards (NAAQS). Section 108 [42 U.S. Code (U.S.C.) 7408] directs the Administrator to identify and list certain air pollutants and then to issue air quality criteria for those pollutants. The Administrator is to list those air pollutants that in their "judgment, cause or contribute to air pollution which may reasonably be anticipated to endanger public health or welfare," "the presence of which in the ambient air results from numerous or diverse mobile or stationary sources," and "for which … [the Administrator] plans to issue air quality criteria …" [42 U.S.C. 7408(a)(1); (CAA, 1990a)]. Air quality criteria are intended to "accurately reflect the latest scientific knowledge useful in indicating the kind and extent of all identifiable effects on public health or welfare, which may be expected from the presence of [a] pollutant in the ambient air …" [42 U.S.C. 7408(b)]. Section 109 [42 U.S.C. 7409; (CAA, 1990b)] directs the Administrator to propose and promulgate "primary" and "secondary" NAAQS for pollutants for which air quality criteria are issued. Section 109(b)(1) defines a primary standard as one "the attainment and maintenance of which in the judgment of the Administrator, based on such criteria and allowing an adequate margin of safety, are requisite to protect the public health."[4] A secondary standard, as defined in Section 109(b)(2), must "specify a level of air quality the attainment and maintenance of which, in the judgment of the Administrator, based on such criteria, is requisite to protect

[4] The legislative history of Section 109 indicates that a primary standard is to be set at "… the maximum permissible ambient air level…which will protect the health of any [sensitive] group of the population," and that for this purpose "reference should be made to a representative sample of persons comprising the sensitive group rather than to a single person in such a group" S. Rep. No. 91:1196, 91st Cong., 2d Sess. 10 (1970).

the public welfare from any known or anticipated adverse effects associated with the presence of [the] air pollutant in the ambient air."[5]

The requirement that primary standards provide an adequate margin of safety was intended to address uncertainties associated with inconclusive scientific and technical information available at the time of standard setting. It was also intended to provide a reasonable degree of protection against hazards that research has not yet identified.[6] Both kinds of uncertainty are components of the risk associated with pollution at levels below those at which human health effects can be said to occur with reasonable scientific certainty. Thus, in selecting primary standards that provide an adequate margin of safety, the Administrator is seeking not only to prevent pollution levels that have been demonstrated to be harmful but also to prevent lower pollutant levels that may pose an unacceptable risk of harm, even if the risk is not precisely identified as to nature or degree. The CAA does not require the Administrator to establish a primary NAAQS at a zero-risk level or at background concentration levels, but rather at a level that reduces risk sufficiently so as to protect public health with an adequate margin of safety.[7] In so doing, protection is provided for both the population as a whole and those groups and lifestages potentially at increased risk for health effects from exposure to the air pollutant for which each NAAQS is set.

In addressing the requirement for an adequate margin of safety, the U.S. Environmental Protection Agency (U.S. EPA) considers such factors as the nature and severity of the health effects involved, the size of the sensitive group(s), and the kind and degree of the uncertainties. The selection of any particular approach to providing an adequate margin of safety is a policy choice left specifically to the Administrator's judgment.[8]

In setting standards that are "requisite" to protect public health and welfare as provided in Section 109(b), the U.S. EPA's task is to establish standards that are neither more nor less stringent than necessary for these purposes. In so doing, the U.S. EPA may not consider the costs of implementing the standards.[9] Likewise, "[a]ttainability and technological feasibility are not relevant considerations in the promulgation of national ambient air quality standards."[10]

---

[5] Section 302(h) of the Act [42 U.S.C. 7602(h)] provides that all language referring to effects on welfare includes, but is not limited to, "effects on soils, water, crops, vegetation, man-made materials, animals, wildlife, weather, visibility and climate, damage to and deterioration of property, and hazards to transportation, as well as effects on economic values and on personal comfort and well-being…" (CAA, 2005).

Section 109(d)(1) requires that "not later than December 31, 1980, and at 5-year intervals thereafter, the Administrator shall complete a thorough review of the criteria published under Section 108 and the national ambient air quality standards…and shall make such revisions in such criteria and standards and promulgate such new standards as may be appropriate…." Section 109(d)(2) requires that an independent scientific review committee "shall complete a review of the criteria…and the national primary and secondary ambient air quality standards…and shall recommend to the Administrator any new…standards and revisions of existing criteria and standards as may be appropriate…." Since the early 1980s, this independent review function has been performed by the Clean Air Scientific Advisory Committee (CASAC).[11]

P.1.1. Overview and History of the Reviews of the Primary and Secondary National Ambient Air Quality Standard for Particulate Matter

NAAQS are defined by four basic elements: indicator, averaging time, level, and form. The indicator defines the pollutant to be measured in the ambient air for the purpose of determining compliance with the standard. The averaging time defines the time period over which air quality measurements are to be obtained and averaged or cumulated, considering evidence of effects associated with various time periods of exposure. The level of a standard defines the air quality concentration used (i.e., an ambient concentration of the indicator pollutant) in determining whether the standard is achieved. The form of the standard defines the air quality statistic that is compared to the level of the standard in determining whether an area attains the standard. For example, the form of the current primary annual fine particulate matter ($PM_{2.5}$) standard is the annual mean averaged over 3 years. The Administrator considers these four elements collectively in evaluating the protection to public health provided by the primary NAAQS.

Particulate matter (PM) is the generic term for a broad class of chemically and physically diverse substances that exist as discrete particles (liquid droplets or solids) over a wide range of sizes. Particles originate from a variety of anthropogenic stationary and mobile sources, as well as from natural sources. Particles may be emitted directly or formed in the atmosphere by transformations of gaseous emissions such as sulfur oxides (SO_X), oxides of nitrogen (NO_X), ammonia (NH_3) and volatile organic compounds (VOC). Examples of secondary particle formation include: (1) the conversion of SO_2 to sulfuric acid (H_2SO_4) vapor that nucleates new particles or condenses on existing particles and further reacts with NH_3 to form various inorganic salts (e.g., ammonium sulfate, $[NH_4]_2SO_4$, or ammonium bisulfate, NH_4HSO_4); (2) the conversion of nitrogen dioxide (NO_2) to nitric acid (HNO_3) vapor that condenses onto existing particles and reacts further with ammonia to form ammonium nitrate (NH_4NO_3); and (3) reactions

[11] Lists of CASAC members and of members of the CASAC Augmented for the Particulate Matter Panel are available at: https://yosemite.epa.gov/sab/sabpeople.nsf/WebCommitteesSubcommittees/CASAC%20Particulate%20Matter%20Review%20Panel%20(2015-2018).

involving gaseous VOC yielding organic compounds with low vapor pressures that nucleate or condense on existing particles to form secondary organic particulate matter (SOPM) (U.S. EPA, 2004). The chemical and physical properties of PM vary greatly with time, region, meteorology, and source category, thus complicating the assessment of health and welfare effects. These reviews are briefly described below, and further details are provided in the Integrated Review Plan (U.S. EPA, 2016).

The U.S. EPA first established NAAQS for PM in 1971 (36 FR 8186, April 30, 1971), based on the original criteria document (NAPCA, 1969).[12] The federal reference method (FRM) specified for determining attainment of the original standards was the high-volume sampler, which collects PM up to a nominal size of 25 to 45 micrometers (μm) (referred to as total suspended particulates or TSP). The primary standards were at 260 μg/m^3, 24-hour average, not to be exceeded more than once per year, and 75 μg/m^3, annual geometric mean. The secondary standards were 150 μg/m^3, 24-hour average, not to be exceeded more than once per year, and 60 μg/m^3, annual geometric mean. Since then, the Agency has completed multiple reviews of the air quality criteria and standards, as summarized in Table P-1.

Table P-1 History of the National Ambient Air Quality Standards for particulate matter, 1971−2012.

Final Rule/Decision	Indicator	Averaging Time	Level	Form
1971 36 FR 8186 Apr 30, 1971	TSP	24 h	260 μg/m^3 (primary) 150 μg/m^3 (secondary)	Not to be exceeded more than once per year
		Annual	75 μg/m^3 (primary) 60 μg/m^3 (secondary)	Annual geometric mean
1987 52 FR 24634 Jul 1, 1987	PM_{10}	24 h	150 μg/m^3	Not to be exceeded more than once per year on average over a 3-yr period
		Annual	50 μg/m^3	Annual arithmetic mean, averaged over 3 yr

[12] Prior to the review initiated in 2007 (see below), the AQCD provided the scientific basis for the NAAQS.

Table P-1 (Continued): History of the National Ambient Air Quality Standards for particulate matter, 1971−2012.

Final Rule/Decision	Indicator	Averaging Time	Level	Form
1997 62 FR 38652 Jul 18, 1997	$PM_{2.5}$	24 h	65 µg/m^3	98th percentile, averaged over 3 yr
		Annual	15 µg/m^3	Annual arithmetic mean, averaged over 3 yr[a]
	PM_{10}	24 h	150 µg/m^3	Initially promulgated 99th percentile, averaged over 3 yr; when 1997 standards were vacated in 1999, the form of 1987 standards remained in place (not to be exceeded more than once per yr on average over a 3-yr period)
		Annual	50 µg/m^3	Annual arithmetic mean, averaged over 3 yr
2006 71 FR 61144 Oct 17, 2006	$PM_{2.5}$	24 h	35 µg/m^3	98th percentile, averaged over 3 yr
		Annual	15 µg/m^3	Annual arithmetic mean, averaged over 3 yr[a]
	PM_{10}	24 h	150 µg/m^3	Not to be exceeded more than once per yr on average over a 3-yr period
2012 78 FR 3085 Jan 15, 2013	$PM_{2.5}$	24 h	35 µg/m^3	98th percentile, averaged over 3-yr[c]
		Annual	12 µg/m^3 (primary) 15 µg/m^3 (secondary)	Annual arithmetic mean, averaged over 3-yr[b]
	PM_{10}[d]	24 h	150 µg/m^3	Not to be exceeded more than once per year on average over 3-yr

TSP = total suspended particulates.

[a]The level of the 1997 annual $PM_{2.5}$ standard was to be compared to measurements made at the community-oriented monitoring site recording the highest level, or, if specific constraints were met, measurements from multiple community-oriented monitoring sites could be averaged ("spatial averaging"). This approach was judged to be consistent with the short-term exposure epidemiologic studies on which the annual $PM_{2.5}$ standard was primarily based, in which air quality data were generally averaged across multiple monitors in an area or were taken from a single monitor that was selected to represent community-wide exposures, not localized "hot spots" (62 FR 38672). These criteria and constraints were intended to ensure that spatial averaging would not result in inequities in the level of protection afforded by the $PM_{2.5}$ standards. Community-oriented monitoring sites were specified to be consistent with the intent that a spatially averaged annual standard provide protection for persons living in smaller communities, as well as those in larger population centers.

[b]In the revisions to the PM NAAQS finalized in 2006, U.S. EPA tightened the constraints on the spatial averaging criteria by further limiting the conditions under which some areas may average measurements from multiple community-oriented monitors to determine compliance (71 FR 61165-61167, October 17, 2006).

[c]The level of the 24-h standard is defined as an integer (zero decimal places) as determined by rounding. For example, a 3-yr average 98th percentile concentration of 35.49 µg/m^3 would round to 35 µg/m^3 and thus meet the 24-h standard and a 3-yr average of 35.50µg/m^3 would round to 36 and, hence, violate the 24-h standard (40 CFR Part 50 Appendix N).

[d]The U.S. EPA revoked the annual PM_{10} NAAQS in 2006.

Note: When not specified, primary and secondary standards are identical.

In October 1979 (44 FR 56730, October 2, 1979), the U.S. EPA announced the first periodic review of the air quality criteria and NAAQS for PM. Revised primary and secondary standards were promulgated in 1987 (52 FR 24634, July 1, 1987). In the 1987 decision, the U.S. EPA changed the

indicator for particles from TSP to PM_{10}, in order to focus on the subset of inhalable particles small enough to penetrate to the thoracic region of the respiratory tract (including the tracheobronchial and alveolar regions), referred to as thoracic particles.[13] The level of the 24-hour standards (primary and secondary) was set at 150 $\mu g/m^3$, and the form was one expected exceedance per year, on average over 3 years. The level of the annual standards (primary and secondary) was set at 50 $\mu g/m^3$, and the form was annual arithmetic mean, averaged over 3 years.

In April 1994, the U.S. EPA announced its plans for the second periodic review of the air quality criteria and NAAQS for PM, and in 1997 the U.S. EPA promulgated revisions to the NAAQS (62 FR 38652, July 18, 1997). In the 1997 decision, the U.S. EPA determined that the fine and coarse fractions of PM_{10} should be considered separately. This determination was based on evidence that serious health effects were associated with short- and long-term exposures to fine particles in areas that met the existing PM_{10} standards. The U.S. EPA added new standards, using $PM_{2.5}$ as the indicator for fine particles (with $PM_{2.5}$ referring to particles with a nominal mean aerodynamic diameter less than or equal to 2.5 μm). These new standards were as follows: (1) an annual standard with a level of 15.0 $\mu g/m^3$, based on the 3-year average of annual arithmetic mean $PM_{2.5}$ concentrations from single or multiple community-oriented monitors;[14] and (2) a 24-hour standard with a level of 65 $\mu g/m^3$, based on the 3-year average of the 98th percentile of 24-hour $PM_{2.5}$ concentrations at each monitor within an area. Also, the U.S. EPA established a new reference method for the measurement of $PM_{2.5}$ in the ambient air and adopted rules for determining attainment of the new standards. To continue to address the coarse fraction of PM_{10} (referred to as thoracic coarse particles or $PM_{10-2.5}$; generally including particles with a nominal mean aerodynamic diameter greater than 2.5 μm and less than or equal to 10 μm), the U.S. EPA retained the annual PM_{10} standard and revised the form of the 24-hour PM_{10} standard to be based on the 99th percentile of 24-hour PM_{10} concentrations at each monitor in an area. The U.S. EPA revised the secondary standards by setting them equal in all respects to the primary standards.

Following promulgation of the 1997 PM NAAQS, petitions for review were filed by a large number of parties, addressing a broad range of issues. In May 1999, the U.S. Court of Appeals for the District of Columbia Circuit (D.C. Circuit) upheld the U.S. EPA's decision to establish fine particle standards, holding that "the growing empirical evidence demonstrating a relationship between fine particle pollution and adverse health effects amply justifies establishment of new fine particle standards."

[13] PM_{10} refers to particles with a nominal mean aerodynamic diameter less than or equal to 10 μm. More specifically, 10 μm is the aerodynamic diameter for which the efficiency of particle collection is 50%. Larger particles are not excluded altogether, but are collected with substantially decreasing efficiency while smaller particles are collected with increasing efficiency.

[14] The level of the 1997 annual $PM_{2.5}$ standard was to be compared to measurements made at the community-oriented monitoring site recording the highest concentration or, if specific constraints were met, measurements from multiple community-oriented monitoring sites could be averaged (i.e., "spatial averaging"). In the last review (completed in 2012) the U.S. EPA replaced the term "community-oriented" monitor with the term "area-wide" monitor. Area-wide monitors are those sited at the neighborhood scale or larger, as well as those monitors sited at micro-or middle scales that are representative of many such locations in the same CBSA (78 FR 3236, January 15, 2013).

American Trucking Associations v. U.S. EPA, 175 F. 3d 1027, 1055−56 (D.C. Cir. 1999). The D.C. Circuit also found "ample support" for the U.S. EPA's decision to regulate coarse particle pollution, but vacated the 1997 PM_{10} standards, concluding that the U.S. EPA had not provided a reasonable explanation justifying use of PM_{10} as an indicator for coarse particles. 175 F. 3d at 1054−55. Pursuant to the D.C. Circuit's decision, the U.S. EPA removed the vacated 1997 PM_{10} standards, and the pre-existing 1987 PM_{10} standards remained in place (65 FR 80776, December 22, 2000). The D.C. Circuit also upheld the U.S. EPA's determination not to establish more stringent secondary standards for fine particles to address effects on visibility. 175 F. 3d at 1027.

The D.C. Circuit also addressed more general issues related to the NAAQS, including issues related to the consideration of costs in setting NAAQS and the U.S. EPA's approach to establishing the levels of NAAQS. Regarding the cost issue, the court reaffirmed prior rulings holding that in setting NAAQS the U.S. EPA is "not permitted to consider the cost of implementing those standards." Id. at 1040-41. Regarding the levels of NAAQS, the court held that the U.S. EPA's approach to establishing the level of the standards in 1997 (i.e., both for PM and for the ozone NAAQS promulgated on the same day) effected "an unconstitutional delegation of legislative authority." Id. at 1034-40. Although the court stated that "the factors U.S. EPA uses in determining the degree of public health concern associated with different levels of ozone and PM are reasonable," it remanded the rule to the U.S. EPA, stating that when the U.S. EPA considers these factors for potential non-threshold pollutants "what U.S. EPA lacks is any determinate criterion for drawing lines" to determine where the standards should be set.

The D.C. Circuit's holding on the cost and constitutional issues were appealed to the U.S. Supreme Court. In February 2001, the Supreme Court issued a unanimous decision upholding the U.S. EPA's position on both the cost and constitutional issues. Whitman v. American Trucking Associations, 531 U.S. 457, 464, 475−76. On the constitutional issue, the Court held that the statutory requirement that NAAQS be "requisite" to protect public health with an adequate margin of safety sufficiently guided the U.S. EPA's discretion, affirming the U.S. EPA's approach of setting standards that are neither more nor less stringent than necessary.[15]

In October 1997, the U.S. EPA published its plans for the third periodic review of the air quality criteria and NAAQS for PM (62 FR 55201, October 23, 1997). After the CASAC and public review of several drafts, the U.S. EPA's NCEA finalized the Air Quality Criteria Document (AQCD) in October 2004 (U.S. EPA, 2004). The U.S. EPA's OAQPS finalized a Risk Assessment and Staff Paper in

[15] The Supreme Court remanded the case to the Court of Appeals for resolution of any remaining issues that had not been addressed in that court's earlier rulings. Id. at 475−76. In a March 2002 decision, the Court of Appeals rejected all remaining challenges to the standards, holding that the EPA's $PM_{2.5}$ standards were reasonably supported by the administrative record and were not "arbitrary and capricious" American Trucking Associations v. EPA, 283 F. 3d 355, 369-72 (D.C. Cir. 2002).

December of 2005 (Abt, 2005; U.S. EPA, 2005).[16] On December 20, 2005, the U.S. EPA announced its proposed decision to revise the NAAQS for PM, and solicited comment on a broad range of options (71 FR 2620, January 17, 2006). On September 21, 2006, the U.S. EPA announced its final decisions to revise the primary and secondary NAAQS for PM to provide increased protection of public health and welfare, respectively (71 FR 61144, October 17, 2006). With regard to the primary and secondary standards for fine particles, the U.S. EPA revised the level of the 24-hour $PM_{2.5}$ standards to 35 $\mu g/m^3$, retained the level of the annual $PM_{2.5}$ standards at 15.0 $\mu g/m^3$, and revised the form of the annual $PM_{2.5}$ standards by narrowing the constraints on the optional use of spatial averaging. For the primary and secondary standards for PM_{10}, the U.S. EPA retained the 24-hour standards, with levels at 150 $\mu g/m^3$, and revoked the annual standards.[17] The Administrator judged that the available evidence generally did not suggest a link between long-term exposure to existing ambient levels of coarse particles and health or welfare effects. In addition, a new reference method was added for the measurement of $PM_{10-2.5}$ in the ambient air, in order to provide a basis for approving federal equivalent methods (FEMs) and to promote the gathering of scientific data to support future reviews of the PM NAAQS.

Several parties filed petitions for review following promulgation of the revised PM NAAQS in 2006. These petitions addressed the following issues: (1) selecting the level of the primary annual $PM_{2.5}$ standard; (2) retaining PM_{10} as the indicator of a standard for thoracic coarse particles, retaining the level and form of the 24-hour PM_{10} standard, and revoking the PM_{10} annual standard; and (3) setting the secondary $PM_{2.5}$ standards identical to the primary standards. On February 24, 2009, the U.S. Court of Appeals for the District of Columbia Circuit issued its opinion in the case American Farm Bureau Federation v. U.S. EPA, 559 F. 3d 512 (D.C. Cir. 2009). The court remanded the primary annual $PM_{2.5}$ NAAQS to U.S. EPA because U.S. EPA failed to adequately explain why the standards provided the requisite protection from both short- and long-term exposures to fine particles, including protection for at-risk populations. American Farm Bureau Federation v. U.S. EPA, 559 F. 3d 512, 520−27 (D.C. Cir. 2009). With regard to the standards for PM_{10}, the court upheld U.S. EPA's decisions to retain the 24-hour PM_{10} standard to provide protection from thoracic coarse particle exposures and to revoke the annual PM_{10} standard. American Farm Bureau Federation, 559 F. 2d at 533−38. For the secondary $PM_{2.5}$ standards, the court remanded the standards to U.S. EPA because the Agency failed to adequately explain why setting the secondary PM standards identical to the primary standards provided the required

[16] Prior to the review initiated in 2007, the Staff Paper, rather than the PA, presented the EPA staff's considerations and conclusions regarding the adequacy of existing NAAQS and, when appropriate, the potential alternative standards that could be supported by the evidence and information.

[17] In the 2006 proposal, the EPA proposed to revise the 24-hour PM_{10} standard in part by establishing a new $PM_{10-2.5}$ indicator for thoracic coarse particles (i.e., particles generally between 2.5 and 10 μm in diameter). The EPA proposed to include any ambient mix of $PM_{10-2.5}$ that was dominated by resuspended dust from high density traffic on paved roads and by PM from industrial sources and construction sources. The EPA proposed to exclude any ambient mix of $PM_{10-2.5}$ that was dominated by rural windblown dust and soils and by PM generated from agricultural and mining sources. In the final decision, the existing PM_{10} standard was retained, in part due to an "inability…to effectively and precisely identify which ambient mixes are included in the [$PM_{10-2.5}$] indicator and which are not" (71 FR 61197, October 17, 2006).

protection for public welfare, including protection from visibility impairment. American Farm Bureau Federation, 559 F. 2d at 528−32. The U.S. EPA responded to the court's remands as part of the next review of the PM NAAQS, which was initiated in 2007 (discussed below).

In June 2007, the U.S. EPA initiated the fourth periodic review of the air quality criteria and the PM NAAQS by issuing a call for information in the Federal Register (72 FR 35462, June 28, 2007). Based on the NAAQS review process, as revised in 2008 and again in 2009,[18] the U.S. EPA held science/policy issue workshops on the primary and secondary PM NAAQS (72 FR 34003, June 20, 2007; 72 FR 34005, June 20, 2007), and prepared and released the planning and assessment documents that comprise the review process [i.e., IRP (U.S. EPA, 2008), ISA (U.S. EPA, 2009a)], REA planning documents for health and welfare (Office of Air and Radiation, 2009; U.S. EPA, 2009b), a quantitative health risk assessment (U.S. EPA, 2010b)[19] and an urban-focused visibility assessment (U.S. EPA, 2010a),[20] and PA (U.S. EPA, 2011)]. In June 2012, the U.S. EPA announced its proposed decision to revise the NAAQS for PM (77 FR 38890, June 29, 2012).

In December 2012, the U.S. EPA announced its final decisions to revise the primary NAAQS for PM to provide increased protection of public health (78 FR 3086, January 15, 2013). With regard to primary standards for $PM_{2.5}$, the U.S. EPA revised the level of the annual $PM_{2.5}$ standard[21] to 12.0 $\mu g/m^3$ and retained the 24-hour $PM_{2.5}$ standard, with its level of 35 $\mu g/m^3$. For the primary PM_{10} standard, the U.S. EPA retained the 24-hour standard, with its level of 150 $\mu g/m^3$, to continue to provide protection against effects associated with short-term exposure to thoracic coarse particles (i.e., $PM_{10-2.5}$). With regard to the secondary PM standards, the U.S. EPA generally retained the 24-hour and annual $PM_{2.5}$ standards[22] and the 24-hour PM_{10} standard to address visibility and non-visibility welfare effects. On judicial review, the revised standards were upheld in all respects. NAM v U.S. EPA, 750 F.3d 921 (D.C. Cir. 2014).

[18] The history of the NAAQS review process, including revisions to the process, is discussed at http://www3.epa.gov/ttn/naaqs/review2.html.

[19] The quantitative assessment of health risks conducted in the last review was presented in the Quantitative Health Risk Assessment for Particulate Matter (U.S. EPA, 2010b). In the current review, quantitative assessments for health-related exposures and risks, if warranted, would be presented in the Health Risk and Exposure Assessment (HREA). For consistency with the documents developed under the current NAAQS process, the Quantitative Health Risk Assessment for Particulate Matter (U.S. EPA, 2010b) from the last review will be referenced in this document as the 2010 HREA.

[20] The quantitative assessment of welfare effects conducted in the last review was presented, in part, in the Urban-Focused Visibility Assessment (U.S. EPA, 2010a). In the current review, quantitative assessments for welfare effects, if warranted, would be presented in the Welfare Risk and Exposure Assessment (WREA). The Urban-Focused Visibility Assessment (U.S. EPA, 2010a) from the last review will be referenced in this document as the 2010 UFVA.

[21] The U.S. EPA also eliminated the option for spatial averaging.

[22] Consistent with the primary standard, the U.S. EPA eliminated the option for spatial averaging with the annual standard.

P.2 Purpose and Overview of the Integrated Science Assessment

The Integrated Science Assessment (ISA) is a comprehensive evaluation and synthesis of the policy-relevant science "useful in indicating the kind and extent of identifiable effects on public health or welfare which may be expected from the presence of [a] pollutant in ambient air," as described in Section 108 of the Clean Air Act (CAA, 1990a). This ISA communicates critical science judgments of the health and welfare criteria for particulate matter (PM). As such, this ISA serves as the scientific foundation for the review of the current primary (health-based) and secondary (welfare-based) National Ambient Air Quality Standards (NAAQS) for PM. In terms of the evaluation of the welfare-based evidence, the PM ISA focuses specifically on the nonecological effects of PM (i.e., visibility, materials effects, and climate) because the ecological effects are assessed in the ISA for Oxides of Nitrogen, Oxides of Sulfur, and Particulate Matter—Ecological Criteria as a result of these criteria pollutants being interrelated through complex chemical and physical atmospheric processes and all contributing to nitrogen (N) and sulfur (S) deposition (U.S. EPA, 2016). While the focus of the evaluation of the visibility and climate evidence is on PM, for materials effects, as detailed in the Integrated Review Plan (IRP), the PM ISA summarizes soiling and deterioration of materials attributable to PM and related N and S components because of the difficulty associated with isolating the effects of gaseous and particulate N and S wet deposition and because the ISA for Oxides of Nitrogen, Oxides of Sulfur, and Particulate Matter—Ecological Criteria focuses only on ecological effects (U.S. EPA, 2016).

This ISA evaluates relevant scientific literature published since the 2009 PM ISA [(U.S. EPA, 2009a) or 2009 PM ISA], integrating key information and judgments contained in the 2009 PM ISA and previous assessments of PM, i.e., 2004 AQCD for PM (U.S. EPA, 2004), 1996 AQCD for PM (U.S. EPA, 1996), 1982 AQCD for PM and Sulfur Oxides (U.S. EPA, 1982) and its Addendum (U.S. EPA, 1986), and the 1969 AQCD for PM (NAPCA, 1969). Thus, this ISA updates the state of the science that was available for the 2009 PM ISA, which informed decisions on the primary and secondary PM NAAQS in the review completed in 2012. In 2012, the U.S. EPA lowered the annual $PM_{2.5}$ standard to a mean of 12 $\mu g/m^3$, which is based on the annual mean averaged over 3 years, while retaining the 24-hour $PM_{2.5}$ standard of 35 $\mu g/m^3$, which is based on the 98th percentile averaged over 3 years (78 FR 3086). As part of the primary annual $PM_{2.5}$ standard, the U.S. EPA eliminated the spatial averaging provision to avoid disproportionate impacts on susceptible populations (i.e., populations potentially at increased risk of a PM-related health effect). The $PM_{2.5}$ standards are meant to provide increased protection for children, older adults, and people with pre-existing heart and lung disease as well as other potential susceptible populations against an array of $PM_{2.5}$-related health effects including premature mortality, increased hospital admissions and emergency department (ED) visits, and the development of chronic respiratory disease. Additionally, the U.S. EPA retained the current primary 24-hour PM_{10} standard at a level of 150 $\mu g/m^3$, which is not to be exceeded more than once per year over 3 years, to protect against health effects due to short-term exposure to thoracic coarse particles ($PM_{10-2.5}$) including premature mortality and increased hospital admissions and ED visits (78 FR 3086).

In terms of the secondary PM standards, the U.S. EPA retained the annual $PM_{2.5}$ standard at 15 μg/m^3 as well as the 24-hour $PM_{2.5}$ standard of 35 μg/m^3 and the 24-hour PM_{10} standard of 150 μg/m^3 (78 FR 3086). However, the form of the annual secondary $PM_{2.5}$ standard was changed to remove the option of spatial averaging. These secondary standards protect against non-visibility welfare effects including ecological effects, effects on materials, and climate impacts. To protect against PM-related visibility impairment, the U.S. EPA identified a target degree of protection defined as a $PM_{2.5}$ visibility index of 30 deciviews (dv), which is based on the 90th percentile of 24-hour average $PM_{2.5}$ concentrations over 3 years (78 FR 3086). However, an U.S. EPA analysis determined that the current secondary 24-hour $PM_{2.5}$ standard would provide sufficient protection, and in some cases greater protection, therefore a distinct secondary standard was not needed to provide requisite protection for both visibility and non-visibility related welfare effects.

This new review of the primary and secondary PM NAAQS is guided by several policy-relevant questions that are identified in The Integrated Review Plan for the National Ambient Air Quality Standards for Particulate Matter (U.S. EPA, 2016). To address these questions and update the scientific judgments in the 2009 PM ISA (U.S. EPA, 2009a), this ISA aims to:

- Assess whether new information (since the last PM NAAQS review) further informs the relationship between exposure to PM and specific health and nonecological welfare effects?
- Inform whether the current indicators (i.e., $PM_{2.5}$ for fine particles and PM_{10} for thoracic coarse particles), averaging times (e.g., 24-hour average, annual average), and levels of the PM NAAQS are appropriate?

In addressing policy-relevant questions, this ISA aims to characterize the independent health and welfare effects of PM, specifically $PM_{2.5}$ (fine PM; particulate matter with a nominal mean aerodynamic diameter less than or equal to 2.5 μm) and $PM_{10–2.5}$ (thoracic coarse or coarse PM; particulate matter with a nominal mean aerodynamic diameter greater than 2.5 μm and less than or equal to 10 μm) and whether there is evidence of an independent health effect for other size fractions [e.g., ultrafine particles (UFP), generally considered as particulates with a diameter less than or equal to 0.1 μm (typically based on physical size, thermal diffusivity or electrical mobility) (U.S. EPA, 2009a)] or specific PM components (e.g., metals). In the characterization of whether there is evidence of an independent health and welfare effect due to PM, the ISA considers possible influences of other atmospheric pollutants, including both gaseous (i.e., O_3, NO_2, SO_2, and CO) and other PM size fractions. The information summarized in this ISA will serve as the scientific foundation for the review of the current primary and secondary PM NAAQS.

P.3 Process for Developing Integrated Science Assessments

The U.S. EPA uses a structured and transparent process for evaluating scientific information and determining the causal nature of relationships between air pollution exposures and health effects [details provided in the Preamble to the Integrated Science Assessments (U.S. EPA, 2015)]. The ISA

development process describes approaches for literature searches, criteria for selecting and evaluating relevant studies, and a framework for evaluating the weight of evidence and forming causality determinations. Table P-2 provides a description of each of the five causality determinations and the types of scientific evidence that is considered for each category for both health and welfare effects.

Table P-2. Weight of evidence for causality determinations.

	Health Effects	Ecological and Other Welfare Effects
Causal relationship	Evidence is sufficient to conclude that there is a causal relationship with relevant pollutant exposures (e.g., doses or exposures generally within one to two orders of magnitude of recent concentrations). That is, the pollutant has been shown to result in health effects in studies in which chance, confounding, and other biases could be ruled out with reasonable confidence. For example: (1) controlled human exposure studies that demonstrate consistent effects, or (2) observational studies that cannot be explained by plausible alternatives or that are supported by other lines of evidence (e.g., animal studies or mode of action information). Generally, the determination is based on multiple high-quality studies conducted by multiple research groups.	Evidence is sufficient to conclude that there is a causal relationship with relevant pollutant exposures. That is, the pollutant has been shown to result in effects in studies in which chance, confounding, and other biases could be ruled out with reasonable confidence. Controlled exposure studies (laboratory or small- to medium-scale field studies) provide the strongest evidence for causality, but the scope of inference may be limited. Generally, the determination is based on multiple studies conducted by multiple research groups, and evidence that is considered sufficient to infer a causal relationship is usually obtained from the joint consideration of many lines of evidence that reinforce each other.
Likely to be a causal relationship	Evidence is sufficient to conclude that a causal relationship is likely to exist with relevant pollutant exposures. That is, the pollutant has been shown to result in health effects in studies where results are not explained by chance, confounding, and other biases, but uncertainties remain in the evidence overall. For example: (1) observational studies show an association, but copollutant exposures are difficult to address and/or other lines of evidence (controlled human exposure, animal, or mode of action information) are limited or inconsistent, or (2) animal toxicological evidence from multiple studies from different laboratories demonstrate effects, but limited or no human data are available. Generally, the determination is based on multiple high-quality studies.	Evidence is sufficient to conclude that there is a likely causal association with relevant pollutant exposures. That is, an association has been observed between the pollutant and the outcome in studies in which chance, confounding, and other biases are minimized but uncertainties remain. For example, field studies show a relationship, but suspected interacting factors cannot be controlled, and other lines of evidence are limited or inconsistent. Generally, the determination is based on multiple studies by multiple research groups.

Table P-2. (Continued): Weight of evidence for causality determinations.

	Health Effects	Ecological and Other Welfare Effects
Suggestive of, but not sufficient to infer, a causal relationship	Evidence is suggestive of a causal relationship with relevant pollutant exposures but is limited, and chance, confounding, and other biases cannot be ruled out. For example: (1) when the body of evidence is relatively small, at least one high-quality epidemiologic study shows an association with a given health outcome and/or at least one high-quality toxicological study shows effects relevant to humans in animal species, or (2) when the body of evidence is relatively large, evidence from studies of varying quality is generally supportive but not entirely consistent, and there may be coherence across lines of evidence (e.g., animal studies or mode of action information) to support the determination.	Evidence is suggestive of a causal relationship with relevant pollutant exposures, but chance, confounding, and other biases cannot be ruled out. For example, at least one high-quality study shows an effect, but the results of other studies are inconsistent.
Inadequate to infer a causal relationship	Evidence is inadequate to determine that a causal relationship exists with relevant pollutant exposures. The available studies are of insufficient quantity, quality, consistency, or statistical power to permit a conclusion regarding the presence or absence of an effect.	Evidence is inadequate to determine that a causal relationship exists with relevant pollutant exposures. The available studies are of insufficient quality, consistency, or statistical power to permit a conclusion regarding the presence or absence of an effect.
Not likely to be a causal relationship	Evidence indicates there is no causal relationship with relevant pollutant exposures. Several adequate studies, covering the full range of levels of exposure that human beings are known to encounter and considering at-risk populations and lifestages, are mutually consistent in not showing an effect at any level of exposure.	Evidence indicates there is no causal relationship with relevant pollutant exposures. Several adequate studies examining relationships with relevant exposures are consistent in failing to show an effect at any level of exposure.

Source: U.S. EPA (2015).

As part of this process, the ISA is reviewed by the Clean Air Scientific Advisory Committee (CASAC), which is a formal independent panel of scientific experts, and by the public. As this ISA informs the review of the primary and secondary PM NAAQS, it integrates and synthesizes information characterizing exposure to PM and potential relationships with health and welfare effects. Relevant studies include those examining atmospheric chemistry, spatial and temporal trends, and exposure assessment, as well as U.S. EPA analyses of air quality and emissions data. Relevant health research includes epidemiologic, controlled human exposure, and toxicological studies on health effects, as well as studies on dosimetry and biological plausibility. Additionally, relevant welfare research includes studies examining visibility impairment, effects on materials, and climate impacts.

The U.S. EPA initiated the current review of the primary and secondary PM NAAQS in December 2014 with a call for information from the public (U.S. EPA, 2013). Subject-area experts and the public were also able to recommend studies and reports to consider for the ISA during a science/policy issue "kick-off" workshop held at the U.S. EPA in February 2015. Thereafter, the U.S. EPA routinely conducted literature searches to identify relevant peer-reviewed studies published since the previous ISA (i.e., since May 2009). Multiple search methods were used [Preamble to the ISAs (U.S. EPA, 2015), Section 2], including searches in the PubMed and Web of Science databases. These

searches were meant to broadly capture all potentially relevant PM literature. To ensure the most policy-relevant evaluation of the current state of the science the scope of this PM ISA reflects not only the evolving PM literature base, but also the ability of the studies evaluated to directly inform the policy-relevant questions that form the basis of this review. Using both the scope of this ISA, detailed below, as well as the policy-relevant questions outlined in the PM IRP, studies that were uninformative based on title screening were excluded. Studies that were judged to be potentially relevant based on review of the abstract or full text and "considered" for inclusion in the ISA are documented in the Health and Environmental Research Online (HERO) website. The HERO project page for this ISA (https://hero.epa.gov/hero/particulate-matter) contains the references that are cited in the ISA, the references that were considered for inclusion but not cited, and electronic links to bibliographic information and abstracts.

P.3.1. Scope of the ISA

As initially detailed in the PM IRP (U.S. EPA, 2016) and further expanded upon here, when evaluating the broad body of literature across scientific disciplines, the U.S. EPA considers whether the studies fall within the scope of the PM ISA (i.e., provide information which can address key policy-relevant questions). As a result, the focus of the PM ISA with respect to the health effects evidence is on studies of short-term (i.e., hours up to 1 month) and long-term (i.e., 1 month to years) exposures conducted at concentrations of PM that are relevant to the range of human exposures across ambient microenvironments (up to 2 mg/m^3, which is one to two orders of magnitude above ambient concentrations), and (1) include a composite measure of PM[23] or (2) characterize PM and apply some approach to assess the direct effect of PM when the exposure of interest is a source-based mixture (e.g., diesel exhaust, gasoline exhaust, wood smoke). For epidemiologic studies, the scope is further refined when evaluating the evidence for those health outcomes where the 2009 PM ISA concluded that a "causal relationship exists" (i.e., short- and long-term $PM_{2.5}$ exposure and mortality and cardiovascular effects) to ensure the evaluation of the evidence focuses on the studies that are the most policy-relevant. As such, the focus is on those studies conducted in areas where mean $PM_{2.5}$ concentrations are <20 $\mu g/m^3$ or in the case of a multicity study where more than half of the cities have concentrations <20 $\mu g/m^3$. However, studies where mean $PM_{2.5}$ concentrations exceed 20 $\mu g/m^3$ are included if the studies address specific areas where the evidence was limited, as identified in the 2009 PM ISA, such as copollutant confounding. The scope is broader for experimental studies when examining biological plausibility for PM health effects, and in some cases, includes in vitro studies, studies that use intratracheal (IT) installation, studies examining relative toxicity, and studies conducted at concentrations >2 mg/m^3.

In the first case, studies that focus on a single component, group of components, or source, must also examine a composite measure of PM (e.g., mass of $PM_{2.5}$ and/or $PM_{10–2.5}$, or in the case of ultrafine particles [UFP] mass, particle number, etc.). This requirement facilitates a comparison of effects or

[23] Composite measures of PM may include mass, volume, surface area, or number concentration.

associations observed for individual components or alternative metrics to the current mass-based PM indicators. For experimental studies, to assess the relationship between $PM_{2.5}$ components and specific health effects this ISA relies on the approach initially outlined in the 2009 PM ISA and further refined in Stanek et al. (2011). This approach is consistent with the Health Effects Institute (HEI) Review Panel of the National Particle Component Toxicity (NPACT) initiative that states both source categories and component concentrations should be used directly in the health analyses with a focus on examining consistencies and differences between the two approaches (Lippmann et al., 2013). As a result, experimental studies included within this ISA fulfill the following four criteria (1) exposures examined consist of $PM_{2.5}$ from U.S. airsheds or those representative of the U.S. (e.g., Europe, Canada); (2) examined at least five PM components; (3) grouped PM components using statistical methods, for which the groups were not predefined based on common physical or chemical properties (e.g., water soluble vs. nonsoluble); and (4) applied a formal statistical analysis to investigate the relationship between groups of PM components or PM sources and health effects. The criteria applied to both experimental and epidemiologic studies in the evaluation of PM components ensures that a systematic approach is used in both identifying and evaluating those studies that examine PM components.

The second case primarily applies to experimental studies that attempt to disentangle the effect of PM on health from a complex air pollution mixture of particles, gases, and components distributed between the gas and particle phases. Studies that conduct an assessment of the PM effect from a source-based mixture (e.g., wood smoke, diesel exhaust, gasoline exhaust, etc.) are only included if they use filtration (e.g., a particle trap) or another approach to differentiate between effects due to the mixture and effects due to the particles alone.

Whereas the preceding paragraphs focused broadly on the scope of the entire PM ISA, there are additional nuances that further frame the scope of the ISA, specifically with respect to UFPs. UFPs have often been defined as particles <0.1 µm (U.S. EPA, 2009a), but depending on the scientific discipline, the methods employed and particle sizes examined to assess the UFP-health effects relationship varies. UFP exposures in animal toxicological and controlled human exposure studies typically use a particle concentrator, which can result in exposures to particles <0.30 µm (Section 2.4.3.1). While toxicological studies typically rely on examining UFP mass, epidemiologic studies examine multiple UFP metrics including particle number concentration (NC), mass concentration (MC), and surface area concentration (SC). However, depending on the monitor used and the metric, the UFP size distribution that could be included within each of these ranges can vary. Some studies that examine NC use no additional size classification, instead measuring NC over the entire size range of the particle counter. In instances where the entire size range is measured, limited available measurement data in the U.S. and Europe indicates that approximately 67 to 90% of NC represents particles <0.1 µm (Section 2.4.3.1). Studies that examine MC or SC often include a range of particle sizes up to 0.3 µm. Currently, a consensus has not been reached within the scientific community on the metric that best represents exposure to UFPs (Baldauf et al., 2016). As a result, in this ISA the focus of the evaluation of the UFP-health effects relationship is on particles <0.3 µm for MC and SC metrics included in experimental studies, and any size range that

includes particles <0.1 μm for NC. Focusing on these criteria when evaluating UFP studies will provide the most comprehensive assessment of UFPs and ensure that the metric examined represents primarily the UFP size range.

Across disciplines, studies defined as examining UFPs, but focusing on the sources, transport, and fate of fibers and unique nano-objects (namely, dots, hollow spheres, plates, rods, fibers, tubes) are not reviewed because substantial exposures to fibers and unique nano-objects generally occur in the occupational settings rather than the ambient environment. Furthermore, the in vivo disposition of unique nano-objects is not likely relevant to the behavior of ultrafine (UF) aerosols found in ambient air, which are created by combustion sources and photochemical formation of secondary organic aerosols. However, some studies focusing on engineered nano- or ultrafine particles (e.g., carbon black, titanium dioxide) are included where they contribute to an understanding of the dosimetry or biological plausibility of PM.

In addition to the specific parameters that broadly form the overall scope of the review of PM and health effects, additional criteria were applied for the evaluation of the evidence for cancer. As detailed in the PM IRP, the PM ISA focuses on whether PM can directly cause cancer through only inhalation exposures at ambient and near-ambient concentrations (i.e., up to 2 mg/m^3). When evaluating the epidemiologic evidence for cancer, consistent with the overall scope of the ISA, the focus is on those studies with composite measures of PM. Whereas the ISA tends not to focus the evaluation of the health effects evidence on in vitro studies, for the purposes of examining the mutagenicity of PM in vitro systems are discussed because they inform the biological pathways underlying cancer. While some components of PM are known carcinogens (e.g., benzene), as previously stated the focus of this ISA is on composite measures of PM (e.g., $PM_{2.5}$) and, where applicable, comparison to effects or associations observed for individual PM components to help inform the adequacy of current mass-based PM indicators. As such, the relationship between PM exposure and cancer is evaluated similarly to that of other health effects, resulting in the exclusion of studies that examine individual PM components without a composite PM measure. The evaluation of cancer includes studies that use PM filter extracts with the understanding that bioavailability of PM components in vivo is a complex issue not easily mimicked by extraction of PM collected on filters. Overall, the evaluation of cancer in the ISA will primarily focus on studies of inhaled PM since these studies are more relevant to ambient exposure conditions with the recognition of the extensive historical evaluations on the mutagenicity, genotoxicity, and carcinogenicity of whole PM exposures (i.e., not defined by size fraction).

For nonecological welfare effects (i.e., visibility, climate, and materials effects), this ISA will build on information available during the last review describing the role of PM in visibility impairment, radiative forcing resulting in global and regional climate change, and materials damage and soiling. For visibility effects, studies are included which advance our understanding of visual impairment of airborne PM, including studies of atmospheric chemistry, visibility preference, or other measures of adversity to public welfare, in urban and rural settings. For climate effects, this ISA focuses on climate as the welfare effect as listed in the Clean Air Act Amendments of 1970 with a focus on radiative forcing, surface

meteorological trends, and climate feedbacks, and not on downstream ecosystem effects, human health effects, or future air quality projections resulting from changes in climate (CAAA, 1970). The primary literature base for the evaluation of the effects of airborne and deposited PM on climate comes from recent national and international climate assessments such as the National Climate Assessment (Melillo et al., 2014) and International Panel on Climate Change (IPCC, 2014), as well as other recent and more focused reports relevant to PM climate forcing [e.g., (U.S. EPA, 2012)]. The focus is on studies that inform the independent role of PM in climate forcing as well as effects on U.S. national and regional climate. For effects on materials, studies included in the PM ISA examine the role of PM and relevant precursor gases on materials damage and soiling. Specifically, studies that examine both particulate and gaseous contributions from oxides of nitrogen and oxides of sulfur along with other PM components are included here due to the difficulty associated with isolating the effects of gaseous and particulate N and S wet deposition.

P.3.2. Evaluation of the Evidence

The Preamble to the ISAs (U.S. EPA, 2015) describes the general framework for evaluating scientific information, including criteria for assessing study quality and developing scientific conclusions. Aspects specific to evaluating studies of PM are described in the Annex to the Preface, which were applied to studies that fit the overall scope of the PM ISA. Categories of health and welfare effects were considered for evaluation in this ISA if they were examined in previous U.S. EPA assessments for PM or in multiple recent studies. Therefore, in this ISA the broad health effects categories evaluated include those considered in the 2009 PM ISA (i.e., respiratory effects, cardiovascular effects, central nervous system effects, cancer, and mortality) along with the addition of metabolic effects, while new research indicates it is more appropriate to further refine the category of reproductive and developmental effects to instead focus overall conclusions specifically on fertility and pregnancy effects, and birth outcomes separately. While the welfare effects categories evaluated include visibility impairment, effects on materials, and climate.

In forming the key science judgments for each of the health and welfare effects categories evaluated, the PM ISA draws conclusions about relationships between PM exposure and health effects by integrating information across scientific disciplines and related health outcomes and synthesizing evidence from previous and recent studies. To impart consistency in the evaluation of health effects evidence for epidemiologic studies, additional parameters to those outlined in the scope (Section P.3.1) were developed. To facilitate a comparison of results across epidemiologic studies, risk estimates were standardized to a defined increment for both short- and long-term exposure to $PM_{2.5}$ and $PM_{10–2.5}$, unless otherwise noted in the text. To determine the appropriate increment the distribution of $PM_{2.5}$ and $PM_{10–2.5}$ concentrations were examined across the three most recent years of air quality data (2012−2014) within the U.S. For both $PM_{2.5}$ and $PM_{10–2.5}$, an increment of 10 $\mu g/m^3$ was defined for short-term exposure studies which approximates the 50th−95th percentile of concentrations and accounts for the variability observed in daily $PM_{2.5}$ concentrations. An increment of 5 $\mu g/m^3$ was defined for long-term exposure

studies which approximates the 25th−75th percentile of concentrations and represents the variation observed in long-term mean concentrations. Due to the lack of an extensive monitoring network for UFPs within the U.S., results from studies examining UFP are not standardized and reflect the increment of exposure defined in each study evaluated. Additionally, in the assessment of correlations, either with other copollutants or variables, in epidemiologic studies high, moderate, or low correlations are explicitly defined as the following: low correlation, $r < 0.40$; moderate correlation, $r \geq 0.40$ and $r < 0.70$; and high correlation, $r \geq 0.70$. Consistency in the interpretation of the epidemiologic evidence through approaches such as the standardization of risk estimates and the evaluation of correlations, in combination with the integration of evidence across scientific disciplines supports a thorough evaluation of the current state of the science for PM.

In the evaluation of the evidence determinations are made about causation, not just association, and are based on judgments of aspects such as the consistency of evidence within a discipline, coherence of effects across disciplines, and biological plausibility of observed effects as well as related uncertainties. The ISA uses a formal causal framework [Table II of the Preamble to the ISAs (U.S. EPA, 2015)] to classify the weight of evidence according to the five-level hierarchy summarized below.

- Causal relationship: the pollutant has been shown to result in health and welfare effects at relevant exposures based on studies encompassing multiple lines of evidence and chance, confounding, and other biases can be ruled out with reasonable confidence.
- Likely to be a causal relationship: there are studies in which results are not explained by chance, confounding, or other biases, but uncertainties remain in the health and welfare effects evidence overall. For example, the influence of co-occurring pollutants is difficult to address, or evidence across scientific disciplines may be limited or inconsistent.
- Suggestive of, but not sufficient to infer, a causal relationship: health and welfare effects evidence is generally supportive but not entirely consistent or is limited overall. Chance, confounding, and other biases cannot be ruled out.
- Inadequate to infer the presence or absence of a causal relationship: there is insufficient quantity, quality, consistency, or statistical power of results from studies of health and welfare effects.
- Not likely to be a causal relationship: several adequate health and welfare effects studies, examining the full range of anticipated exposure concentrations and for health effects, potential at-risk populations and lifestages consistently show no effect.

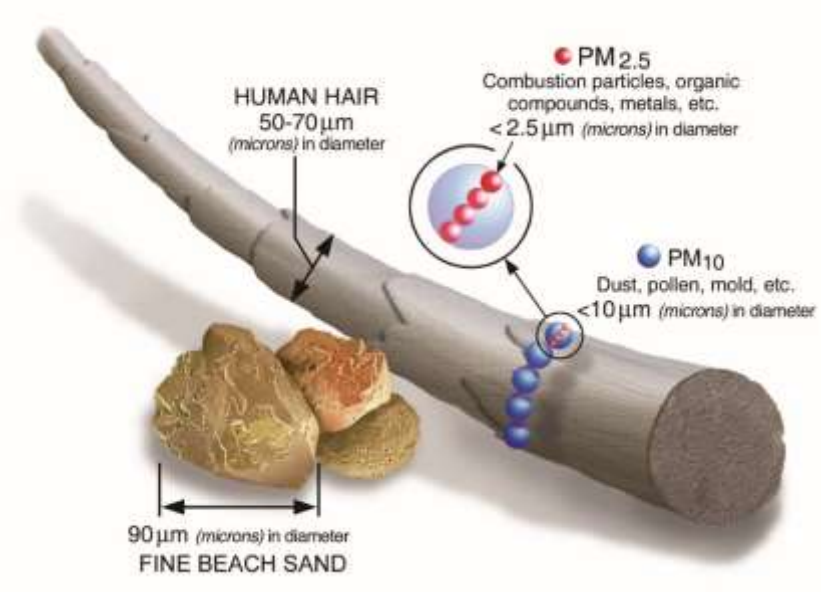
EXECUTIVE SUMMARY

Purpose and Scope of the Integrated Science Assessment

This Integrated Science Assessment (ISA) is a comprehensive evaluation and synthesis of policy-relevant science aimed at characterizing exposures to ambient particulate matter (PM), and health and welfare effects associated with these exposures.[24] PM is a mixture of solid particles and liquid droplets found in the ambient air[25], which encompasses multiple size fractions (e.g., fine PM [$PM_{2.5}$, particulate matter with a nominal mean aerodynamic diameter less than or equal to 2.5 μm]; thoracic coarse or coarse PM [$PM_{10–2.5}$, particulate matter with a nominal mean aerodynamic diameter greater than 2.5 μm and less than or equal to 10 μm]; and ultrafine particles [UFPs, generally considered as particulates with a diameter less than or equal to 0.1 μm, typically based on physical size, thermal diffusivity or electrical mobility]) and is comprised of various components (e.g., metals, black carbon, etc.) (Figure ES-1). The evaluation of the science and the overarching conclusions of the ISA serves as the scientific foundation for the review of the primary (health-based) and secondary (welfare-based) National Ambient Air Quality Standard (NAAQS) for PM. This ISA focuses on nonecological welfare effects[26] because ecological effects resulting from deposition of PM and PM components are being considered in a separate assessment as part of the review of the secondary (welfare-based) NAAQS for oxides of nitrogen and sulfur, and PM (U.S. EPA, 2018).

[24] The general process for developing an ISA, including the framework for evaluating weight of evidence and drawing scientific conclusions and causal judgments, is described in a companion document, *Preamble to the Integrated Science Assessments* (U.S. EPA, 2015), www.epa.gov/isa.
[25] As defined by U.S. EPA, https://www.epa.gov/pm-pollution/particulate-matter-pm-basics.
[26] From this point forward referred to as welfare effects.



Source: Permission pending, U.S. EPA[27]

Figure ES-1 Comparison of PM size fractions.

In 2012, the U.S. Environmental Protection Agency (U.S. EPA) established a new annual $PM_{2.5}$ primary standard of 12 µg/m^3 (the annual mean averaged over 3 years) and retained the 24-hour $PM_{2.5}$ standard of 35 µg/m^3 (the 98th percentile averaged over 3 years) (75 FR 3086).[28] For the primary PM_{10} standard, the U.S. EPA retained the 24-hour standard of 150 µg/m^3 (not to be exceeded more than once per year on average over 3 years) to continue to provide protection against effects associated with short-term exposure to thoracic coarse particles (i.e., $PM_{10–2.5}$). Regarding the secondary PM standards, the U.S. EPA retained the 24-hour (i.e., 35 µg/m^3) and annual (i.e., 15 µg/m^3) $PM_{2.5}$ standards[29] and the 24-hour PM_{10} standard (i.e., 150 µg/m^3) to address visibility and nonvisibility welfare effects. On judicial review, the revised and retained standards were upheld in all respects. NAM v EPA, 750 F.3d 921 (D.C. Cir. 2014).

This ISA updates the 2009 ISA for Particulate Matter [(U.S. EPA, 2009) hereafter referred to as the 2009 PM ISA] with studies and reports published from January 2009 through approximately January 2018. The U.S. EPA conducted in-depth searches to identify peer-reviewed literature on relevant topics such as health and welfare effects, atmospheric chemistry, ambient concentrations, and exposure. Information was also solicited from subject-matter experts and the public during a kick-off workshop held

[27] https://www.epa.gov/pm-pollution/particulate-matter-pm-basics.

[28] The legislative requirements and history of the PM NAAQS are described in detail in the Preface to this ISA.

[29] Consistent with the primary standard, the U.S. EPA eliminated the option for spatial averaging with the annual standard.

at the U.S. EPA in February 2015. To fully describe the state of available science, the U.S. EPA also included in this ISA the most relevant studies from previous assessments.

As in the 2009 PM ISA, this ISA determines the causal nature of relationships between health effects and exposure to $PM_{2.5}$, $PM_{10–2.5}$, and UFPs (CHAPTER 5, CHAPTER 6, CHAPTER 7, CHAPTER 8, CHAPTER 9, CHAPTER 10, and CHAPTER 11). To address this task a defined scope was developed to focus on those studies that inform whether PM exposure directly causes health effects (see Preface). Health effects are considered in relation to exposures at concentrations of PM that are relevant to the range of human exposures across ambient microenvironments, specifically within one to two orders of magnitude of current conditions (i.e., up to 2 mg/m^3) (Preface, Section P.3.1). The ISA also evaluates the relationship between PM components and sources to assess whether there is evidence that a component, group of components, or source is more closely related to health effects than PM mass (see Preface). Additionally, the ISA evaluates whether specific populations or lifestages are at increased risk of PM-related health effects. The ISA also determines the causal nature of relationships between PM and welfare effects. In the evaluation of the welfare-based evidence (CHAPTER 13), the PM ISA focuses specifically on the nonecological welfare effects of PM (i.e., visibility, materials effects, and climate) because the ecological effects are assessed in the ISA for Oxides of Nitrogen, Oxides of Sulfur and Particulate Matter – Ecological Criteria as a result of these criteria pollutants being inter-related through complex chemical and physical atmospheric processes and all contributing to nitrogen (N) and sulfur (S) deposition (U.S. EPA, 2018). However, in the assessment of effects on materials the PM ISA summarizes soiling and deterioration of materials attributable to PM and related nitrogen (N) and sulfur (S) components because of the difficulty associated with isolating the effects of gaseous and particulate N and S wet deposition and because the ISA for Oxides of Nitrogen, Oxides of Sulfur and Particulate Matter – Ecological Criteria focuses only on ecological effects (U.S. EPA, 2018).

Key to interpreting the health and welfare effects evidence is understanding the sources, chemistry, and distribution of PM in the ambient air (CHAPTER 2). It is these atmospheric relationships and processes that influence human exposure (CHAPTER 3) and the uptake of inhaled PM in the respiratory tract (CHAPTER 4). The uptake of PM and its deposition in the body directly influences the biological mechanisms by which PM could potentially result in a health effect (CHAPTER 5, CHAPTER 6, CHAPTER 7, CHAPTER 8, CHAPTER 9, CHAPTER 10, and CHAPTER 11). Further, the ISA aims to characterize the independent effect of PM (i.e., $PM_{2.5}$, $PM_{10–2.5}$, and UFP) on health (CHAPTER 5, CHAPTER 6, CHAPTER 7, CHAPTER 8, CHAPTER 9, CHAPTER 10, and CHAPTER 11). The ISA also informs policy-relevant issues (Section 1.6 and CHAPTER 5, CHAPTER 6, CHAPTER 7, CHAPTER 8, CHAPTER 9, CHAPTER 10, CHAPTER 11, and CHAPTER 12), such as (1) potential copollutant confounding (Section 1.5.1); (2) timing of effects (i.e., averaging time of exposure metric and lag at which associations are observed in epidemiologic studies (Section 1.5.2); (3) PM concentration-response relationship(s), and evaluation of potential thresholds for effects (Section 1.5.3); (4) PM components and sources and relationships with health effects (Section 1.5.4); and (5) populations or lifestages at increased risk for health effects related to PM exposure (Section 1.5.5).

Sources and Exposure to PM

The main objective of the ISA is to characterize health and welfare effects related to ambient PM exposure. This requires understanding PM sources, atmospheric formation, measurement methods, and concentrations. Additionally, with respect to characterizing the health effects of PM it requires understanding the factors that affect both exposure to ambient PM and the uncertainty in estimating exposure. These factors include unmeasured variability in $PM_{2.5}$, $PM_{10–2.5}$, and UFP concentrations and size distributions, exposure to copollutants, and uncharacterized PM composition.

Particulate matter is comprised of components that are directly emitted (primary PM) as well as formed through atmospheric chemical reactions involving gaseous precursors (secondary PM) (Section 2.3). Both primary and secondary PM contribute substantially to overall PM mass in ambient air. Within an urban environment most primary $PM_{2.5}$ emissions are from anthropogenic sources, and include some combination of industrial activities, motor vehicles, cooking, and fuel combustion. However, in many locations secondary PM formed from the precursors sulfur dioxide (SO_2), oxides of nitrogen (NO_X), ammonia (NH_3), and volatile organic compounds (VOCs), accounts for the majority of $PM_{2.5}$ mass. Direct emissions of primary $PM_{2.5}$ have decreased slightly (~9% since 2002) over the past decade, along with a substantial decrease in emissions since 2006 of the major $PM_{2.5}$ precursors SO_2 and NO_X, 65% and 30%, respectively. $PM_{10–2.5}$ is almost entirely primary in origin, composed largely of crustal material, sea salt, and biological material. National average $PM_{10–2.5}$ concentrations have changed little over the past decade. Ambient UFPs originate from two distinct processes, primary particles directly emitted from specific sources like motor vehicles and new particle formation by photochemical processes under favorable atmospheric conditions.

There are well-established federal reference methods (FRM) and national monitoring networks for $PM_{2.5}$, PM_{10}, and $PM_{10–2.5}$ (Section 2.4). Recent monitoring initiatives include the implementation of the National Core multipollutant monitoring network, which includes $PM_{2.5}$ and $PM_{10–2.5}$ measurements along with a suite of other pollutants, a new near road monitoring network that includes $PM_{2.5}$ monitors at 36 sites, and the first routine monitoring of particle number count at 23 sites. Satellite-based measurements in conjunction with chemical transport models have also become increasingly used for estimating $PM_{2.5}$ concentrations. In general, the fraction of PM_{10} accounted for by $PM_{2.5}$ is higher in the eastern U.S. than in the western U.S. Compared to $PM_{2.5}$, $PM_{10–2.5}$ concentrations are more spatially variable. The limited amount of available UFP measurements data indicated that the highest UFP concentrations occur in the winter and near roads with heavy traffic, often over short time periods. Overall, UFP concentrations are more spatially variable than $PM_{2.5}$. As Figure 2-22 shows, national average $PM_{2.5}$ concentrations decreased by about 5 $\mu g/m^3$ from 2000 to 2015. Much of this decrease is accounted for by a corresponding decrease in sulfate concentrations, especially in the eastern U.S., attributed to reduced SO_2 emissions. Sulfate concentrations are mainly associated with $PM_{2.5}$ and have historically been highest in summer. The reduction in $PM_{2.5}$ and sulfate concentrations has coincided with shifts from summer, as the season with the highest national average concentration, to a more even

distribution of $PM_{2.5}$ concentrations between summer and winter, and to an increase in the contribution of $PM_{10-2.5}$ to PM_{10} concentrations.

Fixed-site monitoring is frequently used for obtaining $PM_{2.5}$ exposure surrogates in both short-term and long-term exposure epidemiologic studies (Section 3.3), given that spatial variability in $PM_{2.5}$ concentration tends to be lower than for other size fractions. Fixed-site monitoring for $PM_{10-2.5}$ has been performed by different methods. It is important to consider the method used in order to characterize errors and uncertainties in the data that are related both to the monitoring method and the proximity of the individual receptor to the monitor because $PM_{10-2.5}$ is typically more spatially variable than $PM_{2.5}$. Condensation particle counter (CPC) is most commonly used to measure UFP. However, some portion of the UFP size distribution may be omitted using CPC, since they do not typically measure particles smaller than 10 nm. UFP also tends to be more spatially variable than $PM_{2.5}$, contributing to uncertainties in exposure assignments.

Modeling approaches, such as spatial interpolation methods, land use regression, dispersion models, and chemical transport models (CTMs), have for years provided estimates of exposure concentration where no measurements are available. More recently, hybrid models drawing input from CTMs, satellite observations of aerosol optical density, surface measurements of PM concentration, and land use variables have become available. Most studies using hybrid methods are applied to model $PM_{2.5}$ and have out-of-sample cross-validations with $R^2 > 0.8$. Models are employed less frequently to estimate

$PM_{10–2.5}$ and UFP exposure concentration, despite $PM_{10–2.5}$ and UFP typically being more spatially variable than $PM_{2.5}$. This is related in part to less availability of input data.

When particles enter a building envelope, they may be lost during the process of infiltration to indoor, to produce an infiltration factor (F_{inf}) < 1 (Section 3.4). F_{inf} varies with season, window opening, building age, wind speed and particle size distribution (with F_{inf} lower for $PM_{10–2.5}$ and UFP compared with $PM_{2.5}$). When examining the influence of estimated exposure concentrations on health effect estimates in a time-series study of short-term PM exposure, use of a fixed-site monitor in lieu of a microenvironmental model that accounted for infiltration produced considerably attenuated health effect estimates, which resulted in an underestimation of the health effect. Infiltration of PM through a building envelope may change the temporal variability of the indoor PM concentration time-series, resulting in reduced correlation between the health effect of interest and the estimated exposure concentration. In the examination of how exposure concentration estimates influence health effect estimates in an epidemiologic study of long-term PM exposure, simulating indoor concentrations produced unbiased health effect estimates.

In summary, exposure error tends to produce underestimation of health effects in epidemiologic studies of PM exposure, although bias in either direction can occur. Recent improvements in estimating spatial resolution of the $PM_{2.5}$ concentration surface have reduced bias and uncertainty in health effects estimates. $PM_{10–2.5}$ and UFP concentrations tend to be more spatially variable than $PM_{2.5}$ concentrations, but data are either unavailable or less often available to fit or validate hybrid models for those size fractions. As a result, there is typically less uncertainty in health effect estimates derived from both monitored and modeled exposure estimates for $PM_{2.5}$ compared with either $PM_{10–2.5}$ or UFP.

Dosimetry of Inhaled PM

Particle dosimetry characterizes the intake, deposition, and retention of PM in the respiratory tract (CHAPTER 4). The basic understanding of particle dosimetry has not changed since the last review. Quantification of the fraction of inhaled particles reaching the lung and the small fraction of deposited particles that enter the blood, distribute around the body, and accumulate in organs and tissues has improved. Understanding the dosimetry of particles is crucial to providing evidence that supports whether it is biologically plausible that PM exposure can lead to a range of health effects spanning multiple organ systems.

A variety of factors influence the amount of inhaled particles deposited and retained in the respiratory tract and include exposure concentration and duration, activity and breathing conditions (e.g., nasal vs. oronasal route and minute ventilation), and particle properties (e.g., particle size, hygroscopicity, and solubility in airway fluids and cellular components). Inhalability is particularly important for between species extrapolation since it decreases more rapidly as particle size increases in rodents (commonly used in laboratory studies) compared to humans. In people, the fraction of oral versus nasal breathing is influenced by age, activity level, sex, disease status (e.g., allergies, upper respiratory

infections), and perhaps body mass index, which ultimately contributes to the fraction of particles inhaled and reaching the lower respiratory tract.

Recent evidence shows that in both humans and rodents, a small fraction of gold nanoparticles depositing in the peripheral lung may move into circulation. The fraction of deposited particles that move into circulation is dependent on particle size and is in the range of 0.2% or less for particles between 5 nm and 200 nm, but may reach a few percent for smaller particles. The translocated particles are distributed around the body and may be retained in other organs or eliminated via urine. Some more limited data show that particles may also reach the fetus in a size dependent manner. Although translocation in humans has only been demonstrated for gold nanoparticles and to some degree for titanium dioxide, the translocation of several types of nanoparticles has been demonstrated in rodents. The importance of compound type on particle translocation has not yet been ascertained. These studies suggest that, following deposition in the lung, a small fraction of ambient particles under 200 nm may translocate into circulation.

Health and Welfare Effects of PM Exposure

This ISA integrates information on PM exposure and health effects from epidemiologic, controlled human exposure, and toxicological studies to determine the causal nature of relationships between exposure to PM of various size fractions (i.e., $PM_{2.5}$, $PM_{10–2.5}$, and UFPs) and broad health effect categories. For most health effect categories, except for reproductive and developmental effects, effects are evaluated separately for short-term exposures (i.e., hours up to approximately one month) and long-term exposures (i.e., one month to years). For welfare effects the ISA evaluates evidence as it pertains to the welfare effects of visibility impairment, climate effects, and effects on materials. A consistent and transparent framework [Preamble to the ISA (U.S. EPA, 2015), Table II] is applied to classify the health and welfare effects evidence according to a five-level hierarchy:

1. Causal relationship
2. Likely to be a causal relationship
3. Suggestive of, but not sufficient to infer, a causal relationship
4. Inadequate to infer the presence or absence of a causal relationship
5. Not likely to be a causal relationship

The causality determinations presented in Table ES-1, reflect those PM size fraction, exposure duration, and broad health category combinations for which a "*causal relationship*" or "*likely to be causal relationship*" was concluded in this ISA. The conclusions presented are informed by recent findings in combination with the evidence detailed in the 2009 PM ISA. Important considerations include: (1) determining whether laboratory studies of humans and animals, in combination with epidemiologic studies, inform the biological mechanisms by which PM can impart health effects and provide evidence demonstrating that PM exposure can independently cause a health effect; (2) determining whether there is consistency in epidemiologic evidence across various geographic locations, populations, and methods

used to estimate PM exposure; (3) evaluating epidemiologic studies that examine potential influence of factors (i.e., confounders) that could bias associations observed with PM exposure; (4) determining the coherence of findings integrated across controlled human exposure, epidemiologic, and toxicological studies; and (5) making judgments regarding the influence of error and uncertainty on the relationship between PM exposure and health effects in the collective body of available studies. Table ES-2 details the causality determinations for the welfare effects.

Table ES-1 Summary of "causal relationship" and "likely to be causal relationship" causality determinations for PM exposure and health effects from the current draft PM ISA and corresponding causality determinations from the 2009 PM ISA.

Size Fraction	Health Effect Category[a] and Exposure Duration	Causality Determination

Table ES-1 (Continued): Summary of "Causal Relationship" and "Likely to be Causal Relationship" causality determinations for PM exposure and health effects from the current draft PM ISA and corresponding causality determinations from the 2009 PM ISA.

Size Fraction	Health Effect Category[a] and Exposure Duration	Causality Determination	
		2009 PM ISA	Current Draft PM ISA
UFP	Nervous System Effects—Long-term exposure Section 8.6.7, Table 8-34	Not evaluated	Likely to be a causal relationship

ISA = Integrated Science Assessment; PM = particulate matter; $PM_{2.5}$ = fine particulate matter; UFP = ultrafine particles.

Previous causality determinations taken from the 2009 PM ISA (U.S. EPA, 2009).

[a]An array of outcomes is evaluated as part of a broad health effect category: physiological measures (e.g., airway responsiveness), clinical outcomes (e.g., hospital admissions), and cause-specific mortality. Total mortality includes all nonaccidental causes of mortality and is informed by findings for the spectrum of morbidity effects (e.g., respiratory, cardiovascular) that can lead to mortality. The sections and tables referenced include a detailed discussion of the evidence that supports the causality determinations and the $PM_{2.5}$ and UFP concentrations with which health effects have been associated.

Health Effects of $PM_{2.5}$ Exposure

Across the PM size fractions evaluated within this ISA, the most substantial scientific evidence indicating relationships between short- and long-term PM exposure is for $PM_{2.5}$. The causality determinations for $PM_{2.5}$ reflect the total body of scientific evidence, building off the conclusions presented in the 2009 PM ISA. The following sections detail those exposure duration and broad health effect categories where this ISA concluded a "*causal*" or "*likely to be causal*" causality determination, reflecting the highest degree to which the evidence reduces chance, confounding, and other biases in the exposure—health effect relationship. Those health effect categories where there is still a large degree of uncertainty or limited examination of the relationship between $PM_{2.5}$ exposure and health effects resulting in the causality determination of "*suggestive of, but not sufficient to infer, a causal relationship*" and "*inadequate to determine the presence or absence of a causal relationship*" are summarized in CHAPTER 1, Table 1-7.

Respiratory Effects

As in the 2009 PM ISA, the current ISA concludes there is a "*likely to be causal relationship*" between *short-term $PM_{2.5}$ exposure and respiratory effects* (Section 5.1). Recent epidemiologic studies continue to provide strong evidence for a relationship between short-term $PM_{2.5}$ exposure and several respiratory-related endpoints, including asthma exacerbation, chronic obstructive pulmonary disease (COPD) exacerbation, and combined respiratory-related diseases, particularly from studies examining emergency department visits and hospital admissions. The consistent, positive associations observed for asthma and COPD emergency department visits and hospital admissions are further supported by evidence of increased symptoms and medication use in response to short-term $PM_{2.5}$ exposure, which is

indicative of asthma and COPD exacerbations. Animal toxicological studies of short-term $PM_{2.5}$ exposure provide coherence and biological plausibility for asthma and COPD exacerbations by demonstrating asthma-related responses in an animal model of allergic airways disease and enhanced lung injury and inflammation in an animal model of COPD. Animal toxicological evidence also demonstrates altered host defense, greater susceptibility to bacterial infection, respiratory irritant effects, and other effects. This broad body of experimental evidence indicating $PM_{2.5}$-related respiratory effects in healthy populations generally provides biological plausibility for respiratory effects in association with short-term $PM_{2.5}$ exposure, but does not inform the relationship with asthma or COPD exacerbation. In addition, controlled human exposure studies provide minimal evidence of effects due to short-term $PM_{2.5}$ exposure, such as decrements in lung function and pulmonary inflammation. Recent epidemiologic studies build upon the limited number of studies that previously examined potential copollutant confounding and indicate that $PM_{2.5}$ associations with asthma exacerbation, combined respiratory-related diseases, and respiratory mortality remain relatively unchanged in copollutant models with gaseous pollutants (i.e., O_3, NO_2, SO_2, with more limited evidence for CO) and other particle sizes (i.e., $PM_{10–2.5}$). Animal toxicological studies further support an independent effect of $PM_{2.5}$ on respiratory health by demonstrating asthma- and COPD-related responses in animal models of disease. Evidence of consistent, positive associations between $PM_{2.5}$ and respiratory mortality demonstrate a continuum of respiratory-related effects.

Both the 2009 PM ISA, and the current ISA concluded there is a "*likely to be causal relationship*" between *long-term $PM_{2.5}$ exposure and respiratory effects* (Section 5.2). There is strong evidence from multiple cohorts that varied in study location, exposure assessment methods, and time periods examined that demonstrated an effect of long-term $PM_{2.5}$ exposure on lung development (i.e., lung function growth). Additional, although more limited, evidence from epidemiologic studies indicates associations between long-term $PM_{2.5}$ exposure and asthma development in children, asthma prevalence in children, childhood wheeze, and pulmonary inflammation. Animal toxicological studies demonstrating impaired lung development resulting from pre- and post-natal $PM_{2.5}$ exposure and the development of an allergic phenotype along with an increase in airway responsiveness following long-term $PM_{2.5}$ exposure provide biological plausibility for these findings. Animal toxicological studies also demonstrate $PM_{2.5}$ exposure-induced oxidative stress, inflammation, and morphological changes in both upper and lower airways. There is limited assessment of potential copollutant confounding of respiratory morbidity outcomes, but recent animal toxicological studies partially address the independence of $PM_{2.5}$ effects by demonstrating $PM_{2.5}$ induced oxidative stress, inflammation, and morphologic changes. This broad body of experimental evidence indicating $PM_{2.5}$-related respiratory effects in healthy populations generally provides biological plausibility for respiratory effects in association with long-term $PM_{2.5}$ exposure. Additional epidemiologic evidence, indicates an acceleration of lung function decline in adults, as well as consistent evidence for respiratory mortality and cause-specific respiratory mortality, providing evidence of a continuum of effects in response to long-term $PM_{2.5}$ exposure. The relationship between long-term $PM_{2.5}$ exposure and respiratory effects is further supported by epidemiologic studies demonstrating improvements in lung function growth and bronchitic symptoms in children and improvement in lung function in adults in association with declining $PM_{2.5}$ concentrations.

Cardiovascular Effects

Consistent with the 2009 PM ISA, this ISA concludes there is a "*causal relationship*" between *short-term $PM_{2.5}$ exposure and cardiovascular effects* (Section 6.1). The strongest evidence comes from epidemiologic studies that reported consistent, positive associations between short-term $PM_{2.5}$ exposure and cardiovascular-related emergency department visits and hospital admissions particularly for ischemic heart disease (IHD) and heart failure (HF), as well as cardiovascular-related mortality. Recent examinations of potential copollutant confounding generally indicate that the associations observed with $PM_{2.5}$ and cardiovascular effects in single pollutant models remain relatively unchanged in copollutant models, providing evidence that the observed associations with $PM_{2.5}$ are not artefacts due to confounding by another air pollutant. The independence of a $PM_{2.5}$ cardiovascular effect is further supported by recent experimental studies. Recent controlled human exposure studies expand upon previous findings and demonstrate $PM_{2.5}$-induced changes in endothelial function and blood pressure, which is coherent with animal toxicological studies demonstrating the same effects. Moreover, experimental evidence demonstrating decreased cardiac contractility and left ventricular pressure is coherent with epidemiologic studies observing positive associations between ambient $PM_{2.5}$ and ED visits and hospital admissions for HF. Thus, the collective body of experimental evidence supports and provides biological plausibility for epidemiologic studies reporting associations particularly between short-term $PM_{2.5}$ exposure and IHD and HF outcomes, as well as a range of other cardiovascular-related effects (e.g., arrhythmia, thrombosis) that can result in more severe outcomes possibly leading to death.

The 2009 PM ISA, as well as the current PM ISA, concluded there is a "*causal relationship*" between *long-term $PM_{2.5}$ exposure and cardiovascular effects* (Section 6.2). Epidemiologic studies of multiple recent U.S.-based cohorts along with reanalyses of these cohorts provide strong evidence of consistent, positive associations between long-term $PM_{2.5}$ exposure and cardiovascular mortality. These studies used a variety of exposure assessment and statistical techniques and examined various spatial domains (e.g., 1 × 1 km grid cells, census tract, etc.) in many locations where mean annual average $PM_{2.5}$ concentrations are ≤12 μg/m^3. Recent epidemiologic studies of cardiovascular morbidity have greatly expanded upon the body of evidence available at the completion of the 2009 PM ISA by focusing on populations with distinct demographic characteristics (e.g., post-menopausal woman, male doctors, etc.) and extensively considering potential confounders (e.g., socioeconomic status [SES]). While an extended analysis of the Women's Health Initiative (WHI) cohort strengthened the initial observation of a relationship between long-term $PM_{2.5}$ exposure and coronary events among post-menopausal women, additional cohorts of women similar to the WHI cohort did not report consistent, positive associations with coronary heart disease (CHD), myocardial infarction or stroke. Longitudinal studies examining the progression of atherosclerosis in relation to long-term exposure to $PM_{2.5}$ reported inconsistent results that were dependent upon the vascular bed examined, but there was evidence of $PM_{2.5}$-associated coronary artery calcification, a strong predictor of CHD, within a study focusing on the progression of atherosclerosis in a healthy population, i.e., Multi-Ethnic Study of Arthrosclerosis and Air Pollution (MESA—Air). A limited number of epidemiologic studies examining other cardiovascular effects,

provide some evidence of associations with HF, blood pressure, and hypertension as well as subclinical cardiovascular biomarkers. Recent studies also reduce the uncertainty associated with potential copollutant confounding by reporting that associations between long-term $PM_{2.5}$ exposure and cardiovascular mortality remained relatively unchanged or increased in copollutant models adjusted for O_3, NO_2, SO_2, and $PM_{10-2.5}$. Evidence from animal toxicological studies further supports a direct $PM_{2.5}$ effect on the cardiovascular system and provides coherence with effects observed in epidemiologic studies. For example, animal toxicological studies demonstrating atherosclerotic plaque progression in mice is coherent with epidemiologic studies of atherosclerosis, while animal toxicological studies reporting increased coronary artery wall thickness, decreased cardiac contractility and output, and changes in blood pressure are coherent with epidemiologic studies of HF. Furthermore, when considering the collective body of evidence there are biologically plausible pathways by which long-term exposure to $PM_{2.5}$ could lead to a continuum of effects potentially resulting in death.

Nervous System Effects

The 2009 PM ISA did not make a causality determination for long-term $PM_{2.5}$ exposure and nervous system effects due to the paucity of data available. Since the 2009 PM ISA, the literature base has greatly expanded and the combination of animal toxicological and epidemiologic evidence supports a "*likely to be causal relationship*" between *long-term $PM_{2.5}$ exposure and nervous system effects* (Section 8.2). Animal toxicological studies provide evidence for a range of nervous system effects including neuroinflammation and oxidative stress, neurodegeneration, cognitive effects, and effects on neurodevelopment. Epidemiologic studies, although fewer in number, generally support associations between long-term $PM_{2.5}$ exposure and changes in brain morphology, cognitive decrements, and dementia. Both experimental and epidemiologic evidence is well substantiated and coherent, supporting a pathway involving neuroinflammation in specific regions of the brain (i.e., the hippocampus, cerebral cortex and hypothalamus) and morphologic changes in the brain indicative of neurodegeneration. Overall, the lack of consideration of copollutant confounding introduces some uncertainty in the interpretation of the epidemiologic studies but this uncertainty is addressed, in part, by the direct evidence of effects provided by experimental animal studies. In addition to the nervous system effects primarily observed in adults, there is initial and limited epidemiologic evidence of neurodevelopmental effects, specifically autism spectrum disorder (ASD), which is supported by an animal toxicological study demonstrating $PM_{2.5}$-induced inflammatory and morphologic changes in regions of the brain consistent with ASD.

Cancer

The 2009 PM ISA concluded that evidence was "*suggestive of a causal relationship*"[30] between *long-term $PM_{2.5}$ exposure and cancer* (Section 10.2). Building upon the decades of research on whole PM

[30] Since the 2009 PM ISA, the causality determination language has been updated and this category is now stated as "suggestive of, but not sufficient, to infer a causal relationship".

exposures and evidence presented in the 2009 PM ISA, recent experimental and epidemiologic evidence indicating genotoxicity, epigenetic effects (i.e., hypo- and hyper-methylation of DNA), and increased carcinogenic potential due to $PM_{2.5}$ exposure, along with strong epidemiologic evidence for increases in lung cancer incidence and mortality supports a "*likely to be causal relationship*" between long-term $PM_{2.5}$ exposure and cancer. $PM_{2.5}$ exhibits various characteristics of carcinogens, as shown in studies demonstrating genotoxic effects (e.g., DNA damage), epigenetic alterations, oxidative stress, and electrophilicity. Studies of cancer development have often focused on whole PM exposures[31], not individual PM size fractions, or individual components often found to encompass $PM_{2.5}$ (e.g., hexavalent chromium, arsenic). Ames *Salmonella*/mammalian-microsome mutagenicity assays of $PM_{2.5}$ and $PM_{2.5}$ extracts demonstrate that PM contains mutagenic agents. In vitro and in vivo toxicological studies demonstrate the potential for $PM_{2.5}$ exposure to result in DNA damage, which is supported by limited human evidence. Cytogenic effects (e.g., chromosomal aberrations), and differential expression of genes potentially relevant to genotoxicity or cancer pathogenesis have also been demonstrated. There is also limited evidence for cellular and molecular changes that could lead to genomic instability as well as for the carcinogenic potential of $PM_{2.5}$, as demonstrated by enhanced tumor formation in animals treated with urethane. The experimental and epidemiologic evidence of genotoxicity, epigenetic effects, and carcinogenic potential provides biological plausibility for the results from multiple epidemiologic studies conducted in diverse cohorts in terms of geographic coverage and population demographics reporting primarily consistent, positive associations between long-term $PM_{2.5}$ exposure and lung cancer incidence and mortality, particularly in never smokers. In the limited assessment of potential copollutant confounding, $PM_{2.5}$-lung cancer incidence and mortality associations were found to be relatively unchanged in models with O_3.

Mortality

As in the 2009 PM ISA, the current ISA concludes there is a "*causal relationship*" between *short-term $PM_{2.5}$ exposure and total (nonaccidental) mortality* (Section 11.1). Recent multicity studies conducted in the U.S., Canada, Europe, and Asia in combination with the single- and multicity studies evaluated in the 2009 PM ISA continue to provide evidence of consistent, positive associations between short-term $PM_{2.5}$ exposure and total mortality. The positive associations reported across studies reflect both traditional analyses using ambient monitors as well as analyses conducted in both urban and rural locations that use new exposure assignment techniques and rely on multiple sources of $PM_{2.5}$ data (e.g., ambient monitors, statistical models, and satellite images). Recent studies also expand upon the assessment of potential copollutant confounding and indicate that $PM_{2.5}$-mortality associations are relatively unchanged in copollutant models with gaseous pollutants and $PM_{10–2.5}$. The positive associations reported for total mortality are supported by positive associations for cause-specific mortality (i.e., cardiovascular- and respiratory-related mortality). The consistent and coherent evidence across

[31] Whole PM exposures represent exposures that contain both PM and gaseous pollutants.

scientific disciplines for cardiovascular morbidity, particularly ischemic events and HF (CHAPTER 6), and to a lesser degree for respiratory morbidity, with the strongest evidence for exacerbations of COPD and asthma (CHAPTER 5), provide biological plausibility for cause-specific mortality and ultimately total mortality. Recent studies also further reduce chance, confounding, and other biases in the relationship between short-term $PM_{2.5}$ exposure and total mortality.

Both the 2009 PM ISA and the current ISA concludes there is a "*causal relationship*" between *long-term $PM_{2.5}$ exposure and total (nonaccidental) mortality* (Section 11.2). Additional reanalyses and extensions of the American Cancer Society and Harvard Six Cities cohorts as well as new cohorts consisting of Medicare participants, people that live in Canada, or people employed in a specific job (e.g., teacher, nurse, etc.) further support a positive association between long-term $PM_{2.5}$ exposure and total mortality, particularly in areas with annual mean concentrations <20 $\mu g/m^3$, and in some cases below 12 $\mu g/m^3$. Positive associations persist regardless of the exposure assignment approach used (i.e., ambient monitors or the combination of monitoring, modeling, and satellite data) and in copollutant models, particularly with O_3 and more limited evidence for NO_2 and $PM_{10-2.5}$. The evidence for total mortality is supported by positive associations for cause-specific mortality, including cardiovascular, respiratory, and lung cancer mortality. The coherence of effects across scientific disciplines for cardiovascular morbidity, particularly for CHD, stroke and atherosclerosis, and respiratory morbidity for the development of COPD, contribute to the biological plausibility for mortality due to long-term $PM_{2.5}$ exposure. Additionally, recent studies demonstrating increases in life expectancy due to decreases in long-term $PM_{2.5}$ concentrations further support a relationship between long-term $PM_{2.5}$ exposure and total mortality.

Health Effects of UFP Exposure

Since the completion of the 2009 PM ISA recent studies further explored the relationship between UFP exposure and health effects. The interpretation of epidemiologic study results is complicated by most studies relying on a single monitor to measure UFPs, which is inadequate as has been reflected in some monitoring campaigns that demonstrate a high degree of spatial variability in UFP concentrations and that the size distribution of UFPs changes with distance from source (Section 2.5). Additionally, experimental studies often include size ranges up to 200 nm or higher, which complicates the examination of coherence and biological plausibility of UFP-related health effects. These uncertainties in addition to the inconsistency across studies in the characterization of UFP with respect to size distribution and exposure metric contributed to causality determinations that did not exceed "*suggestive of, but not sufficient to infer, a causal relationship*" for most exposure and health effect category combinations.

Nervous System Effects

Due to the few studies that examined long-term UFP exposure and nervous system effects, the 2009 PM ISA did not make a causality determination; however, it was hypothesized that ambient UFPs may reach the brain via olfactory transport based on a few animal toxicological studies of

laboratory-generated UFPs. Since then, additional strong animal toxicological evidence of neurotoxicity and altered neurodevelopment, in combination with initial evidence suggesting potential translocation of UFPs into the brain via olfactory transport and from a single epidemiologic study indicating effects on attention and memory support a "*likely to be causal relationship*" between *long-term UFP exposure and nervous system effects* (Section 8.6). Animal toxicological studies provide consistent evidence of brain inflammation and oxidative stress in multiple regions of the brain, morphologic changes that are characteristic of neurodegeneration and Alzheimer's disease. Additionally, there is evidence of neurodevelopmental effects, including behavioral, neuroinflammatory, and morphological changes consistent with ASD. The animal toxicological study results are supported by an epidemiologic study reporting evidence of decrements on tests of attention and memory in children. However, epidemiologic studies of long-term UFP exposure are sparse due to difficulties in capturing the spatial variation in long-term UFP concentrations that can result in substantial exposure measurement error.

Policy-Relevant Considerations for Health Effects Associated with Particulate Matter Exposure

This section describes issues relevant for considering the potential significance of impacts of ambient PM, particularly $PM_{2.5}$, exposure on public health (Section 1.6)[32], including potential copollutant confounding of $PM_{2.5}$-health effects associations, the relationship between $PM_{2.5}$ exposure and the timing of health effects, the shape of the concentration-response (C-R) relationship, whether $PM_{2.5}$ components and sources are more closely associated with health effects than $PM_{2.5}$ mass, and the identification of populations and lifestages potentially at increased risk of a $PM_{2.5}$-related health effect.

Recent epidemiologic studies greatly expand upon the evidence informing whether associations observed between short- and long-term $PM_{2.5}$ exposure and health are confounded by other pollutants observed in the air pollution mixture. The examination of potential copollutant confounding in studies of respiratory and cardiovascular effects are primarily limited to studies of emergency department visits and hospital admissions. Across studies of short-term $PM_{2.5}$ exposure and respiratory and cardiovascular effects and mortality, correlations between $PM_{2.5}$ and gaseous (i.e., SO_2, NO_2, CO, and O_3) and particulate pollutants (i.e., $PM_{10-2.5}$) varied across studies, with low-to-moderate correlations (i.e., <0.7). Collectively, studies of short-term $PM_{2.5}$ exposure that examined potential copollutant confounding indicated that associations remained relatively unchanged in copollutant models, and in instances where associations were attenuated they remained positive. Far fewer studies examined potential copollutant confounding and long-term $PM_{2.5}$ exposure, but there has been an expansion of studies focusing on mortality. Studies focusing on respiratory (i.e., lung function and asthma development) and cardiovascular effects (i.e., cardiovascular mortality), along with lung cancer incidence and mortality, provide initial evidence that associations with $PM_{2.5}$ are relatively unchanged in copollutant models with primarily traffic-related pollutants (i.e., NO_2, NO_X, and CO) and O_3. For mortality, the most extensive

[32] Section 1.6 in Chapter 1 integrates the evidence across all health chapters, but each health chapter has individual discussions on the topics discussed within this section.

analyses occurred for O_3, with more limited assessments of other pollutants, but overall associations were reported to remain unchanged in copollutant models for total (nonaccidental) mortality, cardiovascular, and respiratory mortality.

An important question that informs different aspects of the PM NAAQS is the timing of observed effects due to short-term $PM_{2.5}$ exposure, specifically the averaging time of the exposure metric in epidemiologic studies and the lag days over which health effects are observed. Some recent epidemiologic studies focusing on respiratory- and cardiovascular-related emergency department visits and hospital admissions, cardiovascular effects (e.g., ST-elevation, myocardial infarction, and out-of-hospital cardiac arrest), and mortality examined associations between subdaily exposure metrics and the widely used 24-hour average exposure metric. Across the studies evaluated, the available evidence does not indicate that sub-daily averaging periods for $PM_{2.5}$ are more closely associated with health effects than the 24-hour average exposure metric. In addition to examining potential differences in associations by averaging time of the exposure metric, recent epidemiologic studies expanded the assessment of examining the timing of effects by systematically examining lag days by focusing on whether there is evidence of an immediate (e.g., lag 0−1 days), delayed (e.g., lag 2−5 days), or prolonged (e.g., lag 0−5 days) effect of PM on health. Epidemiologic studies examining potential differences in associations in relation to short-term $PM_{2.5}$ exposure focused on respiratory- and cardiovascular-related emergency department visits and hospital admissions as well as mortality. While recent studies provided evidence of associations in the range of 0−5 days for respiratory effects, there was evidence of an immediate effect for cardiovascular effects and mortality (i.e., 0−1 days) with some initial evidence of associations occurring over longer exposure durations (e.g., 0−4 days).

An examination of the C-R relationship between short- and long-term $PM_{2.5}$ exposure and health effects can inform both the shape of the C-R curve and whether there is a threshold (i.e., concentration level) below which there is no evidence of an effect of $PM_{2.5}$ on health. Studies of short-term $PM_{2.5}$ exposure and health are limited to studies of respiratory-related emergency department visits and hospital admissions, and mortality. Epidemiologic studies of respiratory disease and asthma emergency department visits and hospital admissions focusing on the shape of the C-R curve provide initial evidence of a linear relationship with less certainty at concentrations below 10 $\mu g/m^3$. However, studies focusing on whether the $PM_{2.5}$ association changes at different concentration ranges (i.e., cut-point analyses) provide some evidence of potential nonlinearities in the C-R relationship. Epidemiologic studies of mortality greatly expand upon the evidence evaluated in the 2009 PM ISA where C-R analyses were limited to studies of PM_{10}. Evidence from U.S. studies examining short-term $PM_{2.5}$ exposure and mortality indicate a linear relationship at concentrations as low as 5 $\mu g/m^3$ with cut-point analyses providing no evidence of a threshold. For long-term $PM_{2.5}$ exposure, most of evidence on the shape of the C-R curve and whether a threshold exits comes from studies of mortality with some initial recent evidence from studies of respiratory and cardiovascular effects, as well as lung cancer mortality and incidence. Epidemiologic studies of long-term $PM_{2.5}$ exposure and mortality used a variety of statistical approaches and cut-point analyses, which support a linear, no-threshold relationship for total

(nonaccidental) mortality, especially at lower ambient $PM_{2.5}$ concentrations, with confidence in some studies in the range of 5−8 μg/m^3. Additionally, there is initial evidence indicating that the slope of the C-R curve may be steeper (supralinear) at lower concentrations for cardiovascular mortality. Evaluation of the C-R relationship is more limited for respiratory and cardiovascular effects, but overall initial assessments support a linear relationship specifically at long-term $PM_{2.5}$ concentrations ranging from 10 to 12 μg/m^3 and 5−10 μg/m^3, respectively.

Recent epidemiologic and experimental studies extensively build upon those studies evaluated in the 2009 PM ISA that examined relationships between exposure to $PM_{2.5}$ components and sources and health effects. As detailed in the Preface , this ISA focuses on specific study criteria to thoroughly evaluate whether there is evidence that an individual component(s) and/or source(s) is more closely related to health effects than PM mass. Across the health effects categories evaluated in this ISA, most studies that examine PM sources and components focused on $PM_{2.5}$. In studies examining both short- and long-term exposure a variety of health effects were examined ranging from subclinical (e.g., changes in lung function, respiratory symptoms) to more overt e.g., emergency department visits, hospital admissions, and mortality). Across exposure durations and health effects categories it was concluded that many $PM_{2.5}$ components and sources are associated with many health effects, and the evidence does not indicate that any one source or component is consistently more strongly related with health effects than $PM_{2.5}$ mass.

Lastly, an important consideration in evaluating whether the NAAQS provides public health protection with an adequate margin of safety is assessing whether there are specific populations or lifestages at increased risk of a PM-related health effect. While the ISA provides substantial evidence of health effects due to short- and long-term exposure to $PM_{2.5}$ across populations with diverse characteristics (e.g., children, older adults, people with pre-existing cardiovascular diseases, etc.), an evaluation of whether any of these populations are at increased risk of a PM-related health effect relies on evidence from specific types of studies that can directly inform this question as detailed in Section 1.6 and CHAPTER 12. Based on the framework for characterizing the evidence for populations potentially at increased risk of an air pollutant-related health effect detailed in the 2013 O_3 ISA (U.S. EPA, 2013), this ISA concludes there is adequate evidence that children are at increased risk of a $PM_{2.5}$-related health effect based off strong evidence of impaired lung function growth and additional evidence of decrements in lung function and asthma development. Additionally, there is adequate evidence that nonwhite people are at increased of $PM_{2.5}$-related health effects based on studies of long-term $PM_{2.5}$ exposure and mortality and studies demonstrating differential exposure by race. There was also suggestive evidence that populations with pre-existing cardiovascular and respiratory disease, that are overweight or obese, with genetic variants in genes in the glutathione pathway and oxidant metabolism, or that are of low SES are at increased risk for $PM_{2.5}$-related health effects.

PM Exposure and Welfare Effects

Compared to the evaluation of the health effects evidence, the evaluation of the welfare effects evidence focuses broadly on PM and not individual size fractions or exposure durations. Additionally, the evaluation, as noted previously, focuses on the welfare effects of visibility impairment, climate effects, and effects on materials due to the ecological effects of PM being evaluated in the ISA for Oxides of Nitrogen, Oxides of Sulfur and Particulate Matter–Ecological Criteria (U.S. EPA, 2018).

Table ES-2 Summary of causality determinations for relationships between PM exposure and welfare effects from the 2009 and current draft PM ISA.

Welfare Effect Category	Causality Determination	
	2009 PM ISA	Current Draft PM ISA
Visibility Impairment Section 5.1.12, Table 5-18	Causal relationship	Causal relationship
Climate Effects Section 5.2.13, Table 5-28	Causal relationship	Causal relationship
Effects on Materials Section 6.1.16, Table 6-33	Causal relationship	Causal relationship

ISA = Integrated Science Assessment; PM = particulate matter.
Previous causality determinations taken from the 2009 PM ISA (U.S. EPA, 2009).

As noted in Table ES-2, this ISA concludes a "causal relationship" between PM visibility impairment, climate effects, and effects on materials which is consistent with the 2009 PM ISA. For visibility impairment (Section 13.2), the relationship between PM and light extinction has been well characterized. The rapid decline in $PM_{2.5}$ sulfate that has occurrent from 2002−2012 (i.e., −4.6% per year in rural areas and −6.2% per year in urban areas) has contributed to improvements in visibility in many areas, but an increasing amount of light extinction is now due to nitrate and organic matter. There have been no recent visibility preference studies; however, a recent meta-analysis demonstrates that scene-dependent haze metrics better account for preference compared to only using the deciview scale as a metric. For climate (Section 13.3), there is substantial evidence indicating that PM affects the radiative forcing of the climate system, both through direct scattering and absorption of radiation, and indirectly, by altering cloud properties. However, it is important to note there are still substantial uncertainties with respect to key processes linking PM and climate, specifically clouds and aerosols because of the scale between PM-relevant cloud processes and the resolution of state-of-the-art models and the indirect impacts and feedbacks in the climate system due to an initial radiative effect due to PM. Lastly, for effects on materials (Section 13.4), most of the evidence has often focused on examining PM impacts on stone

used for historic monuments and buildings. Recent evidence further expands the understanding of soiling and corrosion process for glass and metals, and demonstrates that atmospheric soiling can impact energy efficiency of photovoltaic systems and some buildings.

Scientific Considerations and Key Findings of the Health and Welfare Effects Evidence

As summarized in the Preface (Section P.3), the Preamble to the ISAs (U.S. EPA, 2015) describes the process by which the U.S. EPA evaluates the strengths and limitations in the scientific evidence using a weight-of-evidence framework to form causality determinations within the ISAs. There are five different causality determinations, which may be used to characterize evidence with each determination delineated by the degree to which chance, confounding, and other biases affect interpretation of the scientific evidence (Table P-2). As documented by the extensive evaluation of evidence throughout the subsequent chapters of this ISA, the U.S. EPA carefully considers uncertainties in the evidence, and the extent to which recent studies have addressed or reduced uncertainties from previous assessments, as well as the strengths of the evidence. Uncertainties considered in the epidemiologic evidence, for example, include the potential for confounding by copollutants or covarying factors and exposure error. The U.S. EPA evaluates many other important considerations (not uncertainties) such as coherence of evidence from animal and human studies, evaluation of different PM components, heterogeneity of risk estimates, and the shape of concentration-response relationships. All aspects are evaluated in drawing scientific conclusions and making causality determinations, and where there is clear evidence linking PM with effects with minimal remaining uncertainties, the U.S. EPA makes a determination of a *causal* or *likely to be causal* relationship.

Key findings of the health effects evidence spanning each of the PM size fractions and welfare effects evaluated in this ISA are summarized below and in Chapter 1 (Section 1.7). These highlights encapsulate the evidence that informed consideration of strengths and limitations and development of causality determinations. For the health (i.e., respiratory and cardiovascular effects, and mortality due to short- and long-term $PM_{2.5}$ exposure) or welfare effects categories for which *causal* or *likely to be causal* determinations were made, recent findings were found to reduce or fully address previous uncertainties in the evidence and increase the strength of U.S. EPA's scientific conclusions. For other PM-effect relationships, the key findings highlighted below indicate where there is strength in the evidence, but uncertainties remain, resulting in causality determinations of *suggestive of, but not sufficient to infer, a causal relationship* or in some cases *inadequate to infer the presence or absence of a causal relationship,* both of which reflect there is limited evidence to evaluate both strengths and weaknesses.

Health Effects Evidence: Key Findings

A large body of scientific evidence spanning many decades clearly demonstrates there are health effects attributed to both short- and long-term PM exposure, with the strongest evidence for a relationship between some health effects and $PM_{2.5}$. Generally, for most health effects and exposures to $PM_{10-2.5}$ and UFPs, there are more limitations and uncertainties across scientific disciplines (i.e., atmospheric chemistry, exposure science, and both epidemiology and experimental sciences), complicating the interpretation of the evidence. The collective body of evidence for each of the PM size fraction, exposure, and health outcome category combinations evaluated in this ISA was carefully considered and assessed, including the inherent strengths, limitations, and uncertainties in the overall body of evidence such as the available methods, models and data used within and across studies. This full assessment of the current state of the science for $PM_{2.5}$, $PM_{10-2.5}$, and UFPs resulted in the causality determinations detailed in Table 1-4. Through identification of the strengths and limitations in the evidence this ISA may help in the prioritization of research efforts to support future PM NAAQS reviews. Examples of the key findings in the health effects evidence considered in this PM ISA include:

$PM_{2.5}$

- There are many recent epidemiologic studies conducted in diverse geographic locations, encompassing different population demographics, and using a variety of exposure assignment techniques, that continue to report consistent positive associations between short- and long-term $PM_{2.5}$ exposure and respiratory and cardiovascular effects and mortality. This evidence continues to support the large body of previously published epidemiologic studies reporting positive $PM_{2.5}$ associations with respiratory and cardiovascular effects and mortality and in some cases strengthens and extends the evidence base for other health effects.
- New $PM_{2.5}$ exposure assignment methods that utilize several sources of available data (i.e., satellite observations, model predictions, and ambient monitors) in epidemiologic studies better allow for the inclusion of less urban areas. These methods are well validated by $PM_{2.5}$ monitors in areas with moderate-to-high population density. Although fewer monitors are available for model validation in sparsely populated rural areas compared with urban areas, $PM_{2.5}$ concentrations are typically lower and more spatially homogeneous in rural areas, resulting in the need for fewer validation sites.
- The large number of animal toxicological and controlled human exposure studies provide coherence and biological plausibility for effects observed, particularly respiratory, cardiovascular, and mortality in epidemiologic studies of short- and long-term $PM_{2.5}$ exposure.
- Both animal toxicological and controlled human exposure studies, using concentrated ambient particle (CAP) exposures, provide evidence of a direct effect of PM exposure on various health effects.
- Epidemiologic studies that conducted copollutant analyses show that associations remain relatively unchanged when adjusting for gaseous pollutants and other particle size fractions (e.g., $PM_{10-2.5}$), addressing a key uncertainty identified in the 2009 PM ISA.
- Recent epidemiologic studies indicate that the observed heterogeneity in risk estimates is not attributed solely to differences in the composition of $PM_{2.5}$, but also reflects city-specific exposure conditions (e.g., housing and commuting characteristics).

- Evidence continues to support a linear, no-threshold concentration—response relationship, but with less certainty in the shape of the curve at lower concentrations (i.e., below about 8 $\mu g/m^3$).
- For health effects where it was concluded that the evidence is suggestive of, but not sufficient to infer, a causal relationship (including short- and long-term $PM_{2.5}$ exposure and metabolic effects, male and female reproduction and fertility, pregnancy and birth outcomes, and short-term exposures and nervous system effects) epidemiologic and experimental studies report inconsistent evidence of an association/effect or there are relatively few studies focusing on the health effect of interest.

$PM_{10–2.5}$

- Routine national monitoring of $PM_{10-2.5}$ was initiated in 2011. $PM_{10-2.5}$ concentrations are more spatially and temporally variable than $PM_{2.5}$. Although some $PM_{10–2.5}$ data are available across the nation, micro-to-neighborhood scale data are not widely available, adding uncertainty to the interpretation of results from epidemiologic studies, especially for long-term exposure studies that rely on spatial contrasts to examine associations with health effects.
- Epidemiologic studies that examined associations between short- and long-term $PM_{10–2.5}$ exposure and various health effects use multiple methods to estimate concentrations, complicating the comparison of results across studies.
- Depending on the health effect, few or no experimental studies examined the relationship between short- and long-term exposure to $PM_{10–2.5}$ and health effects. The few studies conducted provide inconsistent evidence of effects due to $PM_{10–2.5}$ exposures contributing to limited coherence and biological plausibility.
- The causality determinations for all health outcome categories for short- and long-term $PM_{10-2.5}$ exposure were either *suggestive of, but not sufficient to infer, a causal relationship* or *inadequate to infer the presence or absence of a causal relationship*, indicating limitations and uncertainties in the evidence base.

UFPs

- There is no national ambient monitoring network in place to measure UFP concentrations, thus there is limited information on UFP exposures within the U.S.
- There are a limited number of epidemiologic studies that examined short- or long-term UFP exposure and various health effects.
- It is difficult to assess the results across epidemiologic studies due to the different size ranges of UFPs examined, the exposure metrics used, and spatial and temporal variability of UFP concentrations.
- There is strong and consistent animal toxicological evidence linking long-term UFP exposure to nervous system effects, which directly informed the *likely to be causal relationship* conclusion. This evidence is in contrast to the limited evidence base for other health effects.
- For all other health effect categories, animal toxicological studies and controlled human exposure studies provide limited, and in some instances inconsistent, evidence of effects due to short- or long-term UFP exposure contributing to limited coherence and biological plausibility.
- There is evidence of translocation of UFPs to the brain via the olfactory nerve, but it is unclear whether this translocation occurs in humans as well as in animals. There is also uncertainty surrounding the mechanisms and degree to which particles translocate from the respiratory tract

to the brain, however, translocation of particles to the brain may not be required for UFP-related nervous system effects.

- For health effects where it was concluded that the evidence is *inadequate to infer the presence or absence of a causal relationship*, few or no epidemiologic and experimental studies examined the relationship between short- or long-term UFP exposures.

Welfare Effects Evidence: Key Findings

A large body of scientific evidence spanning many decades also demonstrates there are welfare effects attributed to PM. This collective body of evidence contributed to the causality determinations detailed in CHAPTER 13 of this ISA for each of the nonecological welfare effects evaluated (see Table 1-4). Examples of the key findings in the welfare effects evidence considered in this PM ISA include:

- Recent studies further confirm evidence from previous assessments supporting the strong relationship between PM and the nonecological welfare effects of visibility impairment, effects on the climate, and materials damage.
- For visibility impairment and materials damage there is extensive evidence demonstrating the relationship between PM and light extinction and PM impacts on stone, respectively.
- While there is substantial evidence indicating that PM affects the climate system, specifically through radiative forcing, there are still substantial uncertainties in key processes, such as the relationship between clouds and aerosols and the indirect impacts and feedbacks in the climate system due to the radiative effect of PM.

CHAPTER 1 INTEGRATED SYNTHESIS

Overall Conclusions of the Particulate Matter (PM) Integrated Science Assessment (ISA)

- Recent evidence spanning the scientific disciplines (i.e., atmospheric chemistry, exposure science, dosimetry, epidemiology, controlled human exposure, and animal toxicology) builds upon evidence detailed in the 2009 PM ISA and reaffirms that for short- and long-term $PM_{2.5}$ exposure there is a "*causal relationship*" for cardiovascular effects and total (nonaccidental) mortality and a "*likely to be causal relationship*" for respiratory effects.
- Recent experimental and epidemiologic evidence supports a "*likely to be causal relationship*" for long-term $PM_{2.5}$ exposure and nervous system effects.
- Recent evidence, primarily from studies of lung cancer incidence and mortality, in combination with the decades of research on the mutagenicity and carcinogenicity of PM supports a "*likely to be causal relationship*" between long-term $PM_{2.5}$ exposure and cancer.
- Recent evidence from primarily animal toxicological studies supports a "*likely to be causal relationship*" for long-term ultrafine particle (UFP) exposure and nervous system effects.
- Remaining uncertainties and limitations in the scientific evidence contribute to a "*suggestive of, but not sufficient to infer,* a *causal relationship*" and "*inadequate to infer the presence or absence of a causal relationship*" for all other exposure, size fraction, and health effects combinations.
- Recent evidence builds upon and reaffirms that there is a "*causal relationship*" between PM and the nonecological welfare effects: visibility impairment, climate effects, and materials effects.
- The assessment of PM sources and components confirms and continues to support the conclusion from the 2009 PM ISA: *Many $PM_{2.5}$ components and sources are associated with many health effects, and the evidence does not indicate that any one source or component is more strongly related with health effects than $PM_{2.5}$ mass*.
- Many populations (e.g., healthy, diseased, etc.) and lifestages (e.g., children, older adults, etc.) have been shown to be at-risk of a health effect in response to short- or long-term PM exposure, particularly $PM_{2.5}$. However, of the populations and lifestages examined, current scientific evidence indicates that only some populations may be at ***disproportionately increased risk*** of a $PM_{2.5}$-related health effect, including nonwhite populations, children, people with specific genetic variants in genes in the glutathione pathway, people who are overweight or obese, people with pre-existing cardiovascular and respiratory diseases, and people of low socioeconomic status (SES).

1.1 Introduction

1.1.1 Purpose

The subsequent chapters of this ISA provide a detailed evaluation and characterization of the current state of the science with respect to the health and nonecological welfare effects[33] due to exposure to particulate matter (PM). The overall scope of the ISA, which governs the types of studies considered in the evaluation of the scientific evidence, is detailed in the Preface . Aspects specific to evaluating studies of PM that form the basis of the causality determinations detailed within this ISA are described in the Appendix. The main chapters of the ISA provide both the scientific basis for causality determinations[34] and policy-relevant scientific information that supports the review of the National Ambient Air Quality Standards (NAAQS) for PM. The purpose of this CHAPTER 1 is not to summarize each of the chapters, but to synthesize the key findings on each topic considered in characterizing PM exposure and relationships with health and welfare effects. This ISA draws forward and integrates evidence evaluated in prior assessments including the 2009 PM ISA (U.S. EPA, 2009) and earlier assessments e.g., 2004 PM Air Quality Criteria Document (AQCD) (U.S. EPA, 2004) and 1996 PM AQCD (U.S. EPA, 1996).

1.1.2 Organization of the ISA

The ISA consists of the Preface (legislative requirements and history of the primary and secondary PM NAAQS; and purpose and overview of the ISA along with the overall scope, and process for evaluating evidence), Executive Summary, and thirteen chapters. CHAPTER 1 synthesizes the scientific evidence that best informs the policy-relevant questions detailed within the *Integrated Review Plan for the Primary National Ambient Air Quality Standards for Particulate Matter* (PM IRP; (U.S. EPA, 2016)) that frame this review of the primary (health-based) and secondary (welfare-based) PM NAAQS. CHAPTER 2 characterizes the sources, atmospheric processes related to PM formation, and trends in ambient PM concentrations, for specifically $PM_{2.5}$ (fine PM; PM with a nominal mean aerodynamic diameter less than or equal to 2.5 μm), $PM_{10–2.5}$ (thoracic coarse or coarse PM; PM with a nominal mean aerodynamic diameter greater than 2.5 μm and less than or equal to 10 μm), and ultrafine particles [UFPs, generally considered as particulates with a diameter less than or equal to 0.1 μm (typically based on physical size, thermal diffusivity or electrical mobility)]. CHAPTER 3 describes methods to estimate human exposure to PM and the impact of exposure measurement error on

[33] Hereafter welfare effects refers to nonecological welfare effects, unless otherwise noted. The ecological effects resulting from the deposition of PM and PM components are being considered in a separate assessment as part of the review of the secondary (welfare-based) NAAQS for oxides of nitrogen, oxides of sulfur, and PM (U.S. EPA, 2018)
[34] The general process for developing an ISA, including the framework for evaluating weight of evidence and drawing scientific conclusions and causal judgments, is described in a companion document, Preamble to the Integrated Science Assessments (U.S. EPA, 2015).

associations with health effects. CHAPTER 4 describes the dosimetry of the various size fractions of PM. CHAPTER 5, CHAPTER 6, CHAPTER 7, CHAPTER 8, CHAPTER 9, CHAPTER 10, and CHAPTER 11 evaluate and integrate epidemiologic, controlled human exposure, and animal toxicological evidence and characterize the biological plausibility for health effects related to short-term and long-term exposure to $PM_{2.5}$, $PM_{10–2.5}$, and UFPs for respiratory effects, cardiovascular effects, metabolic effects, nervous system effects, reproductive and developmental effects, cancer, and mortality, respectively. CHAPTER 12 evaluates the scientific evidence on populations and lifestages potentially at increased risk of a PM-related health effect. Lastly, CHAPTER 13 evaluates the scientific evidence for welfare effects, focusing specifically on the nonecological welfare effects of visibility impairment, climate effects, and effects on materials.

A key consideration in the health effects assessment is the extent to which evidence indicates that $PM_{2.5}$, $PM_{10–2.5}$, and UFPs exposures independently cause health effects. To that end, this chapter draws upon information about the sources, atmospheric chemistry, distribution, background sources of ambient PM, as well as exposure to ambient PM of different size fractions and identifies pollutants and other factors related to the distribution of or exposure to ambient PM that can potentially influence epidemiologic associations observed between health effects and $PM_{2.5}$, $PM_{10–2.5}$, and UFP exposures (Section 1.2). The chapter also summarizes information on the dosimetry of inhaled PM of different size fractions (Section 1.3). The discussions of the health effects evidence and causality determinations (Section 1.4) details the extent to which there is biological plausibility for the various PM exposure duration-health effects relationships evaluated, and provides an integrated summary of the epidemiologic and experimental (i.e., animal toxicological and controlled human exposure) evidence and whether it collectively supports independent relationships between $PM_{2.5}$, $PM_{10–2.5}$, or UFPs exposure and health effects.[35] This chapter also integrates evidence across the ISA for specific policy-relevant issues that are informative in the PM NAAQS review (Section 1.5), specifically: potential copollutant confounding (Section 1.5.1); the timing of effects, which includes the lag structure of associations and averaging time for exposure metrics (Section 1.5.2); the shape of the concentration-response relationship and whether a threshold exits (Section 1.5.3); and whether individual PM components or exposure metrics representative of PM sources are a better indicator for the PM-health effects relationship than PM mass (Section 1.5.4). Additionally, within the policy-relevant considerations discussion, this chapter summarizes the evidence as to whether specific populations or lifestages are at increased risk of a PM-related health effect, which is an important consideration in the context of the NAAQS and ensuring public health is protected with an adequate margin of safety (Section 1.5.5). This chapter also characterizes the welfare effects evidence and the role of PM, specifically non-ecological effects on visibility, climate, and materials (Section 1.6). Lastly, Section 1.7, summarizes the causality determinations for all PM size fraction, exposure duration, and health and welfare effects combinations evaluated within this ISA.

[35] When discussing epidemiologic evidence, as detailed in the Preface, risk estimates are for a 10 $\mu g/m^3$ increase in 24-hour average $PM_{2.5}$ and $PM_{10–2.5}$ concentrations and a 5 $\mu g/m^3$ increase in annual $PM_{2.5}$ and $PM_{10–2.5}$ concentrations.

1.2 From Emissions Sources to Exposure to Particulate Matter

The characterization of human exposure is key to understanding the relationships between ambient PM (i.e., $PM_{2.5}$, $PM_{10–2.5}$, and UFP) and health effects. Exposure to PM is influenced by a variety of factors including, but not limited to, time-activity patterns, building characteristics, and amount of PM in the ambient air. The latter is influenced by sources and atmospheric processes contributing to ambient PM concentrations that together can influence the spatial and temporal patterns of PM. These patterns have implications for variation in exposure in the population, the adequacy of methods used to estimate exposure, and in turn, the strength of inferences that can be drawn about the health and welfare effects related to PM exposure.

1.2.1 Emission Sources and Distribution of Ambient Concentrations

PM is well defined as a complex mixture of solid and liquid droplets that is often characterized by distinct size fractions, i.e., $PM_{2.5}$, $PM_{10–2.5}$, and UFPs. The characteristics of each PM size fraction can vary in terms of: sources and emissions, atmospheric processes that result in PM formation, variability in concentrations over time and space, and monitoring.

Observations and new developments in the characterization of ambient PM build on the conclusions reported in the 2009 PM ISA, as summarized in CHAPTER 2. In the 2009 PM ISA, a decreasing trend in $PM_{2.5}$ concentrations were reported between 1999−2007, and a decreasing trend in PM_{10} concentrations between 1988−2007. In addition, for the years 2005−2007, there was considerable variability in daily average concentrations of $PM_{2.5}$. PM size was also observed to vary with location, with a generally larger fraction of PM_{10} mass accounted for by $PM_{10–2.5}$ size in western cities (e.g., Phoenix and Denver) and by $PM_{2.5}$ mass in eastern U.S. cities (e.g., Pittsburgh and Philadelphia). Compared to the larger PM size fractions, there was more limited information on the regional and temporal variability of UFPs. The composition of $PM_{2.5}$ nationally was also observed to vary, with higher sulfate concentrations in the summer and in the eastern U.S., and higher particulate organic carbon (OC) concentrations in the western and southeastern U.S. Little information was available on $PM_{10–2.5}$ or UFP composition. In urban areas, $PM_{2.5}$, PM_{10}, and UFPs were all observed to peak during morning rush hour and exhibited an evening rush hour peak that was broader than the morning peak and extended into the overnight period, reflecting the collapse of the mixing layer after sundown. In terms of measuring PM, notable advances had taken place in real-time PM mass measurement methods, single particle aerosol mass spectrometry methods, organic speciation methods, and dichotomous samplers for distinguishing $PM_{2.5}$ and $PM_{10–2.5}$. Major PM sources identified included combustion of fossil fuel, either by stationary sources or by transportation for primary PM, and formation of sulfates from SO_2 emitted mainly by electric power generating units (EGUs). Progress was also noted in understanding the chemistry of new particle formation and of secondary organic aerosol (SOA) formation. Background PM typically accounts for a

small fraction of urban $PM_{2.5}$ or PM_{10}, but high PM concentrations can occur during episodic events like wildfires or dust storms.

Changes in ambient PM characteristics as well as new research developments have occurred since the 2009 PM ISA. Ambient annual average $PM_{2.5}$ concentrations in the U.S. on average were 3.4 $\mu g/m^3$ lower in the period from 2013−2015 than in the period from 2005−2007 decreased from a 3-year average of 12 $\mu g/m^3$ for 2013−2015 to 8.6 $\mu g/m^3$ for 2005−2007, continuing the downward trend in national ambient $PM_{2.5}$ concentrations. However, while $PM_{2.5}$ concentrations were observed to decline, national average $PM_{10-2.5}$ concentrations were similar in both time periods. While monthly national average $PM_{2.5}$ concentrations were higher in summer than in winter from 2002−2008, this pattern is reversed from 2012−2015, when monthly average $PM_{2.5}$ concentrations became higher in winter than in summer. A greater reduction in sulfate concentrations than other component concentrations resulted in smaller sulfate contributions to $PM_{2.5}$ mass in 2013−2015 compared to 2005−2007, especially in the Eastern U.S. At many locations sulfate has been replaced by organic material as the greatest contributor to $PM_{2.5}$ mass. Much of the organic material is SOA, and there has been continued progress in understanding SOA precursors, formation processes, and components. The declines in $PM_{2.5}$ and sulfate concentrations are consistent with a large reduction in SO_2 emissions, mainly from decreased EGU coal combustion. Monitoring network changes have provided a more extensive set of observations for understanding the contributions of $PM_{2.5}$ and $PM_{10-2.5}$ to PM_{10}. The decrease in $PM_{2.5}$ concentrations has resulted in smaller $PM_{2.5}/PM_{10}$ ratios in many locations. PM_{10} in the East and Northwest is in the range of 50−60% $PM_{2.5}$, while PM_{10} in the Western U.S. is generally less than 50% $PM_{2.5}$. Routine measurement of UFPs is in its beginning stages, with only a few monitors beginning to report data.

1.2.1.1 Sources and Emissions of PM

PM is comprised of components that are directly emitted (primary particles) as well as formed through atmospheric chemical reactions involving gaseous precursors (secondary particles). The sources of PM vary with PM size fraction.

$PM_{2.5}$ can be generated from both natural and anthropogenic sources., The greatest contributors to primary $PM_{2.5}$ at the national level are agricultural dust, dust resuspended through on-road activities, and fires (i.e., wildfires, prescribed fires, and agricultural fires; see Section 2.3.1.1: and Figure 2-2). On a national scale, anthropogenic emissions have been estimated to account for 40% of total primary $PM_{2.5}$ emissions and 16% of total PM_{10} emissions (U.S. EPA, 2017). However, this does not account for secondary PM, most of which is derived from anthropogenic precursors. On an urban scale, sources that emit $PM_{2.5}$ vary from city-to-city. Generally, anthropogenic sources account for nearly all urban primary $PM_{2.5}$ emissions, and they include some combination of industrial activities, motor vehicles, cooking, and fuel combustion, and often wood smoke as well as construction and road dust. (Section 2.3.1.2). These

urban anthropogenic primary sources and more regional secondary generation both contribute substantially to $PM_{2.5}$ mass in urban locations.

Source contributions to primary $PM_{2.5}$ emissions have changed over time. For example, changes in both gasoline and diesel emissions controls have led to reductions in primary $PM_{2.5}$ emitted from newer vehicles, and primary emissions from stationary fuel combustion, industrial activities, and nonroad vehicles have also decreased (Section 2.3.1.2). Natural and international sources are generally minor contributors to $PM_{2.5}$ in urban areas. In many locations secondary PM accounts for the majority of $PM_{2.5}$ mass. The major PM precursors that can ultimately contribute to $PM_{2.5}$ mass include sulfur dioxide (SO_2), oxides of nitrogen (NO_X), ammonia (NH_3), and volatile organic compounds (VOCs) (Section 2.3.2.1). SO_2 emissions are mainly from electricity generating units (EGUs, 67%) while NO_X is emitted by several combustion sources, including on-road vehicles (34%), off-road vehicles (21%), and EGUs (13%). NH_3 emissions are dominated by livestock waste (55%) and fertilizer application (26%), and VOCs, on a national scale, mainly biogenic in origin (70%) (Section 2.3.2.1). Emissions of some $PM_{2.5}$ precursors, and subsequently their overall contribution to $PM_{2.5}$ mass, have changed over time (Section 2.3.2.1). Since the 2009 PM ISA, SO_2 emissions have been reduced from 13.9 million metric tons (MMT) in 2006 to 4.8 MMT in 2014, representing a 65% reduction and the greatest reduction among all precursor emissions (Section 2.3.2.1). NO_X emissions were also substantially reduced during the same time, decreasing from 19.4 MMT in 2006 to 13.5 MMT in 2014, representing an overall reduction of 30%. NH_3 emissions, however, have remained relatively constant over time, with estimates of 3.8 MMT in 2006 and 3.9 MMT in 2014 (Section 2.3.2.1).

While $PM_{2.5}$ is comprised of both primary PM, generated mostly from combustion-related activities, and secondary PM from atmospheric chemical reactions of precursor emissions, $PM_{10–2.5}$ is almost entirely primary in origin. $PM_{10–2.5}$ is produced by surface abrasion or by suspension of sea spray or biological material (e.g., microorganisms, pollen, plant and insect debris) (Section 2.3.3). Major sources on a national scale are unpaved road dust and agricultural dust, and in urban areas paved road dust and construction dust are usually major sources. Dust events can also result from international transport, and some of the dust particles in these events fall into the $PM_{10–2.5}$ size range. Primary biological aerosol particles can also be an important contributor to $PM_{10–2.5}$, including fungal spores, bacteria, viruses, and plant debris.

Ambient UFPs originate from two distinct processes, primary particles directly emitted from specific sources and new particle formation (NPF), which occurs because of particular atmospheric conditions that allow for particle nucleation (Section 2.3.4). UFP and $PM_{2.5}$ primary sources are largely indistinguishable because UFP is usually emitted by the same sources as $PM_{2.5}$, and grow out of the ultrafine size range through coagulation or gas-to-particle condensation over a short duration to form particles within the $PM_{2.5}$ size range. (Section 2.3.4.1). However, differences in the impact of various sources while particles are still mostly in the UFP size range can lead to differences in sources of greatest concern in both size ranges. For example, freshly emitted motor vehicle exhaust often occurs on busy

urban streets in residential neighborhoods, while emissions from electric power generation occur further away from human activity, and particles are likely to grow out of the UFP size range to a greater extent before reaching populated areas. It typically takes between about half a day and three days before newly-formed particles grow larger than 100 nm in diameter. As a result, although UFP size increases from 10 nm to 25 nm within 100 m, vehicle-related PM components are still mainly in the UFP size range as far as 1 km from a major highway.

Although relatively limited information is available on a source-by-source basis to capture changes in UFP emissions over time, analyses of individual sources where new source requirements have been instituted allow for an assessment of source contributions to UFP emissions. Most new research on UFP emissions has been focused on automobile exhaust, in part because of some of the highest observed UFP concentrations have been observed in near-road environments. For example, new requirements on heavy-duty diesel highway engines that were phased in from 2007−2010 and focused on reducing PM and NO_X emissions have led to reductions in UFP number concentration (NC) of more than 90% compared to earlier diesel engine models (Section 2.3.4.1). Although these newer diesel highway engines generate, on average, a smaller amount of UFP emissions compared to earlier models, there can still be discrete periods of extremely high UFP formation. This is due to thermal desorption of adsorbed sulfates that build up within the exhaust catalyst system and then can be released in a single burst (Section 2.3.4.1). Motor vehicles are a leading source of UFP emissions especially near roadways and recently similar observations of high UFP levels downwind of airports have also been reported. However, stationary point sources are also important, particularly at further distances from roadways. Gasoline and diesel-powered highway vehicles, nonroad diesel engines, and industrial sources are likely the largest sources of UFP in populated areas, where relative contributions of mobile and stationary sources of UFP are likely to vary considerably depending on location, season, and time of day.

1.2.1.2 Atmospheric Processes and PM Formation

The atmospheric processes that result in PM formation, specifically oxidation reactions to form ammonium sulfate and ammonium nitrate, have been well characterized in previous assessments (U.S. EPA, 2009, 2004) (Section 2.3.2.2). As a result, recent research has focused primarily on the formation of SOA, and has shown that SOA is a sizeable contributor to $PM_{2.5}$ mass under a variety of atmospheric conditions (Section 2.3.2.3). New research has increased our understanding of how a substantial amount of SOA is produced by several important processes: reactions of the biogenic VOC isoprene; cloud processing; and further oxidation of gas phase products formed from atmospheric VOC oxidation. Additionally, PM formation from biogenic VOC reactions has been reported to be enhanced by anthropogenic influences, including NO_X and SO_2 precursor emissions. (Section 2.3.2.3). Compositional analyses have shown that organosulfates and organonitrates often account for a large fraction of SOA, up to 5−10% for organosulfates and up to 10−20% for organic nitrates (Section 2.3.2.3). Examination of atmospheric processes that lead to SOA formation has led to observations that atmospheric aging

(oxidation) of organic aerosols increases reactive oxygen species activity of ambient PM (Section 2.5.1.1.7). Reactive oxygen species (ROS) have been shown to contribute to cellular oxidative stress in respiratory tract cells (Section 5.1.1).

In addition to exploring SOA formation, recent studies have further examined particle nucleation. New instrumentation has made it possible to measure atmospheric molecular clusters and to directly observe the process of particle nucleation (Section 2.3.4). This research has also focused on identifying the chemical species important in the particle nucleation process. Previous research had focused mainly on the role of sulfate and water, with increasing evidence that organic species were also involved. More recent research identified the importance of additional species, including ammonia and amines as well as extremely low volatility organic compounds in particle nucleation. (Section 2.3.4.2).

1.2.1.3 Monitoring and Modeling of PM

Broadly, PM is measured through the following: well-established long-term national monitoring networks based on well-established monitoring methods; individual monitors established for a specific period for the purposes of characterizing air quality or conducting an epidemiologic study using a variety of established or experimental methods; and satellite measurements. Depending on the PM size fraction, the extent to which information is available on ambient concentrations will vary as a direct result of the monitoring capabilities currently available.

For $PM_{2.5}$ and PM_{10}, extensive national air monitoring networks have been established based on Federal Reference Methods (FRMs) for supporting air quality analyses for the purposes of monitoring for compliance with the PM NAAQS, measurement of spatial and temporal trends of air pollutants, and to support research to assess exposure and health risks from PM exposures (Section 2.4.6). Because PM itself is a complex mixture, additional monitoring networks have been established to capture information on $PM_{2.5}$ components. Specifically, the Chemical Speciation Network (CSN), and the Interagency Monitoring of Protected Visual Environments (IMPROVE) network, which was established for the specific purpose of understanding the relationship between PM composition and atmospheric visibility impairment, both monitor $PM_{2.5}$ components (Section 2.4.6).

Two new national monitoring networks provided additional monitoring of $PM_{2.5}$ and/or $PM_{10–2.5}$ (Section 2.4.6). The first national monitoring network was established as a result of the 2010 NO_2 NAAQS. This network instituted near-road monitors that were placed within 50 m of heavily trafficked roads in urban areas, and many of these near-road monitoring sites also conducted routine monitoring of $PM_{2.5}$. The NCore monitoring network was deployed starting in January 2011 and included measurements for $PM_{2.5}$ and $PM_{10–2.5}$. The $PM_{10–2.5}$ measurements were based on improved monitoring methods specified for $PM_{10–2.5}$ measurement methods to qualify as FRMs and Federal Equivalence Methods (FEMs), and compared to previously used methods that relied on taking the difference between PM_{10} and $PM_{2.5}$ FRM measurements (Section 2.4.6). The new $PM_{10–2.5}$ monitoring requirements are met by using

identical instrumentation for both $PM_{2.5}$ and PM_{10} except for the sampler cut-point; i.e., using the same sampler design, filter type, and filter face velocity for both $PM_{2.5}$ and $PM_{10–2.5}$ in the same sampler.

To date, most monitoring efforts with respect to PM focus on mass-based measurements of $PM_{2.5}$, PM_{10}, and $PM_{10–2.5}$. Recently, some monitors have been deployed to measure UFP concentrations. Routine network particle number concentration (NC) measurements were initiated at a few sites, mostly in New York state, which were made possible by the recent development of water-based condensation particle counters (CPCs) (Section 2.4.6). In other research, new CPCs have been developed, which are capable of measuring NC of particles with aerodynamic diameter 0.001 μm and larger, and these are especially useful for investigating the atmospheric nucleation of particles. (Section 2.4.3.1). Analysis of particle number count data from field studies shows that UFPs are likely to vary considerably among widely used methods, reflecting differences in the size ranges measured. While size ranges of ambient UFP measurements can vary depending on the monitor used, it is important to note that the ambient UFP size range varies from that used in experimental (i.e., animal toxicological and controlled human exposure) studies that rely on concentrated ambient particle (CAP) UFP exposures. Specifically, UFP CAPs result in particle size ranges up to 0.18−0.3 μm, which is larger than the nominal UFP size limit of less than 0.1 μm, which has previously been defined as the upper size cut as detailed in the 2009 PM ISA. Because the contribution to mass from particles less than 0.1 μm is relatively small, much of the mass may be associated with particles greater than 0.1 μm. However, as described in Section 2.4.3.1, the difference in particle number measurements between PM delivered with usual methods in controlled exposure studies and ambient UFP from which it originates is likely to be much less than the difference in mass (Section 2.4.3.3).

Some of the biggest developments since the 2009 PM ISA include the use of satellite-based measurements to estimate $PM_{2.5}$ concentrations and the continued evolution of chemical transport models (CTMs). Satellite-based measurements have become widely used and combined with modeled data and ground level measurements to extend spatial coverage and improve spatial resolution of $PM_{2.5}$ estimates (Section 2.4.5). Although satellite based $PM_{2.5}$ measurements allow for an expansion of the spatial coverage of epidemiologic studies, they are subject to measurement errors not encountered with FRM or other ground-based measurements, particularly due to data availability because of the inability to provide measurements during days with cloud or snow cover. This is because $PM_{2.5}$ is not directly measured and its estimation is based on computational algorithms involving a range of assumptions, such as vertical distribution and particle composition (Section 2.4.5). With respect to CTMs, advances have included the addition of biogenic VOC chemistry, organic aerosol aging, cloud chemistry, dry deposition, meteorological processes, wind-blown dust, and ammonia emissions. Collectively, these additions have resulted in demonstrable improvements in the prediction of seasonal variation and long-term changes in $PM_{2.5}$ concentrations (Section 2.4.7).

1.2.1.4 National PM Concentrations

Recent assessments of ambient PM concentrations have shown a general decline over time. $PM_{2.5}$ concentrations are generally lower than those reported in the 2009 PM ISA, decreasing from a national 3-year average of 12 μg/m^3 for 2005−2007 to 8.6 μg/m^3 for 2013−2015 (Section 2.5.1.1.1 and Section 2.5.2.1.1). Similar to the trend in $PM_{2.5}$ concentrations, national 3-year average PM_{10} concentrations have declined by 15% compared to those reported for 2005−2007, and are estimated at 21.1 μg/m^3 for 2013−2015, at least in part reflecting decreases in $PM_{2.5}$ concentrations. As detailed in Section 1.2.1.3, limited data are available from national monitors for $PM_{10-2.5}$ and UFP. As a result, it is difficult to assess trends in UFP and $PM_{10-2.5}$ concentrations over time (Section 2.5.1.1.5 and Section 2.5.2.1.3).

An examination of $PM_{2.5}$ composition trends further informs the overall reductions in $PM_{2.5}$ concentrations that have occurred over time. The biggest change in $PM_{2.5}$ composition that has occurred since the 2009 PM ISA, is the reduction in sulfate concentrations. Between 2000 and 2015 nationwide annual average sulfate concentration decreased by 17% at urban sites and 20% at rural sites. This change in sulfate concentrations is most evident in the eastern U.S., and has resulted in organic matter or nitrate now being the greatest contributor to $PM_{2.5}$ mass in most locations (Section 2.5.1.1.6). The observed decline in $PM_{2.5}$ sulfate concentrations can be attributed to a similar decline in SO_2 emissions. The overall reduction in sulfate concentrations likely contributed substantially to the decrease in national average $PM_{2.5}$ concentrations as well as the decline in the fraction of PM_{10} accounted for by $PM_{2.5}$, when compared to the years 2005−2007 (Section 2.5.1.1.6).

1.2.1.5 Spatial and Temporal Variability in PM Concentrations

Although there has been an overall reduction in national PM concentrations over time, there are distinct spatial and temporal patterns in PM concentrations. At a macro scale, $PM_{2.5}$ concentrations are generally higher and more spatially uniform in the eastern U.S. than in the western U.S. (Section 2.5.1.1.1). While $PM_{2.5}$ concentrations are generally higher in the eastern U.S., the highest reported concentrations are an exception to this trend, occurring in California. Especially high $PM_{2.5}$ concentrations are observed in the San Joaquin Valley, where multiple monitors recorded 3-year average concentrations greater than 14 μg/m^3, and in the Los Angeles basin, where 3-year average concentrations exceeded 12 μg/m^3 at several monitors. In the Eastern U.S., the highest $PM_{2.5}$ concentrations are in or near the Ohio Valley, extending eastward into Pennsylvania, where 3-year average concentrations for numerous monitors exceeded 10 μg/m^3. On a national scale there are distinct east and west patterns in long-term average $PM_{2.5}$ concentrations, but on an urban scale there is not a clear pattern of $PM_{2.5}$ spatial variability with some observations indicating relatively uniform concentrations while others depict a high degree of variability (Section 2.5.1.2.1).

Seasonal analyses have shown a change in the season with the highest $PM_{2.5}$ concentrations. Compared to the 2009 PM ISA, where the examination of seasonal $PM_{2.5}$ concentrations depicted higher concentrations in the summer, recent data indicate higher average $PM_{2.5}$ concentrations in the winter, which reflects lower SO_2 emissions and subsequently sulfate concentrations in the summer (Section 2.5.1.1.1 and Section 2.5.2.2.1). Within most urban areas, $PM_{2.5}$ exhibit a rush hour peak in the morning and evening (Section 2.5.2.3).

In general, the fraction of PM_{10} accounted for by $PM_{2.5}$ is higher in the eastern U.S. than in the western U.S. (Section 2.5.1.1.4). Compared to $PM_{2.5}$, $PM_{10–2.5}$ concentrations are more spatially variable (Section 2.5.1.2.3). Ninety-eighth percentile $PM_{10–2.5}$ concentrations greater than 40 µg/m^3 were observed in multiple locations in California, as well as in the southwestern states of Nevada, Arizona, New Mexico, Texas, and the central plains states of Oklahoma, Missouri, and Iowa, and the urban areas of St. Louis, MO, Cleveland, OH, and south Florida. While not directly comparable, PM_{10} concentrations, monitoring data for which are available for many more years, can inform, and are often consistent with, the observed spatial and temporal pattern of $PM_{10–2.5}$ concentrations. Compared to the 2004 AQCD (U.S. EPA, 2004), more PM_{10} in the eastern U.S. is now accounted for by $PM_{10–2.5}$ than before based on examining the fraction of PM_{10} comprised of $PM_{2.5}$. The $PM_{2.5}$ fraction of PM_{10} appears to have decreased from about 60−70% in –the 2004 PM AQCD to about 50−60% in 2013–2015 reported in this document, although the 2013−2015 observations are based on national network data and the 2004 data are based on a limited number of field study samples (Section 2.5.1.1.4). All U.S. regions display clear seasonal variations in $PM_{10–2.5}$ concentrations, with the lowest concentrations occurring around January and the highest occurring in the summer months (Section 2.5.2.2.2). Most $PM_{10–2.5}$ measurements have been based on 24-hour monitoring, however, considerably higher $PM_{10–2.5}$ concentrations have been observed using monitors capable of recording higher time resolution measurements, potentially indicating a tendency for intense $PM_{10–2.5}$ short-term episodes not captured by 24-hour monitoring (Section 2.5.1.1.3).

Data on the spatial and temporal variability in UFP concentrations is rather limited, particularly in the U.S. However, a single U.S. study that measured a full year of urban size-resolved particle number count measurements indicated about 90% of particles were smaller than 0.1 µm. (Section 2.5.1.1.5). The limited amount of available UFP measurements data indicated that the highest UFP concentrations occur in the winter and near roads with heavy traffic, often over short time periods (Section 2.5.1.2.4 and Section 2.5.2.2.3). Overall, UFP concentrations are more spatially variable than $PM_{2.5}$ (Section 2.5.1.2.4). Examinations of temporal variability show that UFP concentrations typically rise substantially in the morning and remain high into the evening hours when they reach their maximum, with distinct rush hour and early afternoon peaks. Additionally, there is evidence of seasonal impacts on the temporal variability of UFP concentrations, with high afternoon concentrations during warmer months possibly due to photochemical formation, and lower concentrations through the night (Section 2.5.1.1.5 and Section 2.5.2.2.3).

A detailed evaluation of the composition of $PM_{2.5}$, $PM_{10–2.5}$, and UFPs finds that each size fraction is dominated by a few components. For $PM_{2.5}$, there are clear geographic differences in its composition. In the eastern U.S., sulfate and organic matter are the highest contributors to total mass while in the western U.S. organic matter most often is the highest contributor, although sulfate, nitrate, and crustal material can also be abundant (Section 2.5.1.1.6). When examining the absolute concentrations of specific components, the highest nitrate concentrations are observed in the western U.S., particularly in California, but with some elevated concentrations in the upper Midwest. Seasonally, nitrate concentrations are much higher in the winter than summer in all locations (Section 2.5.1.1.6). Organic and elemental carbon concentrations are both more uniformly distributed in the eastern U.S., but more variable among western U.S. locations. The highest urban concentrations in the western U.S. occur during fall and winter (Section 2.5.1.1.6). Crustal material is a substantial contributor to $PM_{2.5}$ mass in dry areas of the western U.S., such as in Phoenix and Denver (Section 2.5.1.1.6). For $PM_{10–2.5}$, as noted previously concentrations are highest in southwestern U.S. and are observed to be largely dominated by crustal material, but organic material can also represent a substantial contribution to mass, as well as biological material like bacteria, viruses, fungal spores, pollen, and plant debris (Section 2.5.1.1.6). For UFPs there is still relatively limited information on its composition, but initial data indicate that urban UFPs are rich in organic and elemental carbon, while sulfate and ammonium are likely to be substantial contributors to UFPs in areas where new particle formation occurs (Section 2.5.1.1.6).

Background PM generally refers to PM that is formed by sources or processes that cannot be influenced by actions to control PM concentrations. Various background definitions have been used for NAAQS reviews. U.S. background concentration of a pollutant is the concentration resulting from natural primary and precursor sources everywhere in the world plus anthropogenic sources outside of the U.S., Canada, and Mexico. Similarly, North American background concentrations is the concentration resulting from natural primary and precursor sources everywhere in the world plus anthropogenic sources outside of the U.S., Canada, and Mexico. U.S. background sources of PM include wind erosion of natural surfaces, volcanic production, wildfires, sea salt, biological material like pollen and spores, SOA produced by oxidation of biogenic hydrocarbons, and international transport. Background PM can be episodic, as in the case of volcanic eruptions, forest fires, and dust storms or more consistent, as in the case of a relatively constant, low level contributions from natural and intercontinental sources outside of major events. Nationally, it has been estimated that wildfire smoke contributes between 10% and 20% of primary $PM_{2.5}$ emissions per year, and intercontinental transport contributes 0.05 to 0.15 $\mu g/m^3$ to annual average $PM_{2.5}$ concentrations in the U.S., but that this contribution varies by region and season. On average, natural sources including soil dust and sea salt have been estimated to account for approximately 10% of U.S. urban $PM_{2.5}$ (Section 2.5.4).

1.2.1.6 Summary

Since the 2009 PM ISA there are new developments and observations in the characterization of ambient PM. For $PM_{2.5}$, these include observations of a steep decline in SO_2 precursor concentrations, replacement of sulfate with organic matter as the greatest contributor to $PM_{2.5}$ mass in many locations in the eastern U.S., and a substantial decrease in national average $PM_{2.5}$ concentration. A large body of new research has also refined the overall understanding of SOA formation processes. Improvements in CTM methods have resulted in demonstrable improvements in the prediction of seasonal variation and long-term changes in $PM_{2.5.}$ Extensive new network monitoring for $PM_{10–2.5}$ has greatly increased the amount of data available for assessing relative amounts of $PM_{2.5}$ and $PM_{10–2.5}$, showing that $PM_{10–2.5}$ as a fraction of PM_{10} has increased in the eastern U.S. as sulfate and $PM_{2.5}$ have decreased, and that in many western locations the contribution of $PM_{10–2.5}$ to PM_{10} exceeds the contribution of $PM_{2.5}$ to PM_{10}. This new monitoring effort has further informed the understanding of seasonal and regional differences in $PM_{10–2.5}$ concentrations. Recent studies focusing on UFPs, largely supports observations in the 2009 PM ISA, but new areas of emphasis include instrumentation for measuring particles as small as 1 nm and the initiation of long-term monitoring in a few U.S. locations, which will facilitate future research. However, network data are still sparse, and there is still far less information regarding patterns of spatial and temporal variability of UFP in comparison to $PM_{2.5}$ or $PM_{10–2.5}$. Differences in monitoring methods and the lack of a consistent definition also make comparison of UFP data difficult between different field studies or methods.

1.2.2 Assessment of Human Exposure

Findings from the recent exposure assessment literature build on evidence presented in the 2009 PM ISA for the assessment of PM exposures. The 2009 PM ISA found that spatial variability of $PM_{10–2.5}$ and UFP at micro-to-neighborhood scales was greater than that of $PM_{2.5}$, and primary $PM_{2.5}$ components, such as EC, exhibited greater spatial variability than $PM_{2.5}$ components produced through atmospheric chemical reactions, such as NO_3^- or SO_4^{2-}. Regional variability in PM composition was also noted and thought to result from differences among sources in different parts of the country. Models, such as land use regression (LUR), were discussed as tools intended to characterize spatially variable components or size fractions, but limitations in the LUR's ability to adequately capture spatial variability were identified in several papers reviewed. Additionally, variability in the PM size distribution, PM composition, and infiltration was identified across regions as factors that could influence individual exposure to PM. Unmeasured variability in ambient PM concentration, size fractions, and composition were noted to cause potential uncertainty in estimates of exposure concentrations and health effect estimates. The recent literature advances the state of exposure science by presenting innovative methodologies to estimate PM exposure, detailing new and existing measurement and modeling methods, and further informing the influence of exposure measurement error due to new and existing exposure concentration estimation methods on associations between PM and health effects reported in the epidemiologic study literature.

New evidence supports older findings that appropriate surrogates for exposure concentration may depend on PM size distribution, because spatial variability in PM concentrations varies with particle size (Section 3.4.3.2). Multiple techniques have recently been developed or improved to assign PM exposure concentrations in epidemiologic studies. These methods include personal monitors, data averaging across monitors, interpolation methods, LUR models, spatiotemporal models, CTMs, dispersion models, microenvironmental models, and satellites (Section 3.3). Fixed-site monitors also continue to be used frequently to estimate exposure concentration. Each method has strengths and limitations. Accordingly, errors and uncertainties in the exposure assessment methods can add bias and uncertainty to health effect estimates from epidemiologic studies on the health effects of PM exposure.

Ambient PM data from individual sites continue to be used widely in health studies as a surrogate for PM exposure concentration, because fixed-site monitors provide a continuous record of ambient PM concentrations over many years (Section 3.3.1.1). For $PM_{2.5}$, the concentration profile tends to be more homogeneous across the urban or neighborhood scale, ambient concentrations estimated at fixed-site monitors may reflect exposure concentrations. However, the higher degree of spatial variability in ambient $PM_{10–2.5}$ and UFP across an urban area may not be captured by a fixed-site monitor. As a result, uncharacterized variability in a time-series of exposure concentrations across space, resulting from use of fixed-site monitoring data, in a time-series epidemiologic study of $PM_{10–2.5}$ or UFP exposure may tend to attenuate health effect estimates (Section 3.4.5.1). For long-term exposure studies, bias may occur in either direction depending on whether the fixed-site monitor is over- or underestimating ambient $PM_{10–2.5}$ or UFP exposure concentration for the population of interest (Section 3.4.5.2). In all study types, use of fixed-site monitoring ambient $PM_{10–2.5}$ or UFP concentrations in lieu of the true exposure is expected to widen confidence intervals beyond what would be obtained if the true exposure were used. Personal monitors directly measure PM exposure, but they produce a relatively limited data set, making them most suitable for panel epidemiologic studies (Section 3.4.5.1.2). Without accompanying geographic positioning system (GPS) or time-activity diary data, it is impossible to distinguish ambient PM exposure from exposure to PM of nonambient origin in these studies.

Models of PM concentration can be used to develop exposure surrogates for individuals and large populations when personal exposure measurements are unavailable (Section 3.3.2). Recent developments have been made to advance techniques for spatiotemporal modeling, which typically combine universal kriging with variables describing land use, population characteristics, emissions, and geographic features (Section 3.3.2.3). GIS-based spatiotemporal models of concentration that are used as exposure surrogates have produced out-of-sample cross-validation (i.e., out-of-sample $R^2 > 0.8$) for $PM_{2.5}$ and its components, some of which have more spatially varying concentration fields than $PM_{2.5}$ mass concentration. Overly-smoothed exposure concentration surfaces from spatiotemporal models have been shown to bias the health effect estimate towards the null (i.e., underestimating the true health effect) with decreased probability that the confidence intervals contain the true health effect, particularly when the actual spatial variability is much higher than what is represented by the model (Section 3.4.5.2). Bias correction and bootstrap calculation of standard errors have been shown to improve health effect estimate prediction

from spatiotemporal models when the exposure estimates have a classical-like error structure. A study of $PM_{2.5}$ mass and components, including EC, OC, Si, and S, where the exposure model errors had a Berkson structure, did not exhibit improvement of the health effect estimate when bootstrap simulation of the standard error was applied. When the exposure estimates have a Berkson-like error structure, health effect estimate predictions would only be expected to improve when model covariates are chosen so that the statistical distribution of the modeled exposure concentrations is close to the distribution of the true exposure concentrations.

Recent developments have been made for mechanistic models, such as dispersion models and CTMs, to simulate the transport, dispersion, and (in the case of CTMs) atmospheric chemistry of ambient PM (Section 3.3.2.4). Hybrid approaches to combine exposure concentration predictions from CTMs with those from fixed-site monitoring data or dispersion models have grown since the 2009 PM ISA. CTMs are limited in their spatial resolution, which is typically at length scales of 4 km or 12 km (and sometimes down to 1 km). Data fusion techniques merge CTMs with dispersion model results or fixed-site monitoring data. They are designed to estimate spatial variability of exposure concentrations at the subgrid scale, typically through a hierarchical modeling framework. These models have good cross-validation and have the potential to reduce exposure measurement error and resulting bias and uncertainty in health effect estimates produced by epidemiologic models of long-term exposure to PM, even for spatially-varying size fractions and components.

Several advancements to data fusion techniques have been made since the 2009 PM ISA to merge aerosol optical density (AOD) observations from satellite images with surface-level PM measurements from fixed-site monitors (Section 3.3.3). Regression models have been developed to calibrate the AOD observations to surface measurements of $PM_{2.5}$, and $PM_{2.5}$ exposure concentrations have then been estimated from those models in locations where surface measurements are unavailable. Land use or other geographical variables incorporated in these models have been shown to improve cross-validation and reduce error in estimates of exposure concentrations, and increasing the number of monitors used to fit the model has reduced bias and uncertainty in the exposure estimates. Hence, hybrid modeling approaches combining satellite data with fixed-site monitoring data and LUR or spatiotemporal modeling results have the potential to reduce bias and uncertainty in health effect estimates reported in epidemiologic studies of short- and long-term exposure to $PM_{2.5}$. Satellite data techniques have not typically been applied to model spatially-variable UFP, $PM_{10–2.5}$, or $PM_{2.5}$ component exposure concentration fields. Epidemiologic studies where PM exposure concentration is derived from a hybrid satellite-LUR model have reported larger magnitude health effect estimates with increasing spatial resolution (i.e., dividing the spatial domain into many smaller areas in which concentration is modeled) of the exposure concentration surfaces. If the effect estimate derived from the hybrid model was shown by cross-validation to be more accurate than a low-resolution model, then this finding suggests that low spatial resolution (i.e., a spatial domain with a small number of large areas in which concentration is modeled) of the PM exposure concentration surface may cause bias of the health effect estimate towards the null to underestimate the true health effect in a long-term exposure study (Section 3.4.5.2).

Among the methods evaluated, only personal monitoring and microenvironmental modeling account for indoor exposure to ambient PM (Section 3.3.1.2). Particles are deposited during the process of infiltration to indoor or vehicle microenvironments, to produce an infiltration factor (F_{inf}) <1 (Section 3.4.1.1). As described in the 2009 PM ISA, F_{inf} varies with season, window opening, building age, wind speed and particle size distribution (with F_{inf} lower for $PM_{10–2.5}$ compared with $PM_{2.5}$). Recent studies have reported lower F_{inf} for UFP compared with F_{inf} for $PM_{2.5}$, potentially reflecting diffusion-driven surface deposition losses for UFP during the infiltration process. In a study of the influence of exposure estimates on health effect estimates in a time-series epidemiologic study of PM exposure, use of a fixed-site monitor in lieu of a microenvironmental model that accounted for infiltration produced considerably attenuated health effect estimates (Section 3.4.5.1). Infiltration of PM through a building envelope may change the temporal variability of the indoor PM concentration time-series, resulting in reduced correlation between the health effect of interest and the estimated exposure concentration. In a study of the influence of modeled exposure concentrations on health effect estimates in an epidemiologic study of long-term average PM exposure, simulating indoor concentrations produced unbiased health effect estimates. Furthermore, the health effect estimate was biased towards the null with inflated confidence intervals after omitting a term for infiltration in a LUR or spatiotemporal model. Bias towards the null leads to underestimation of the true health effect (Section 3.4.5.2).

Exposure to copollutants may result in some confounding of the PM health effect estimate if exposure to the copollutants and their relationships to the health effect of interest are both correlated with PM exposure (Section 3.4.3). Median correlations of 24-hour ambient $PM_{2.5}$ with concentrations of some ambient gases (CO, NO_2, O_3) from the U.S. EPA Air Quality System (AQS) during 2013−2015 were as high as Pearson R = 0.5, although correlation varied with season (highest for O_3 in summer and for CO and NO_2 in winter). The upper end of the distribution of correlations approached one for these gases. Copollutant correlation data for short-term concentration measurements from the literature since the 2009 PM ISA were consistent with the AQS data. For $PM_{10–2.5}$, median correlations of 24-hour ambient concentrations during the same time period were as high as Pearson R = 0.4 but with upper correlations typically below Pearson R = 0.7−0.8. Median correlations between $PM_{2.5}$ and $PM_{10–2.5}$ range between 0.2 and 0.5, with higher values in summer and fall. Data for UFP correlations were very limited, but they indicate correlations as high as Pearson R = 0.5 for NO_2 and NO_X. Sites with moderate-to-strong correlations (R > 0.4) may introduce a greater degree of confounding into epidemiologic results, depending on the relationship between the copollutants and the health effect of interest.

Some epidemiologic studies of the health effects of PM exposure have examined potential associations between health effects and exposure to PM components (Section 3.4.4) since the 2009 PM ISA. An examination of the composition of $PM_{2.5}$ using data from AQS found that the highest Pearson correlations between $PM_{2.5}$ mass and $PM_{2.5}$ component concentrations occurred for OC, SO_4^{2-}, EC, and NO_3^-. A large percentage of $PM_{2.5}$ mass concentration is a product of atmospheric chemistry. The recent peer-reviewed literature showed high correlations of $PM_{2.5}$ mass concentrations with concentrations of secondary SO_4^{2-} and NO_3^- as well as primary V and Zn. Similarly, high correlations between the

quasi-ultrafine $PM_{0.25}$ and V were observed in recent studies for $PM_{0.25}$ exposure concentrations, and correlations near Pearson $R = 1$ during the winter support the notion that heating oil combustion plays a role in these associations. For $PM_{10–2.5}$, the largest correlation was for Si, possibly in dust. Median correlations reported from AQS and the literature for $PM_{10–2.5}$ with all other $PM_{10–2.5}$ components were Pearson $R < 0.5$, indicating that $PM_{10–2.5}$ is not strongly associated with combustion. Generally, $PM_{2.5}$ components reflect the secondary nature of their production, the $PM_{0.25}$ components reflect combustion, and $PM_{10–2.5}$ components reflect mechanical generation.

In summary, exposure error tends to produce underestimation of health effects in epidemiologic studies of PM exposure, although bias in either direction can occur. There are new developments in assessment of PM exposure, including hybrid spatiotemporal models that incorporate satellite observations of AOD, land use variables, surface monitoring data from FRMs, and/or CTMs. Improvements in spatial resolution of the $PM_{2.5}$ concentration surface have reduced bias and uncertainty in health effects estimates. However, high correlations with some gaseous copollutants necessitate evaluation of the impact of confounding on health effects estimates, using two-pollutant models to ascertain robustness of epidemiologic study results. $PM_{10–2.5}$ and UFP concentrations tend to be more spatially variable than $PM_{2.5}$ concentrations, and data are either unavailable or less often available to fit or validate hybrid models for those size fractions. As a result, there is typically less uncertainty in health effect estimates derived from both monitored and modeled exposure estimates for $PM_{2.5}$ compared with $PM_{10–2.5}$ and UFP.

1.3 Dosimetry of PM

Particle dosimetry refers to the characterization of deposition, translocation, clearance, and retention of particles and their components within the respiratory tract and extra-pulmonary tissues. The dose from inhaled particles deposited and retained in the respiratory tract is governed by several factors. These factors include exposure concentration and duration, activity and breathing conditions (e.g., nasal vs. oronasal route and minute ventilation), and particle properties (e.g., particle size, hygroscopicity, and solubility in airway fluids and cellular components). Basic information related to the mechanisms of particle deposition and clearance and the influence of disease severity on these mechanisms has not changed over the last several PM NAAQS reviews. Compared to prior reviews, species similarities and differences in the amounts of inhaled PM reaching the lower respiratory tract is now better understood and quantified. Additionally, some older literature on route of breathing in humans, that was not included in prior reviews, has come to light and shows differences in route of breathing as a function of age and sex. New data on particle translocation across the olfactory mucosa into the brain and from the alveolar epithelium into the blood also now allows for improved estimates of the importance of these processes in humans.

To be deposited in the respiratory tract, particles need to first be inhaled. Inhalability refers to the fraction of particles that can enter the upper respiratory tract (i.e., the head) during inhalation and is dependent on the aerodynamic diameter of the particle (d_{ae}). A commonly used occupational criterion of particle inhalability in humans based on the d_{ae} of particles, predicts that as d_{ae} increases from 1−10 µm, inhalability decreases from ~97 to ~77%, plateauing at 50% for particles ~40 µm in diameter (Section 4.1.5). The occupational criterion is for relatively high wind speeds (>1 m/s). In calm air, inhalability decreases toward zero with increasing d_{ae} above about 20 µm for nasal and 30 µm for oral breathing. There is evidence for much lower particle inhalability in infants than adults. In rodents, inhalability decreases more rapidly than in humans, from 80 to 44%, as d_{ae} of particles increases from 2.5 to 10 µm especially for faster breathing rates. Inhalability and nasal deposition are particularly important considerations influencing how much PM makes it into the lower respiratory tract of rodents relative to humans (Section 4.1.6).

The route of breathing, breathing pattern (volume and rate), and particle size are among the factors affecting the amount of PM that enters the body and may subsequently deposit in the respiratory tract. With increasing physical activity, there is an increase in minute ventilation and a shift from nasal to oronasal breathing, and depending on the size fraction of PM inhaled, potentially greater PM penetration into the lower respiratory tract (i.e., the lungs). Even at rest, differences have been observed by age, sex, disease status, and body mass index in the fraction of oral versus nasal breathing (Section 4.1.3). Children inhale a larger fraction of air through their mouth than adults, and males tend inhale a larger fraction of air through their mouth than females (across all ages). Individuals with allergies or upper respiratory infections experience increased nasal resistance, and thus, an increased fraction of oral breathing. Obesity, especially in boys, may also contribute to increased nasal resistance and an increased oral fraction of breathing relative to normal weight children. Due to their increased amount of oral breathing, these individuals may be expected to have greater PM penetration into the lower respiratory tract than healthy, normal weight adults. Children may also be expected to have a greater intake dose of PM per body mass than adults. Route of breathing is instrumental in determining the amount of PM inhaled and also impacts the size of particles that can reach the lower respiratory tract. In humans, the fraction of a breath entering through the mouth increases the fraction of particles reaching the lower respiratory tract (Figure 4-3). In contrast, rodents are obligatory nasal breathers and only a small percentage of larger particles (i.e., >3 µm) reaches the lower respiratory tract (Figure 4-4).

Particle deposition in the respiratory tract occurs predominantly by diffusion, impaction, and sedimentation (Section 4.2). Total respiratory tract particle deposition can reach nearly 100% in humans for particles smaller than approximately 0.01 µm (via diffusion) and greater than 10 µm (via sedimentation and impaction), but is minimal for particles between 0.3 to 0.7 µm. The nose and mouth represent the first line of defense against particles depositing in the lower respiratory tract, with roughly 100% of particles 10 µm or greater depositing in the human nose. Inter-species differences in the inhalability and nasal deposition of particles has also been shown to affect the size of particles that can enter the respiratory tract and the percentage of particles deposited in various regions. While larger

particles tend to deposit in the nose in humans, in rodents almost 100% of particles >5 μm are deposited in the nose. Additionally, oronasal breathing in humans contributes to greater penetration of coarse particles into the lower respiratory tract, whereas rats breath only nasally. There are also differences between children and adults in terms of breathing patterns and ventilation, indicating that children may receive a higher dose per lung surface area of ambient PM in the lower respiratory tract. Respiratory disease can lead to differences in both total deposition and deposition patterns relative to the disease-free lung. In general, the PM dose rate is increased by lung disease, but depends on the severity of and type of disease.

For any given particle size, the pattern of poorly soluble particle deposition influences clearance by partitioning deposited material between regions of the respiratory tract (Section 4.3). While particles depositing in the mouth are generally swallowed or removed by expectoration, particles deposited in the posterior nasal passages or tracheobronchial (TB) airways are moved by mucociliary transport towards the nasopharynx and swallowed. In the alveolar region clearance occurs mainly via macrophage phagocytosis. Clearance is more rapid in rodents than humans and has been shown to decrease with age beyond adulthood. Human studies have shown that ultrafine carbon particles do not rapidly or significantly translocate from the lungs into the circulation (Section 4.3.3.2). However, a new human study has demonstrated some translocation of nano-sized gold particles from the lungs into circulation. The finding of material in the blood in this new human study, but not prior human studies may, in part, be a matter of an increased signal to noise afforded in this new methodology and/or an indication that there is a difference in particle translocation from the lung depending on the inhaled particle type. Animal studies using poorly soluble nano-sized gold and iridium (Ir) particles have provided more extensive evidence of translocation into blood and secondary organs. The estimated urinary elimination by 24 hours post-inhalation of the gold nanoparticles is nearly identical between humans and rats. Soluble materials deposited in the respiratory tract can enter the blood more rapidly than insoluble materials. Recent evidence across species indicates that particles of varying composition, particle size (less than 200 nm diameter), and solubility can also translocate to the brain via the olfactory bulb. It remains unclear, though, whether translocation to the olfactory bulb and brain regions varies by species and whether certain species are more predisposed to this translocation route.

There is a dosimetric basis for several particle sampling conventions used to quantify airborne PM concentrations. The U.S. EPA has size-selective sampling conventions for fine particles indicated by $PM_{2.5}$ and PM_{10} as an indicator for the purposes of regulating the thoracic coarse particles (i.e., the inhalable particles that remain if $PM_{2.5}$ particles are removed from a sample of PM_{10}; aka $PM_{10–2.5}$). $PM_{2.5}$ is not well representative [nor was it intended to be] of the occupational definition of respirable particles which has a 50% cut-point at 4 μm versus 2.5 μm for the $PM_{2.5}$ sampler (Figure 4-2). The selection of $PM_{2.5}$ for the NAAQS was mainly to delineate the atmospheric fine (combustion derived, aggregates, acid condensates, secondary aerosols) and coarse (crustal, soil-derived dusts) PM modes and for consistency with community epidemiologic health studies reporting various health effects associated with $PM_{2.5}$ but not on dosimetric considerations as was the case for the respirable particle sampler convention. Although

the respirable sampling convention has a dosimetric basis, it is reflective of the total PM mass concentration to which the alveolar region may be exposed not the PM mass deposition or dose. PM_{10} is often referred to as the thoracic fraction of inhalable particles and there is an occupational sampling convention for thoracic particles both of which have a 50% cut-point at about 10 µm (Figure 4-2). However, it should be recognized that the fraction of inhaled 10 µm particles reaching the thorax is <20% for most activity levels and breathing habits. Breathing completely through the mouth, fraction of inhaled 10 µm particles reaching the thorax approaches 40%. Thus, using a 50% cut-point at 10 µm provides a conservative (protective) overestimate of thoracic particles.

1.4 Evaluation of the Health Effects of PM

This ISA evaluates relationships between an array of health effects and short-term and long-term exposures to PM (i.e., $PM_{2.5}$, $PM_{10-2.5}$, and UFPs) in epidemiologic, controlled human exposure, and animal toxicological studies. In assessing the overall evidence, strengths and limitations of individual studies were evaluated based on scientific considerations detailed in the Appendix. Short-term exposures are defined as those with durations of hours up to one month, with most studies examining effects related to exposures in the range of 24 hours to 1 week. Long-term exposures are defined as those with durations of more than 1 month to years. As detailed in the Preface , the evaluation of the health effects evidence focuses on exposures conducted at concentrations of PM that are relevant to the range of human exposures across ambient microenvironments (up to 2 mg/m^3, which is one to two orders of magnitude above ambient concentrations), and (1) include a composite measure of PM[36] or (2) apply some approach to assess the direct effect of a specific PM size-fraction when the exposure of interest is a source-based mixture (e.g., diesel exhaust, gasoline exhaust, wood smoke). Drawing from evidence related to the biological plausibility of PM-related health effects and the broader health effects evidence described in detail in Chapters 5−11, information on dosimetry in CHAPTER 4 and Section 1.4, as well as issues regarding exposure assessment and potential confounding described in CHAPTER 3 and Section 1.3, the subsequent sections and accompanying table (Table 1-2) summarize the key evidence that informed the causality determinations for relationships between PM exposure and health effects, specifically those relationships where a "*causal*" or "*likely to be causal*" relationship has been concluded (Table 1-1). Those relationships between PM and health effects where a "*suggestive of, but not sufficient to infer*" or "*inadequate*" causality determination has been concluded are noted in Table 1-7, but more fully discussed in the respective health effects chapters.

[36] Composite measures of PM may include mass, volume, surface area, or number concentration.

Table 1-1 "Causal" and "likely to be causal" causality determinations for short- and long-term PM exposure.

Size Fraction	Health Effects Category	Exposure Duration	Causality Determination	Section
$PM_{2.5}$	Respiratory	Short-term	Likely to be causal	1.4.1.1.1
		Long-term	Likely to be causal	1.4.1.1.2
	Cardiovascular	Short-term	Causal	1.4.1.2.1
		Long-term	Causal	1.4.1.2.2
	Nervous System	Long-term	Likely to be causal	1.4.1.3.1
	Cancer	Long-term	Likely to be causal	1.4.1.4.1
	Mortality	Short-term	Causal	1.4.1.5.1
		Long-term	Causal	1.4.1.5.2
UFP	Nervous System	Long-term	Likely to be causal	1.4.3.1

1.4.1 Health Effects of $PM_{2.5}$

Substantial scientific evidence exists across disciplines (i.e., animal toxicology, controlled human exposure, and epidemiology), with additional support from studies examining biological plausibility, showing that both short- and long-term $PM_{2.5}$ exposure can result in a range of health effects, from changes in circulating biomarkers to mortality. However, the overall confidence in the $PM_{2.5}$ exposure – health effects relationship varies depending on the exposure duration (i.e., short- or long-term) and broad health category (e.g., cardiovascular effects, respiratory effects) examined. Across the broad health effects categories examined, the evidence supporting biological plausibility varies, but generally includes modulation of the autonomic nervous system and inflammation as part of the pathways leading to overt health effects. Discussions of subsequent events that could occur due to deposition of inhaled $PM_{2.5}$ in the respiratory tract are detailed in the biological plausibility sections of each health chapter and summarized in the following sections when detailing the health effects evidence.

1.4.1.1 Respiratory Effects

Recent scientific evidence continues to support a "*likely to be causal relationship*" between both short- and long-term $PM_{2.5}$ exposure and respiratory effects, which is consistent with the conclusions of

the 2009 PM ISA. These causality determinations are based on the consistency of findings within disciplines, coherence among evidence from controlled human exposure, epidemiologic, and toxicological studies, and biological plausibility for respiratory effects, such as asthma exacerbation, development of asthma, COPD exacerbation, and respiratory mortality.

1.4.1.1.1 Respiratory Effects Associated with Short-Term $PM_{2.5}$ Exposure

Epidemiologic studies provide strong evidence for overt respiratory effects, including respiratory-related emergency department visits and hospital admissions and respiratory mortality due to short-term $PM_{2.5}$ exposure, but there is more limited evidence of respiratory effects from experimental studies to provide coherence. Collectively this evidence supports a "*likely to be causal relationship*" between short-term $PM_{2.5}$ exposure and respiratory effects, which is consistent with the conclusions of the 2009 PM ISA (Table 1-2). This conclusion is based on multiple recent epidemiologic studies demonstrating generally consistent, positive associations with emergency department visits for asthma and combined respiratory-related diseases, as well as with respiratory mortality. Evidence from animal toxicological studies, although limited, is supportive of and provides biological plausibility for the associations observed in the epidemiologic studies.

Recent epidemiologic studies continue to provide strong evidence for a relationship between short-term $PM_{2.5}$ exposure and several respiratory-related endpoints, including asthma exacerbation (Section 5.1.2.1), COPD exacerbation (Section 5.1.4.1), and combined respiratory-related diseases (Section 5.1.6), particularly from studies examining emergency department visits and hospital admissions. The consistent positive associations between short-term $PM_{2.5}$ exposure and asthma and COPD emergency department visits and hospital admissions are supported by epidemiologic studies demonstrating associations with other respiratory-related effects such as symptoms and medication use that are indicative of asthma and COPD exacerbations (Section 5.1.2.2 and Section 5.1.4.2). The collective body of epidemiologic evidence for asthma exacerbation is more consistent in children than in adults. Epidemiologic studies examining the relationship between short-term $PM_{2.5}$ exposure and respiratory mortality provide evidence of consistent positive associations, demonstrating a continuum of effects (Section 5.1.9).

Building off the studies evaluated in the 2009 PM ISA, recent epidemiologic studies expand the assessment of potential copollutant confounding. There is some evidence that $PM_{2.5}$ associations with asthma exacerbation, combined respiratory-related diseases, and respiratory mortality remain relatively unchanged in copollutant models with gaseous pollutants (i.e., O_3, NO_2, SO_2, with more limited evidence for CO) and other particle sizes (i.e., $PM_{10–2.5}$) (Section 5.1.10.1). The uncertainty related to whether there is an independent effect of $PM_{2.5}$ on respiratory health, is partially addressed by findings of animal toxicological studies. Specifically, short-term exposure to $PM_{2.5}$ enhanced asthma-related responses in an animal model of allergic airways disease and enhanced lung injury and inflammation in an animal model of COPD (Section 5.1.2.4.3 and Section 5.1.4.4.2). Although there is a broad body of experimental

evidence demonstrating respiratory effects due to short-term $PM_{2.5}$ exposure it is not entirely coherent with the results of epidemiologic studies. However, the experimental evidence does provide biological plausibility for some respiratory-related endpoints. This includes limited evidence of altered host defense and greater susceptibility to bacterial infection as well as consistent evidence of respiratory irritant effects. Animal toxicological evidence for other respiratory effects is inconsistent. Additionally, controlled human exposure studies conducted in people with asthma or COPD show minimal respiratory effects due to short-term $PM_{2.5}$ exposure, such as decrements in lung function and pulmonary inflammation.

1.4.1.1.2 Respiratory Effects Associated with Long-Term $PM_{2.5}$ Exposure

Epidemiologic studies provide strong evidence for effects on lung development, with additional evidence for the development of asthma in children due to long-term $PM_{2.5}$ exposure. Evidence from animal toxicological studies, although limited in number, supports the findings of these epidemiologic studies. There is also epidemiologic evidence for a decline in lung function in adults. Collectively this evidence supports a "*likely to be causal relationship*" between long-term $PM_{2.5}$ exposure and respiratory effects, which is consistent with the conclusions of the 2009 PM ISA (Table 1-2).

Recent epidemiologic studies continue to support an association between long-term $PM_{2.5}$ exposure and several respiratory-related endpoints in children and adults. In children, studies in multiple cohorts provide strong evidence for decrements in lung function growth (Section 5.2.2.1.1). Robust and persistent effects were observed across study locations, exposure assessment methods, and time periods. An animal toxicological study demonstrating impaired lung development resulting from pre- and post-natal $PM_{2.5}$ exposure provides biological plausibility for these findings (Section 5.2.2.1.2). Results of prospective cohort studies in children also provide some evidence for asthma development in children, and are supported by studies of asthma prevalence in children, childhood wheeze, and pulmonary inflammation (Section 5.2.3). Biological plausibility is provided by an animal toxicological study of long-term $PM_{2.5}$ exposure demonstrating the development of an allergic phenotype and increase in airway responsiveness (Section 5.2.3.3.2). There is limited evidence of increased bronchitic symptoms and hospitalization in children with asthma in relation to long-term $PM_{2.5}$ exposure (Section 5.2.7). In adults, long-term $PM_{2.5}$ exposure was associated with an acceleration of lung function decline (Section 5.2.2.2.2). Consistent evidence was observed for respiratory mortality and cause-specific respiratory mortality for COPD and infection (Section 5.2.10), providing evidence of a continuum of effects in response to long-term $PM_{2.5}$ exposure.

Although still limited in number, recent epidemiologic studies further examine potential copollutant confounding. There is some evidence that $PM_{2.5}$ associations with respiratory mortality remained robust in models with some gaseous pollutants (Section 5.2.10); however, there is limited assessment of potential copollutant confounding when examining respiratory morbidity outcomes. The uncertainty related to the independence of $PM_{2.5}$ effects is partially addressed by findings of animal

toxicological studies. Long-term exposure to $PM_{2.5}$ resulted in oxidative stress, inflammation, and morphologic changes in both upper and lower airways (Section 5.2.8), in addition to the asthma-related and lung development-related effects mentioned above. Epidemiologic studies examining the effects of declining $PM_{2.5}$ concentrations provide additional support for a relationship between long-term $PM_{2.5}$ exposure and respiratory health by demonstrating improvements in lung function growth and bronchitic symptoms in children and improvement in lung function in adults in association with declining $PM_{2.5}$ concentrations (Section 5.2.11). However, the limited examination of copollutant confounding in studies of declining $PM_{2.5}$ concentrations is a notable uncertainty given the corresponding decline in other pollutants over the time-period of the evaluated studies.

1.4.1.2 Cardiovascular Effects

Consistent with the conclusions of the 2009 PM ISA, more recently published scientific evidence further strengthens that there is a "*causal relationship*" between both short- and long-term $PM_{2.5}$ exposure and cardiovascular effects. These causality determinations are based on the consistency of findings within disciplines, coherence among evidence from controlled human exposure, epidemiologic, and toxicological studies, and biological plausibility for cardiovascular effects, such as reduced myocardial blood flow, altered vascular reactivity, myocardial infarctions, and cardiovascular mortality.

1.4.1.2.1 Cardiovascular Effects Associated with Short-Term $PM_{2.5}$ Exposure

Strong evidence from epidemiologic studies demonstrating associations between cardiovascular emergency department visits and hospital admissions in combination with evidence for $PM_{2.5}$-induced cardiovascular effects from controlled human exposure and animal toxicological studies confirms and extends the conclusion of a "*causal relationship*" between short-term $PM_{2.5}$ exposure and cardiovascular effects from the 2009 PM ISA (Table 1-2). This conclusion is based on multiple high-quality epidemiologic studies demonstrating associations with cardiovascular effects such as ischemic heart disease (IHD) and heart failure (HF) related emergency department visits and hospital admissions, as well as cardiovascular mortality. The epidemiologic evidence is primarily supported by experimental studies demonstrating endothelial dysfunction, changes in blood pressure, and alterations in heart function in response to short-term $PM_{2.5}$ exposure. Additional evidence from epidemiologic, controlled human exposure, and animal toxicological studies also provides ample evidence of biologically plausible pathways by which short-term exposure to $PM_{2.5}$ can result in overt cardiovascular effects.

Consistent with the 2009 PM ISA, the strongest evidence comes from epidemiologic studies that reported consistent positive associations between short-term $PM_{2.5}$ exposure and cardiovascular-related emergency department visits and hospital admissions particularly for IHD and HF, as well as cardiovascular-related mortality. While the evidence is generally consistent across the copollutants

evaluated, the evidence was especially consistent for air pollutants that are not typically associated with traffic (i.e., ozone, SO_2, $PM_{10–2.5}$). In some instances, associations in copollutant models were attenuated, but this was only observed for the traffic-related pollutants (i.e., NO_2, CO), which generally had higher correlations with $PM_{2.5}$ than other copollutants. This recent evidence generally indicates that the associations observed with $PM_{2.5}$ and cardiovascular effects in single pollutant models remain relatively unchanged in copollutant models, indicating that the observed associations with $PM_{2.5}$ are not artefacts due to confounding by another air pollutant (Section 6.1.14.1). These epidemiologic studies reduce a key uncertainty identified in the 2009 PM ISA by providing evidence that gaseous pollutants are not likely to confound the $PM_{2.5}$-cardiovascular relationship.

The independence of $PM_{2.5}$ effects is further addressed by findings of recent controlled human exposure and animal toxicological studies. The most consistent evidence from controlled human exposure studies is for a $PM_{2.5}$ effect on endothelial function. More specifically, in contrast to the previous review where a single controlled human exposure study did not find changes in endothelial function following short-term $PM_{2.5}$ exposure, multiple recent controlled human exposure studies that examined endothelial function reported that $PM_{2.5}$ impaired at least some measure of vessel dilation following reactive hyperemia or pharmacological challenge relative to filtered air exposure. Given the relationship between endothelial function and blood pressure, these results are coherent with controlled human exposure studies that reported changes in blood pressure following short-term $PM_{2.5}$ exposure. The results of these controlled human exposure studies are also coherent with evidence from animal toxicological studies demonstrating endothelial dysfunction and changes in blood pressure or the renin angiotensin system following short-term $PM_{2.5}$ exposure. Moreover, changes in endothelial function and blood pressure reported in experimental studies are consistent with time-series and case-crossover epidemiologic studies reporting associations between short-term $PM_{2.5}$ exposure and IHD, as well as with limited epidemiologic panel study evidence of associations with blood pressure. In addition, animal toxicological studies demonstrating that short-term $PM_{2.5}$ exposure results in decreased cardiac contractility and left ventricular pressure are coherent with epidemiologic studies reporting associations between short-term $PM_{2.5}$ exposure and HF.

Collectively, the evidence from controlled human exposure, animal toxicological and epidemiologic panel studies provide a biologically plausible pathway by which short-term $PM_{2.5}$ exposure could result in cardiovascular effects such as an emergency department visits, hospital admission, or mortality. This proposed pathway (Section 6.1.1) begins with pulmonary inflammation and/or activation of sensory nerves in the respiratory track. It progresses to autonomic nervous system imbalance and/or systemic inflammation that can potentially affect cardiovascular endpoints such as endothelial function, HRV, hemostasis, and/or BP. Changes in the aforementioned cardiovascular endpoints may then lead to the development of arrhythmia, thrombosis, and/or acute myocardial ischemia, potentially resulting in outcomes such as myocardial infarction, IHD, HF, and possibly death.

Overall, across the scientific disciplines, recent studies extend and support the previous evidence for a continuum of cardiovascular-related health effects following short-term exposure to $PM_{2.5}$. These effects range from relatively modest increases in biomarkers related to inflammation, to subclinical cardiovascular endpoints such as endothelial dysfunction, the overt outcomes of emergency department visits and hospital admissions, specifically for IHD and HF, and ultimately cardiovascular-related mortality.

1.4.1.2.2 Cardiovascular Effects Associated with Long-Term $PM_{2.5}$ Exposure

Multiple recent and previously available epidemiologic studies that extensively control for potential confounders provide strong evidence of positive associations with cardiovascular mortality, which in combination with supporting evidence from recent studies examining cardiovascular morbidity reaffirms the conclusion of a "*causal relationship*" between long-term $PM_{2.5}$ exposure and cardiovascular effects in the 2009 PM ISA (Table 1-2). This conclusion is based on recent U.S. and Canadian cohort studies demonstrating consistent, positive associations between long-term $PM_{2.5}$ exposure and cardiovascular mortality with more limited evidence from studies examining long-term $PM_{2.5}$ exposure and cardiovascular morbidity.

Epidemiologic studies consisting of U.S.-based cohorts and subsequent analyses of these cohorts, provided the basis of the conclusions in the 2009 PM ISA. These studies in combination with recent cohort studies, continue to demonstrate consistent, positive associations and support a strong relationship between long-term $PM_{2.5}$ exposure and cardiovascular mortality. The results of these recent cohort studies are consistent across various spatial extents, exposure assessment techniques, and statistical techniques in locations where mean annual average concentrations are near or below 12 $\mu g/m^3$ (Section 6.2.10).

The body of literature examining the relationship between long-term $PM_{2.5}$ exposure and cardiovascular morbidity has greatly expanded since the 2009 PM ISA. Recent epidemiologic studies examining cardiovascular morbidity endpoints consist of several large U.S. cohort studies each focusing on populations with distinct demographic characteristics (e.g., post-menopausal woman, male doctors, etc.) and extensive consideration of potential confounders. These studies have reported heterogeneous results, with several high-quality studies that adjusted for important covariates, including socioeconomic status (SES), reporting positive associations for cardiovascular morbidity endpoints. The strong associations reported between long-term $PM_{2.5}$ exposure and coronary events (e.g., coronary heart disease [CHD] and stroke) among post-menopausal women in the Women's Health Initiative (WHI) cohort, highlighted in 2009 PM ISA, were strengthened in an extended analysis that considered individual and neighborhood level SES. Recent analyses of other cohorts of women (i.e., Nurses' Health Study, California Teachers Study) that were comparable to WHI in that they considered menopausal status or hormone replacement therapy did not show consistent positive associations with CHD, myocardial infarction or stroke. Longitudinal studies demonstrated that changes in the progression of atherosclerosis

in relation to long-term exposure to $PM_{2.5}$ were variable across cohorts and found to depend, in part, on the vascular bed in which atherosclerosis was evaluated. However, within a study focusing on the progression of atherosclerosis in a healthy population, i.e., Multi-Ethnic Study of Arthrosclerosis and Air Pollution (MESA-Air), an association was observed between long-term $PM_{2.5}$ exposure and coronary artery calcification (CAC), which is a strong predictor of CHD (Section 6.3.4). A small number of studies report positive associations between long-term $PM_{2.5}$ exposure and HF, blood pressure and hypertension. Longitudinal epidemiologic analyses also support the observation of positive associations with markers of systemic inflammation, coagulation and endothelial dysfunction. These HF studies are coherent with animal toxicological studies demonstrating decreased contractility and cardiac output, and increased coronary artery wall thickness following long-term $PM_{2.5}$ exposure (Section 6.2.4.2). Moreover, animal toxicological studies finding a relationship between long-term exposure to $PM_{2.5}$ and changes in BP in rats and mice are coherent with epidemiologic studies reporting positive associations between long-term exposure to $PM_{2.5}$ and hypertension. Similarly, evidence of atherosclerotic plaque progression in a genetically susceptible mouse model is consistent with epidemiologic studies reporting associations between atherosclerosis and long-term $PM_{2.5}$ exposure.

The current body of evidence also reduces uncertainties identified in the 2009 PM ISA related to potential copollutant confounding and the shape of the concentration-response relationship for CVD effects following long-term $PM_{2.5}$ exposure. Generally, most of the $PM_{2.5}$ effect estimates relating long-term $PM_{2.5}$ exposure and cardiovascular mortality remained relatively unchanged or increased in copollutant models adjusted for O_3, NO_2, SO_2, and $PM_{10-2.5}$ (Section 6.2.15). In addition, most of the results from analyses examining the C-R function for cardiovascular mortality supported a linear, no-threshold relationship for cardiovascular mortality, especially at mean annual $PM_{2.5}$ concentrations $\leq$12 $\mu g/m^3$ (Section 6.2.10). Some studies reported that the slope of the concentration-response function tended to be steeper at lower concentrations, especially for IHD mortality, suggesting a supralinear concentration-response relationship. A limited number of cardiovascular morbidity studies examined the shape of the concentration-response relationship and generally reported steeper concentration-response functions at lower concentrations (starting at ~10 $\mu g/m^3$) with the slope of the concentration-response function decreasing at higher $PM_{2.5}$ concentrations (Section 6.2.16).

Evidence from animal toxicological and epidemiologic studies also provide biologically plausible pathways by which long-term $PM_{2.5}$ exposure could lead to cardiovascular effect such as CHD, stroke, and CVD-related mortality (Section 6.2.1). These pathways initially involve autonomic nervous system changes and/or systemic inflammation that can potentially effect endpoints related to vascular function, altered hemostasis, hypertension, atherosclerotic plaque progression, and arrhythmia. Changes in cardiovascular endpoints such as these may then lead to IHD, HF, and possibly death.

Overall, there is consistent evidence from multiple, high-quality epidemiologic studies that long-term exposure to $PM_{2.5}$ is associated with cardiovascular mortality. Associations with CHD, stroke and atherosclerosis progression were observed in several recent high-quality epidemiologic studies

providing coherence with the mortality findings. Results from copollutant models generally support the independence of the $PM_{2.5}$ associations. Additional evidence of the direct effect of $PM_{2.5}$ on the cardiovascular system is provided by experimental studies in animals demonstrating effects including atherosclerosis plaque progression, changes in cardiac contractility and BP.

1.4.1.3 Nervous System Effects

1.4.1.3.1 Nervous System Effects Associated with Long-Term $PM_{2.5}$ Exposure

The 2009 PM ISA evaluated a small number of experimental animal studies pertaining to the effects of long-term exposures to $PM_{2.5}$ on the nervous system. The literature base has greatly expanded with recent studies providing new information that strengthens the lines of evidence indicating that long-term $PM_{2.5}$ exposure can lead to effects on the brain associated with neurodegeneration (i.e., neuroinflammation and reductions in brain volume), as well as cognitive effects in older adults (Table 1-2). Specifically, animal toxicological studies provide evidence for a range of nervous system effects including neuroinflammation and oxidative stress, neurodegeneration, cognitive effects, and effects on neurodevelopment. The epidemiologic evidence is more limited but multiple studies generally support associations between long-term $PM_{2.5}$ exposure and changes in brain morphology, cognitive decrements and dementia. The consistency and coherence of the evidence across disciplines as it relates to region-specific brain inflammation, morphologic changes in the brain, cognitive effects and dementia in adult populations supports that there is a "*likely to be causal relationship*" between long-term $PM_{2.5}$ exposure and nervous system effects, which is the first time a causality determination has been made for long-term $PM_{2.5}$ exposure and nervous system effects.

There is strong evidence that long-term exposure to $PM_{2.5}$ can modulate the autonomic nervous system leading to downstream consequences including cardiovascular effects (Section 6.2.1). In addition, the pathway involving neuroinflammation in specific regions of the brain (i.e., the hippocampus, cerebral cortex and hypothalamus) and morphologic changes in the brain indicative of neurodegeneration, is well substantiated and coherent across experimental animal and epidemiologic studies (Section 8.2.3, Section 8.2.4). Specifically, morphologic changes induced in the hippocampus of animals were accompanied by impaired learning and memory and there is consistent evidence from multiple, high quality, epidemiologic studies that long-term $PM_{2.5}$ exposure is associated with reduced cognitive function (Section 8.2.5). Further, the presence of early markers of Alzheimer's disease pathology was demonstrated in animals following long-term exposure to $PM_{2.5}$ CAPs and associations with neurodegenerative changes in the brain (i.e., decreased brain volume) and Alzheimer's disease or all-cause dementia were observed in a limited number of epidemiologic studies (Section 8.2.6). Although the loss of dopaminergic neurons in the substantia nigra, which is a hallmark of Parkinson disease, was demonstrated in animals (Section 8.2.4), high quality epidemiologic studies do not report associations

with Parkinson disease (Section 8.2.6. Overall, the lack of consideration of copollutant confounding introduces some uncertainty in the interpretation of the epidemiologic studies but this uncertainty is addressed, in part, by the direct evidence of effects provided by experimental animal studies.

In addition to the findings described above, which are most relevant to adults, several recent studies of neurodevelopmental effects in children have also been conducted. Positive associations between long-term exposure to $PM_{2.5}$ during the prenatal period and autism spectrum disorder (ASD) were consistently observed across multiple epidemiologic studies (Section 8.2.7.2). However, several studies of performance on tests of cognitive function provided little support for an association. Overall, these epidemiologic studies of developmental effects are limited due to their lack of control for potential confounding by copollutants, the small number of studies, and uncertainty regarding critical exposure windows. Biological plausibility is provided for the ASD findings, by a study in animals that found inflammatory and morphologic changes in the corpus collosum and hippocampus, as well as ventriculomegaly in young animals following prenatal exposure to $PM_{2.5}$ CAPs.

1.4.1.4 Cancer

1.4.1.4.1 Cancer Associated with Long-Term $PM_{2.5}$ Exposure

Experimental and epidemiologic evidence indicating genotoxicity, epigenetic effects (i.e., hypo- and hyper-methylation of DNA), and increased carcinogenic potential due to $PM_{2.5}$ exposure, along with strong epidemiologic evidence for increases in lung cancer incidence and mortality, supports a "*likely to be causal relationship*" between long-term $PM_{2.5}$ exposure and cancer (Table 1-2). This causality determination represents a change from the "*suggestive of a causal relationship*"[37] determination reported in the 2009 PM ISA. The evidence base underlying this conclusion encompasses the decades of research on whole PM exposures and more recent research focusing specifically on $PM_{2.5}$.

$PM_{2.5}$ exhibits various characteristics of carcinogens, as shown in studies demonstrating genotoxic effects (e.g., DNA damage), epigenetic alterations, oxidative stress, and electrophilicity. The examination of the role of $PM_{2.5}$ in cancer development has often focused on whether whole PM, not specific size fractions, has mutagenic properties and whether exposure to whole PM results in genotoxicity or carcinogenicity. Additionally, it has been well characterized that some components of $PM_{2.5}$, specifically hexavalent chromium, nickel, arsenic, and PAHs are known human carcinogens. Extensive analyses of $PM_{2.5}$ and $PM_{2.5}$ extracts in the Ames *Salmonella*/mammalian-microsome mutagenicity assay demonstrate that PM contains mutagenic agents (Section 10.2.2.1). Additional in vitro and in vivo toxicological studies indicate the potential for $PM_{2.5}$ exposure to result in DNA damage,

[37] Since the 2009 PM ISA, the causality determination language has been updated and this category is now stated as "*suggestive of, but not sufficient to infer, a causal relationship*".

which is supported by limited human evidence (Section 10.2.2.2). Some studies have also demonstrated that $PM_{2.5}$ exposure can result in cytogenetic effects, specifically micronuclei formation and chromosomal aberrations (Section 10.2.2.3), as well as differential expression of genes potentially relevant to genotoxicity or other aspects of cancer pathogenesis (Section 10.2.2.4). Although inconsistently examined across studies, changes in cellular and molecular markers of genotoxicity and epigenetic alterations, which may lead to genomic instability, are demonstrated in response to $PM_{2.5}$ exposure. Further, the carcinogenic potential of $PM_{2.5}$ was demonstrated in an animal toxicological study in which chronic inhalation enhanced tumor formation that was initiated by exposure to urethane. (Section 10.2.4). Additionally, recent epidemiologic studies encompassing multiple cohorts that are diverse in terms of both geographic coverage and population characteristics, provide evidence of primarily consistent positive associations between long-term $PM_{2.5}$ exposure and lung cancer incidence and mortality, particularly in never smokers (Section 10.2.5.1). Experimental and epidemiologic evidence of genotoxicity, epigenetic effects, and carcinogenic potential provides biological plausibility for epidemiologic results of lung cancer incidence and mortality. Although limited in number, the assessment of potential copollutant confounding, particularly with O_3, indicates that $PM_{2.5}$ associations with lung cancer incidence and mortality are relatively unchanged in copollutant models (Section 10.2.5.1.3). There is limited evidence that long-term $PM_{2.5}$ exposure is associated with cancers in other organ systems; however, there is initial evidence that $PM_{2.5}$ exposure may reduce survival in individuals with cancer.

1.4.1.5 Mortality

Consistent with the conclusions of the 2009 PM ISA, more recently published scientific evidence reaffirms and further strengthens that there is a "*causal relationship*" between both short- and long-term $PM_{2.5}$ exposure and total mortality. These causality determinations are based on the consistency of findings across a large body of epidemiologic studies and coherence among evidence from controlled human exposure, epidemiologic, and toxicological studies, as well as biological plausibility for respiratory and cardiovascular morbidity effects by which short- and long-term $PM_{2.5}$ exposure could result in mortality.

1.4.1.5.1 Mortality Associated with Short-Term $PM_{2.5}$ Exposure

Strong recent and previously available epidemiologic evidence, in combination with evidence for biological plausibility for cause-specific mortality from studies that examined the relationship between short-term $PM_{2.5}$ exposure and cardiovascular and respiratory morbidity, collectively indicates there is a "*causal relationship*" between short-term $PM_{2.5}$ exposure and total (nonaccidental) mortality, which is consistent with the conclusions of the 2009 PM ISA (Table 1-2). This conclusion is based on multiple recent multi-city studies conducted in the U.S., Canada, Europe, and Asia that continue to provide evidence of consistent, positive associations between short-term $PM_{2.5}$ and total mortality, as well as

epidemiologic studies that use study design and/or statistical analyses that further reduce chance, confounding, and other biases.

Recent multi-city studies add to the body of evidence evaluated in the 2009 PM ISA and continue to support a positive association between short-term $PM_{2.5}$ exposure and total mortality with percentage increases in mortality ranging from 0.19−2.80% at lags of 0 to 1 day in studies where mean 24-hour average concentrations were primarily <20 $\mu g/m^3$ (Figure 11-1; Table 11-1). The positive associations observed across studies reflect traditional analyses using ambient monitors as well as analyses conducted in both urban and rural locations that use new exposure assignment techniques and rely on multiple sources of $PM_{2.5}$ data (e.g., ambient monitors, statistical models, and satellite images). Whereas the analysis of potential copollutant confounding was limited to single-city studies and studies of PM_{10} in the 2009 PM ISA, recent multi-city studies conducted in Europe and Asia focusing on $PM_{2.5}$ indicate that $PM_{2.5}$-mortality associations are relatively unchanged in copollutant models with gaseous pollutants and $PM_{10-2.5}$ (Section 11.1.4). These results from copollutant models further support an independent effect of $PM_{2.5}$ on mortality. The associations reported for total mortality are also supported by analyses demonstrating increases in cause-specific mortality, specifically for cardiovascular and respiratory mortality which comprise ~33 and ~9%, respectively, of total mortality (NHLBI, 2017) (Figure 11-2). The consistent and coherent evidence across scientific disciplines for cardiovascular morbidity, particularly ischemic events and heart failure (CHAPTER 6), and to a lesser degree for respiratory morbidity, with the strongest evidence for exacerbations of COPD and asthma (CHAPTER 5), provide biological plausibility for cause-specific mortality and ultimately total mortality. The relationship between short-term $PM_{2.5}$ exposure and total mortality is additionally supported by analyses that examined the concentration-response (C-R) relationship that continue to provide evidence of a linear, no-threshold relationship, although studies have not conducted extensive systematic evaluations of alternatives to linearity (Section 11.1.10).

1.4.1.5.2 Mortality Associated with Long-Term $PM_{2.5}$ Exposure

Strong recent and previously available epidemiologic evidence from cohorts in the U.S., Canada, and Europe demonstrates that there is a "*causal relationship*" between long-term $PM_{2.5}$ exposure and total mortality, which is consistent with the conclusions of the 2009 PM ISA (Table 1-2). This conclusion is based on multiple cohorts that continue to provide evidence of consistent, positive associations, as well as continued characterization of the relationship between long-term $PM_{2.5}$ exposure and total (nonaccidental) mortality through analyses that further reduce chance, confounding, and other biases. Additional evidence indicating coherence of effects across scientific disciplines for cardiovascular and respiratory morbidity and metabolic disease provides biological plausibility for cause-specific mortality, and supports the causal relationship with total mortality.

Additional reanalyses and extensions of the American Cancer Society (ACS) and Harvard Six Cities (HSC) cohorts as well as new cohorts consisting of Medicare participants, people that live in

Canada, or people employed in a specific job (e.g., teacher, nurse, etc.) further support a positive association between long-term $PM_{2.5}$ exposure and total mortality, particularly in areas with annual mean concentrations <20 μg/m^3, and in some cases below 12 μg/m^3 (Figure 11-17 and Figure 11-18). Across studies, positive associations were consistently observed regardless of the exposure assignment approach employed, with some studies relying on ambient monitors while others used modeled or remote sensing data or hybrid methods that combine two or more data sources. Recent studies have conducted analyses to examine potential copollutant confounding and indicate that associations between long-term $PM_{2.5}$ exposure and total mortality are relatively unchanged in copollutant models particularly with O_3, with more limited evidence for NO_2, and $PM_{10-2.5}$ (Section 11.2.3; Figure 11-20, Figure 11-21). The evidence for total mortality is further supported by analyses of cause-specific mortality, which report positive associations with cardiovascular, respiratory, and lung cancer mortality. The coherence of effects across scientific disciplines for cardiovascular morbidity, particularly for CHD, stroke and atherosclerosis, and respiratory morbidity for the development of COPD, contribute to providing biological plausibility for mortality due to long-term $PM_{2.5}$ exposure. Recent studies extensively examined the C-R relationship between long-term $PM_{2.5}$ exposure and total mortality, specifically in several U.S. and Canadian cohorts, and collectively continue to support a linear, no-threshold C-R relationship (Section 11.2.4; Table 11-7).

A recent series of studies evaluates the relationship between long-term exposure to $PM_{2.5}$ and mortality by examining the temporal trends in $PM_{2.5}$ concentrations and changes in life expectancy, testing the hypothesis that decreases in $PM_{2.5}$ concentrations would be associated with increases in life expectancy (Section 11.2.2.6). These studies reported that decreases in long-term $PM_{2.5}$ concentrations were associated with an increase in life expectancy across the U.S. for multiple time periods examined.

Table 1-2 Key Evidence contributing to "causal" and "likely to be causal" causality determinations for $PM_{2.5}$ exposure and health effects evaluated in the current draft Integrated Science Assessment for Particulate Matter.

Key Evidence	Health Effect Category[a] and Causality Determination	$PM_{2.5}$ Concentrations Associated with Effects
Respiratory Effects and Short-Term $PM_{2.5}$ Exposure (Section 5.1.12): Likely to be Causal Relationship *No change in causality determination from the 2009 PM ISA; new evidence further supports the previous determination.*		
Section 5.1.12 Table 5-18	Epidemiologic evidence, consisting mainly of hospital admissions and emergency department visits, strongly supports a relationship with asthma exacerbation, COPD exacerbation, and combinations of respiratory-related diseases. Evidence for associations with respiratory symptoms and medication use are coherent with other findings for asthma exacerbation and COPD exacerbation. Some epidemiologic studies examined copollutant confounding and reported that results are robust in models with gaseous pollutants (i.e., O_3, NO_2, SO_2, and with more limited evidence for CO) and other particle sizes (i.e., $PM_{10-2.5}$), especially for asthma exacerbation, aggregated respiratory conditions, and respiratory mortality. There is a large body of experimental evidence, some of which is coherent with epidemiologic study results, demonstrating respiratory effects due to short-term $PM_{2.5}$ exposure. These experimental studies provide evidence for biologically plausible pathways by which $PM_{2.5}$ exposure can impart a respiratory effect. Specifically, animal toxicological studies provide biological plausibility for asthma exacerbation, COPD exacerbation and respiratory infection and some evidence of an independent effect of $PM_{2.5}$ on respiratory endpoints. Controlled human exposure studies provide minimal evidence of respiratory effects, specifically decrements in lung function and pulmonary inflammation. Consistent positive associations with respiratory mortality provide evidence of a continuum of effects.	Mean ambient concentrations from epidemiologic studies for: *Hospital Admissions and Emergency Department Visits for Asthma, COPD, Respiratory Infections and Combinations of Respiratory-related Diseases:* U.S. and Canada: 4.7−24. 6 µg/m³ Europe: 8.8−27.7 µg/m³ Asia: 11.8−69.9 µg/m³ *Respiratory mortality:* U.S. and Canada: 7.9−19.9 µg/m³ Europe: 8.0−27.7 µg/m³ Asia: 11.8−69.9 µg/m³ Concentrations from animal toxicological studies for: *Allergic airway disease:* 442−596 µg/m³

Table 1-2 (Continued): Key Evidence contributing to "causal" and "likely to be causal" causality determinations for $PM_{2.5}$ exposure and health effects evaluated in the current draft Integrated Science Assessment for Particulate Matter.

Key Evidence	Health Effect Category[a] and Causality Determination	$PM_{2.5}$ Concentrations Associated with Effects
Section 5.1.12 Table 5-18 (continued)		*COPD:* 171−1,200 µg/m³ *Altered host defense:* 100−350 µg/m³
Respiratory Effects and Long-Term $PM_{2.5}$ Exposure (Section 5.2.13): Likely to be Causal Relationship *No change in causality determination from the 2009 PM ISA; new evidence further supports the previous determination.*		
Section 5.2.13 Table 5-28	Epidemiologic evidence strongly supports a relationship with decrements in lung function growth in children. Additional epidemiologic evidence supports a relationship with asthma development in children, with increased bronchitic symptoms in children with asthma, with an acceleration of lung function decline in adults, and with respiratory mortality and cause-specific respiratory mortality for COPD and respiratory infection. Some epidemiologic studies examined copollutant confounding and reported that results are robust in models with O_3, NO_2, and CO, especially for respiratory mortality. There is limited experimental evidence for these respiratory effects due to long-term $PM_{2.5}$ exposure. However, animal toxicological studies provide biological plausibility for decrements in lung function and asthma development in children, and reduce uncertainty regarding the independent effect of $PM_{2.5}$ for these endpoints. Animal toxicological studies also provide evidence for a wide variety of other biological effects, such as oxidative stress, inflammation and morphologic changes. Epidemiologic studies examining the effects of declining $PM_{2.5}$ concentrations, strengthen the relationship between long-term $PM_{2.5}$ exposure and respiratory health by demonstrating improvements in lung function growth and reduced bronchitic symptoms in children and improved lung function in adults as a result of lower $PM_{2.5}$ concentrations. However, within these studies there is limited examination of copollutant confounding, which is a notable uncertainty due to the corresponding decline in concentrations of other pollutants.	Mean ambient concentrations from epidemiologic studies for: *Decrement in lung function growth:* 6–28 µg/m³ *Asthma development in children:* 5.2−16.5 µg/m³ *Bronchitic symptoms in children with asthma:* 9.9−13.8 µg/m³ *Accelerated lung function decline in adults:* 9.5−17.8 µg/m³ *Respiratory mortality:* 6.3−23.6 µg/m³ Concentrations from animal toxicological studies for: *Impaired lung development:* 16.8 µg/m³ *Development of allergic airway disease:* 100 µg/m³

Table 1-2 (Continued): Key Evidence contributing to "causal" and "likely to be causal" causality determinations for $PM_{2.5}$ exposure and health effects evaluated in the current draft Integrated Science Assessment for Particulate Matter.

Key Evidence	Health Effect Category[a] and Causality Determination	$PM_{2.5}$ Concentrations Associated with Effects
Cardiovascular Effects and Short-Term $PM_{2.5}$ Exposure (Section 6.1.16): Causal Relationship *No change in causality determination from the 2009 PM ISA; new evidence further supports the previous determination.*		
Section 6.1.16 Table 6-33	There is strong evidence for coherence of effects across scientific disciplines and biological plausibility for a range of cardiovascular effects in response to short-term $PM_{2.5}$ exposure. Consistent epidemiologic evidence from multiple, high-quality studies at relevant $PM_{2.5}$ concentrations provide evidence of increases in emergency department visits and hospital admissions for IHD and HF, as well as cardiovascular mortality in multi-city studies conducted in the U.S., Canada, Europe, and Asia. These associations remain positive, but in some cases are reduced with larger uncertainty estimates, in copollutant models with gaseous pollutants. Evidence from controlled human exposure studies provide coherent and consistent evidence for changes in various measures of endothelial dysfunction and generally consistent evidence of changes in blood pressure. These controlled human exposure studies are in agreement with animal toxicological studies also demonstrating endothelial dysfunction and changes in blood pressure or the renin angiotensin system. In addition, animal toxicological studies demonstrating that short-term $PM_{2.5}$ exposure results in decreased cardiac contractility and left ventricular pressure are coherent with epidemiologic studies reporting associations between short-term $PM_{2.5}$ exposure and HF.	Mean ambient concentrations from epidemiologic studies for: *IHD:* 5.8−18.6 µg/m³ *HF:* 5.8−18.0 µg/m³ Concentrations from controlled human exposure studies: 24−325 µg/m³ for 2 h Concentrations from animal toxicological studies: 178−190 µg/m³

Table 1-2 (Continued): Key Evidence contributing to "causal" and "likely to be causal" causality determinations for $PM_{2.5}$ exposure and health effects evaluated in the current draft Integrated Science Assessment for Particulate Matter.

Key Evidence	Health Effect Category[a] and Causality Determination	$PM_{2.5}$ Concentrations Associated with Effects
Cardiovascular Effects and Long-Term $PM_{2.5}$ Exposure (Section 6.2.18): Causal Relationship *No change in causality determination from the 2009 PM ISA; new evidence further supports the previous determination.*		
Section 6.2.18 Table 6-52	Multiple high-quality epidemiologic studies continue to provide evidence of consistent, positive associations between long-term $PM_{2.5}$ exposure and cardiovascular mortality at lower ambient concentrations. The cardiovascular mortality associations were observed across different exposure assignment and statistical methods, and were relatively unchanged in copollutant models with both gaseous (i.e., O_3, NO_2, SO_2) and particle (i.e., $PM_{10-2.5}$) pollutants. The evidence for cardiovascular mortality, is supported by a smaller body of epidemiologic studies that further explored associations between long-term $PM_{2.5}$ exposure and cardiovascular morbidity, and reported some evidence for increased risk of $PM_{2.5}$-related MI and stroke, specifically in individuals with a pre-existing cardiovascular disease or diabetes. Recent epidemiologic studies also present evidence for an effect of long-term $PM_{2.5}$ exposure on subclinical features of cardiovascular morbidity, particularly progression of atherosclerosis as reflected by associations with coronary artery calcification (CAC), with more limited evidence for other measures, such as carotid intima-media thickness (CIMT). Key evidence from long-term animal toxicological studies includes consistent evidence for changes in BP, as well as some evidence for decreases in measures of heart function (e.g., contractility and cardiac output) and cardiac remodeling. Moreover, as in the previous review, there is also some additional evidence for atherosclerotic plaque progression in a genetically susceptible mouse model.	Mean ambient concentrations from epidemiologic studies for: *Cardiovascular mortality*: 4.1−17.9 µg/m^3 *Coronary events*: 13.4 µg/m^3 *CAC*: 14.2 µg/m^3 *CHD and Stroke (in those with pre-existing disease)*: 13.4−23.9 µg/m^3 Concentrations from animal toxicological studies for: *Blood pressure*: 85−375 µg/m^3 (up to 15 weeks)
Nervous System Effects and Long-Term $PM_{2.5}$ Exposure (Section 8.2.9): Likely to be Causal Relationship *Not evaluated in the 2009 PM ISA; new evidence showing brain inflammation and oxidative stress, neurodegeneration, cognitive effects, and neurodevelopmental effects.*		
Section 8.2.9 Table 8-20	There is evidence that long-term exposure to $PM_{2.5}$ can modulate the autonomic nervous system leading to downstream consequences including cardiovascular effects (Section 6.2.1). A second pathway involving neuroinflammation and morphologic changes in the brain indicative of neurodegeneration, is well substantiated and coherent across experimental animal and epidemiologic studies. The evidence relating to Parkinson disease, and neurodevelopmental effects was more limited. Consideration of copollutant confounding was generally lacking in the epidemiologic studies but the uncertainty in the interpretation of study findings was addressed, in part, by the direct evidence of effects provided by experimental animal studies.	Mean annual concentrations from epidemiologic studies for: *Brain volume:* 11.1−12.2 µg/m^3 *Cognition:* 8.5 (5-yr avg)–14.9 µg/m^3 *Autism:* 14.0−19.6 µg/m^3

Table 1-2 (Continued): Key Evidence contributing to "causal" and "likely to be causal" causality determinations for $PM_{2.5}$ exposure and health effects evaluated in the current draft Integrated Science Assessment for Particulate Matter.

Key Evidence	Health Effect Category[a] and Causality Determination	$PM_{2.5}$ Concentrations Associated with Effects
Section 8.2.9 Table 8-20 (continued)		Concentrations from animal toxicological studies for: *Brain inflammation/Oxidative stress:* 65.7−441.7 μg/m^3 *Neurodegenerative changes:* 94.4 μg/m^3 *Neurodevelopment:* 92.7 μg/m^3
Cancer and Long-Term $PM_{2.5}$ Exposure (Section 10.2): Likely to be Causal Relationship *Change in causality determination from the 2009 PM ISA (suggestive of a causal relationship) due to increased evidence of genotoxicity, carcinogenicity, and epigenetic effects for $PM_{2.5}$ and lung cancer incidence and mortality.*		
Section 10.2.6 Table 10-8	Primarily positive associations from multiple, high-quality studies for increases in lung cancer incidence and mortality. This evidence is supported by analyses focusing on never smokers and limited evidence of associations with histological subtypes of lung cancer found in never smokers. Across studies that examined lung cancer incidence and mortality potential confounding by smoking status and exposure to SHS was adequately controlled. A limited number of studies examined potential copollutant confounding, but associations were relatively unchanged in models with O_3 with more limited assessment of other gaseous pollutants and particle size fractions. Experimental and epidemiologic studies provide evidence for a relationship between $PM_{2.5}$ exposure and genotoxicity, epigenetic effects, and carcinogenic potential. Uncertainties exist due to the lack of consistency in specific cancer-related biomarkers associated with $PM_{2.5}$ exposure across both experimental and epidemiologic studies; however, $PM_{2.5}$ exhibits several characteristics of carcinogens. This provides biological plausibility for $PM_{2.5}$ exposure contributing to cancer development. Additionally, there is limited evidence of cancer occurring in other organ systems, but there is some evidence that $PM_{2.5}$ exposure may detrimentally impact survival from any type of cancer.	Mean annual concentrations from epidemiologic studies for: *Lung cancer incidence and mortality*: U.S. and Canada: 6.3−23.6 μg/m^3 Europe: 6.6−31.0 μg/m^3 Asia: 33.7 μg/m^3 Concentrations from animal toxicological studies for: *Carcinogenic potential:* 17.66 μg/m^3

Table 1-2 (Continued): Key Evidence contributing to "causal" and "likely to be causal" causality determinations for $PM_{2.5}$ exposure and health effects evaluated in the current draft Integrated Science Assessment for Particulate Matter.

Key Evidence	Health Effect Category[a] and Causality Determination	$PM_{2.5}$ Concentrations Associated with Effects
Total Mortality and Short-Term $PM_{2.5}$ Exposure (Section 11.1.12): Causal Relationship *No change in causality determination from the 2009 PM ISA; new evidence further supports the previous determination.*		
Section 11.1.12 Table 11-4	There is consistent epidemiologic evidence from multiple, high quality studies of increases in total (nonaccidental) mortality in multi-city studies conducted in the U.S., Canada, Europe, and Asia at ambient concentrations often below 20 µg/m^3. The associations observed were relatively unchanged in copollutant models with gaseous pollutants and $PM_{10-2.5}$, which is consistent with copollutant analyses for cardiovascular and respiratory mortality, but copollutant analyses were limited to studies conducted in Europe and Asia. Biological plausibility for the epidemiologic evidence for total mortality is provided by the strong cardiovascular morbidity evidence, particularly for ischemic events and heart failure, while support for biological plausibility is more limited from the respiratory morbidity evidence, with the strongest evidence for exacerbations of COPD and asthma. Although alternatives to linearity have not been systematically evaluated, recent mortality studies continue to support a linear, no-threshold C-R relationship.	Mean 24-h avg concentrations from epidemiologic studies for: *Total Mortality*: U.S. and Canada: 4.37−17.97 µg/m^3 Europe: 13−27.7 µg/m^3 Asia: 11.8−69.9 µg/m^3

Table 1-2 (Continued): Key Evidence contributing to "causal" and "likely to be causal" causality determinations for $PM_{2.5}$ exposure and health effects evaluated in the current draft Integrated Science Assessment for Particulate Matter.

Key Evidence	Health Effect Category[a] and Causality Determination	$PM_{2.5}$ Concentrations Associated with Effects
Total Mortality and Long-Term $PM_{2.5}$ Exposure (Section 11.2.7): Causal Relationship *No change in causality determination from the 2009 PM ISA; new evidence further supports the previous determination.*		
Section 11.2.7 Table 11-8	There is consistent epidemiologic evidence from multiple, high-quality studies of increases in total (nonaccidental) mortality from extended follow-ups of the American Cancer Society (ACS) cohort and Harvard Six Cities (HSC) cohort, as well as multiple studies focusing on a Medicare cohort, Canadian cohorts, and North American employment cohorts. The consistent increases in total mortality are observed across different exposure metrics based on ambient measurements, models, remote sensing, or hybrid methods that combine two or more of these methods, providing additional support for the mortality associations due to long-term $PM_{2.5}$ exposure reported in the 2009 PM ISA that relied on exposure metrics from ambient monitors. The consistent epidemiologic evidence for total mortality is supported by positive associations for cardiovascular, respiratory, and lung cancer mortality. Biological plausibility for total mortality is provided by the strong cardiovascular morbidity evidence, particularly for CHD, stroke, and atherosclerosis, while there is more limited evidence for biological plausibility from the respiratory morbidity evidence, with some evidence for development of COPD. Extensive epidemiologic evidence provides additional support for a linear, no-threshold concentration-response (C-R) relationship. A recent series of studies demonstrates that decreases in long-term $PM_{2.5}$ concentrations were associated with an increase in life expectancy across the U.S. for multiple time periods examined.	Mean annual concentrations from epidemiologic studies for: *Total mortality*: ACS/HSC Cohorts: 11.4−23.6 µg/m^3 Medicare Cohort: 8.12−12.0 µg/m^3 Canadian Cohorts: 8.7−9.1 µg/m^3 Employment Cohorts: 12.7−17.0 µg/m^3

CHD = coronary heart disease; COPD = chronic obstructive pulmonary disease; SHS = second hand smoke.

[a]A large spectrum of outcomes is evaluated as part of a broad health effect category including physiological measures (e.g., airway responsiveness, lung function), clinical outcomes (e.g., respiratory symptoms, hospital admissions), and cause-specific mortality. Total mortality includes all nonaccidental causes of mortality and is informed by the nature of the evidence for the spectrum of morbidity effects (e.g., respiratory, cardiovascular) that can lead to mortality. The sections and tables referenced include a detailed discussion of the available evidence that informed the causality determinations.

1.4.2 Health Effects of $PM_{10-2.5}$

At the completion of the 2009 PM ISA, substantial uncertainties remained in the evaluation of the health effects due to short- and long-term $PM_{10-2.5}$ exposures (U.S. EPA, 2009). This was due to a variety of factors including the inability of particles within the $PM_{10-2.5}$ size range to reach the lower respiratory tract of rodents due to nasal deposition (see Figure 4-4) and instead relying on intra-tracheal instillation to assess health effects, and epidemiologic studies relying on multiple methods of varying quality to estimate $PM_{10-2.5}$ concentrations (e.g., direct measurement through dichotomous samplers, difference between collocated PM_{10} and $PM_{2.5}$ monitors, difference between county-wide average PM_{10} and $PM_{2.5}$ when monitors were not collocated), which had not been systematically compared and potentially contributed to different degrees of exposure measurement error. Limited availability of data and higher spatial variability of $PM_{10-2.5}$ compared with $PM_{2.5}$ also contributed to uncertainty about the representativeness of the $PM_{10-2.5}$ concentrations as a surrogate for exposure.

Recent epidemiologic and experimental studies continue to examine the relationship between short- and long-term $PM_{10-2.5}$ exposure and health effects; however, the uncertainties in the evidence identified in the 2009 PM ISA have, to date, still not been addressed. Specifically, within the epidemiologic studies, there is evidence of positive associations across the various health effects evaluated, but the methods used to estimate $PM_{10-2.5}$ concentrations and subsequently assign exposures to $PM_{10-2.5}$ have not been systematically evaluated in the peer-reviewed literature (see Section 3.3.1.1). Overall, this contributes to uncertainty with respect to the spatial and temporal correlations in $PM_{10-2.5}$ concentrations across methods, which may add to uncertainties in $PM_{10-2.5}$ exposure surrogates given the larger spatial and temporal variability in $PM_{10-2.5}$ concentrations compared to $PM_{2.5}$ (see Section 2.5.1.2.3). Evidence from experimental studies in humans combined with evidence from epidemiologic panel studies and limited evidence from animal toxicological studies continues to provide some evidence to support biologically plausible pathways by which $PM_{10-2.5}$ could impart a variety of health effects. Overall, the uncertainties surrounding the evidence providing biological plausibility for health effects related to $PM_{10-2.5}$ exposure and the methods used to assign $PM_{10-2.5}$ exposure in epidemiologic studies collectively contributed to causality determinations across health effects categories of "*suggestive of, but not sufficient to infer, a causal relationship*" or "*inadequate to infer the presence or absence of a causal relationship*" (Table 1-7).

1.4.3 Health Effects of UFPs

At the completion of the 2009 PM ISA, relatively few studies examined the health effects attributed to short- and long-term UFP exposures. Across broad health categories there was limited and often inconsistent evidence of effects. There was some evidence of cardiovascular and respiratory effects due to UFP CAPs from controlled human exposure and animal toxicological studies with more evidence

from studies of diesel exhaust, but in the diesel exhaust studies it was not possible to determine if the effect observed was due to UFPs, gaseous components, or a combination of the two. Additionally, there were broader uncertainties that spanned atmospheric chemistry, exposure assessment, and epidemiology due to limited information on the spatial and temporal variability in UFP concentrations; the lack of a UFP monitoring network in the U.S.; and insufficient data on the composition of UFPs. These uncertainties were further reflected in epidemiologic studies as a result of most studies relying on a single monitor to estimate UFP exposure.

Recent studies have further explored the relationship between short- and long-term UFP exposure and health effects; however, the assessment of study results across experimental and epidemiologic studies is complicated by the size distribution examined in each discipline and the nonuniformity in the exposure metric examined (i.e., the particle size range and indicators [e.g., particle number concentration (NC), surface area concentration (SC), and mass concentration (MC)]) (see Preface). Specifically, experimental studies include size ranges up to 200 nm or higher. Epidemiologic studies often focus on various size ranges below 100 nm. However, if an epidemiologic study is focusing on NC it can include larger particle sizes, but it has been shown that 67−90% of NC represents particles <100 nm (Section 2.4.3.1).

Although there is some evidence of positive but imprecise associations across epidemiologic studies examining a range of health effects (e.g., cardiovascular and respiratory effects, and mortality), study results are difficult to interpret. This is due to most studies' reliance on a single monitor, which is inadequate as has been reflected in some monitoring campaigns that demonstrate a high degree of spatial variability in UFP concentrations and that the size distribution of UFPs changes with distance from source (Section 2.5.1). As noted above, examining coherence and biological plausibility of UFP-related health effects is complicated by the larger size distribution of UFPs examined in experimental studies compared with the size distribution examined in epidemiologic studies. Based on these overarching uncertainties and inconsistency across studies in the characterization of UFP with respect to size distribution and exposure metric, across most health effects categories the evidence collectively contributed to causality determinations that did not exceed "*suggestive of, but not sufficient to infer, a causal relationship*" (Table 1-7).

1.4.3.1 Nervous System Effects Associated with Long-Term UFP Exposure

The limited findings reported in the 2009 PM ISA indicated that subchronic exposure to UFP CAPs resulted in pro-inflammatory changes in the cortical region of the brains of mice and it was hypothesized that ambient UFP may reach the brain via olfactory transport based on studies demonstrating this mechanism using laboratory generated UFPs. The recent literature has greatly expanded, demonstrating overt neurological changes and providing some evidence suggesting potential translocation of UFPs via olfactory transport. Animal toxicological studies provide evidence for several

nervous system effects due to long-term UFP exposure including brain inflammation and oxidative stress, morphologic changes, and behavioral effects. Epidemiologic evidence is limited to a single study providing initial evidence of effects on attention and memory, but more broadly uncertainties remain with respect to effects due to long-term UFP exposure, specifically due to the uncharacterized temporal and spatial variability in UFP concentrations. Overall, the strong animal toxicological evidence of neurotoxicity and altered neurodevelopment supports a "*likely to be causal relationship*" between long-term UFP exposure and nervous system effects, which represents the first time a causality determination has been made for long-term UFP exposure and nervous system effects (Table 1-3).

Multiple toxicological studies of long-term UFP exposure conducted in adult animals provide consistent evidence of brain inflammation and oxidative stress in the whole brain, hippocampus, and cerebral cortex (Section 8.6.3). Studies also found morphologic changes, specifically neurodegeneration in specific regions of the hippocampus and pathologic changes characteristic of Alzheimer's disease, and initial evidence of behavioral effects in adult mice (Section 8.6.4 and Section 8.6.5). Toxicological studies examining pre- and post-natal UFP exposures provide extensive evidence for behavioral effects, altered neurotransmitters, neuroinflammation, and morphologic changes (Section 8.6.6.2). Persistent ventriculomegaly was observed in male, but not female mice, exposed postnatally to UFP (Section 8.6.6). Epidemiologic evidence is limited to a study of school children that provides support for the experimental results. This study, which did not consider copollutant confounding, reported an association between long-term exposure to UFP, which was measured at the school, and decrements on tests of attention and memory. In general, epidemiologic studies of long term exposure to UFP are sparse because there are challenges in capturing the spatial variation in long-term UFP concentrations that can result in substantial exposure measurement error (Section 8.6.7).

Table 1-3 Key Evidence contributing to a "likely to be causal" causality determination for UFP exposure and health effects evaluated in the current draft Integrated Science Assessment for Particulate Matter.

Key Evidence	Health Effect Category[a] and Causality Determination	UFP Concentrations Associated with Effects
Nervous System Effects and Long-Term UFP Exposure (Section 8.6.7): Likely to be Causal Relationship *Not evaluated in the 2009 PM ISA; new evidence showing brain inflammation and oxidative stress, neurodegeneration, cognitive effects, and neurodevelopmental effects.*		
Section 8.6.7 Table 8-34	Animal toxicological studies provide strong evidence for nervous system effects due to long-term UFP exposure including neuroinflammation, neurodegeneration, and altered neurodevelopment. Multiple toxicological studies conducted in adult animals provided consistent evidence of inflammation and oxidative stress in the whole brain, hippocampus, and cerebral cortex, as well as more limited evidence for neurodegeneration, Alzheimer's disease-related pathology, and behavioral effects. Experimental animal studies examining pre- and post-natal UFP exposures provide evidence for behavioral effects, altered neurotransmitters, neuroinflammation, and morphologic changes, including persistent ventriculomegaly. The epidemiologic evidence was limited to a study, that did not consider copollutant confounding, that provides initial evidence of that UFP may affect attention and memory in school children.	Concentrations from animal toxicological studies for: *Brain inflammation/Oxidative stress:* MC: 342−468 μg/m^3 NC: 140,000−254,000 particles/cm^3 *Neurodegenerative changes:* MC: 342−468 μg/m^3 NC: 140,000−254,000 particles/cm^3 *Cognitive and behavioral effects in adults:* MC: 342 μg/m^3 NC: 140,000 particles/cm^3 *Neurodevelopment:* 96.4−350 μg/m^3 NC: 180,000−200,000 particles/cm^3

MC = mass concentration; NC = number concentration.

[a]A large spectrum of outcomes is evaluated as part of a broad health effect category including physiological measures (e.g., airway responsiveness, lung function), clinical outcomes (e.g., respiratory symptoms, hospital admissions), and cause-specific mortality. The sections and tables referenced include a detailed discussion of the available evidence that informed the causality determinations.

1.5 Policy-Relevant Considerations

In the process of evaluating the current state of the science with respect to the effect of short- and long-term PM exposure on health, studies were identified that conducted analyses focused on addressing some of the main policy-relevant questions of this review, as detailed in the PM IRP (U.S. EPA, 2016), such as:

- Is there new evidence aimed at disentangling the effect of PM from the complex air pollution mixture to inform a direct effect of PM on health, specifically the assessment of potential copollutant confounding?
- Is there new evidence to inform the current indicators (i.e., $PM_{2.5}$ for fine particles and PM_{10} for thoracic coarse particles), averaging times (i.e., 24-hour average, annual average), and levels of the PM NAAQS?
- Is there new evidence on the shape of the concentration-response relationship and whether a threshold hold exists between PM exposure and various health outcomes (e.g., mortality, hospital admissions, etc.), especially for concentrations near or below the levels of the current PM NAAQS?
- Is there new evidence that individual PM component(s) or source(s) (e.g., industrial facilities, roads, atmospheric formation), are more strongly associated with health effects than PM mass, particularly for health effects for which there is sufficient evidence of a strong relationship (e.g., cardiovascular effects, mortality) with PM exposure?
- Is there new evidence indicating that specific populations or lifestages are at increased risk of a PM-related health effect compared to a referent population?

The following sections summarize the evidence that can inform consideration of these policy-relevant questions, specifically: potential copollutant confounding (Section 1.5.1), timing of effects (Section 1.5.2), concentration-response (C-R) relationship (1.5.3), PM components and sources (Section 1.5.4), and populations potentially at increased risk of a PM-related health effect (Section 1.5.5).

1.5.1 Potential Copollutant Confounding

Recent studies further evaluated the potential confounding effects of copollutants, both gaseous and particulate, on the relationship between short- and long-term $PM_{2.5}$ exposure and health effects. These studies build upon the evidence detailed in the 2009 PM ISA and continue to provide evidence indicating that associations with $PM_{2.5}$ are relatively unchanged in copollutant models. Evidence from epidemiologic studies, in combination with experimental studies detailed in previous chapters (i.e., Respiratory Effects-CHAPTER 5 and Cardiovascular Effects-CHAPTER 6) that examined exposure to PM (e.g., CAPs, resuspended PM, and whole mixtures in the presence and absence of a particle trap), demonstrate a direct effect of PM on health.

1.5.1.1 Short-term $PM_{2.5}$ Exposure

Building upon the studies evaluated in the 2009 PM ISA, recent epidemiologic studies have further examined whether copollutants confound associations between short-term $PM_{2.5}$ exposure and respiratory and cardiovascular effects and mortality. These studies continue to demonstrate $PM_{2.5}$-associations are relatively unchanged in copollutant models with both gaseous (i.e., O_3, NO_2, SO_2, and CO) and particulate (i.e., $PM_{10–2.5}$) pollutants.

The examination of potential copollutant confounding on the relationship between short-term $PM_{2.5}$ exposure and respiratory effects has been assessed most extensively through studies examining respiratory-related emergency department visits and hospital admissions, particularly for asthma, with more limited assessments of COPD and respiratory infection, and studies examining respiratory mortality (Section 5.1.10.1). Correlations between $PM_{2.5}$ and gaseous and particulate pollutants varied across studies, with low-to-moderate correlations (i.e., <0.7) observed for NO_2, SO_2, CO, and $PM_{10–2.5}$, and correlations spanning low-to-high for O_3. O_3 was most commonly examined, followed by NO_2, across the studies that assessed copollutant confounding, and $PM_{2.5}$ results were relatively unchanged in copollutant models. Although fewer studies focused on SO_2 and CO, the results from copollutant analyses were consistent with studies evaluated in the 2009 PM ISA, indicating that results are relatively unchanged in copollutant models. Recent studies that examined $PM_{10–2.5}$ further expand upon the initial results detailed in the 2009 PM ISA, and although results are consistent with observations from analyses of gaseous pollutants, there is greater uncertainty in these results due to the various methods employed across studies to estimate $PM_{10–2.5}$ concentrations.

While studies of respiratory-related emergency department visits and hospital admissions and respiratory mortality reported the strongest correlations between $PM_{2.5}$ and O_3, for cardiovascular effects moderate-to-strong correlations were reported for NO_2 and CO, with low to moderate correlations for O_3, SO_2, and $PM_{10–2.5}$. Across studies of various cardiovascular-related emergency department visits and hospital admissions and cardiovascular mortality, results were relatively unchanged in copollutant models, but there were some instances of attenuation of the $PM_{2.5}$ association in models with NO_2 and CO (Section 6.1.14.1). Overall, there was not an observed difference in the trend or pattern of copollutant model results across cardiovascular endpoints (e.g., aggregate CVD endpoints, IHD, heart failure, cardiovascular mortality). However, the few instances of attenuation were with traffic-related pollutants (i.e., NO_2, CO), which generally had higher correlations with $PM_{2.5}$ than the other copollutants. As a result, it is difficult to distinguish if the instances of observed attenuation in $PM_{2.5}$ associations are due to confounding or collinearity between pollutants.

Compared to epidemiologic studies that examined the potential confounding effects of copollutants on respiratory and cardiovascular effects, a more limited number of studies focused on mortality (Section 11.1.4). Recent multi-city studies conducted in Europe and Asia support the single- and multi-city studies examined in the 2004 PM AQCD and 2009 PM ISA that reported limited evidence of confounding by copollutants. Across studies examining both gaseous and particulate (i.e., $PM_{10–2.5}$)

pollutants, low-to-moderate correlations were reported with $PM_{2.5}$. Associations with $PM_{2.5}$ were relatively unchanged in copollutant models across the various study locations examined.

In addition to conducting traditional copollutant analyses, epidemiologic studies of respiratory (Section 5.1.10.1.1) and cardiovascular (Section 6.1.14.1.1) effects have also examined the role of PM within the broader air pollution mixture. These studies do not inform whether PM is independently associated with a respiratory effect, but they can assess whether days with higher $PM_{2.5}$ concentrations are more closely related to health effects. Studies of respiratory effects demonstrate that days where the air pollution mixture has high $PM_{2.5}$ concentrations often represent the days with the largest associations (in terms of magnitude) with a respiratory effect. Additionally, results indicate that risk estimates for a mixture are often similar, but in some cases larger, than those reported for $PM_{2.5}$ alone. However, for cardiovascular effects, generally, the evidence neither consistently or coherently indicated a stronger or weaker effect of combined exposure to $PM_{2.5}$ and another pollutant compared to exposure to $PM_{2.5}$ and other pollutants alone.

1.5.1.2 Long-term $PM_{2.5}$ Exposure

Epidemiologic studies focusing on long-term $PM_{2.5}$ exposure and health effects have traditionally provided a more limited assessment of the potential confounding effects of copollutants on $PM_{2.5}$ associations. Recent studies provide the initial evidence to inform copollutant confounding for some health outcomes, while in other instances (e.g., mortality) an assessment of copollutant confounding directly addresses a previously identified uncertainty in the scientific evidence.

Across the health effects evaluated within this ISA, relatively few studies examined the potential confounding effects of copollutants on the relationship between long-term $PM_{2.5}$ exposure and respiratory (Section 5.2.13), cardiovascular (Section 6.2.18), and cancer (Section 10.2.7), with a general lack of studies of assessing the role of copollutant confounding on observed associations with nervous system effects (Section 8.2.9). These studies often did not examine the full suite of gaseous pollutants, but tended to focus on traffic-related pollutants (i.e., NO_2, NO_X, and CO) and O_3, with some studies also examining $PM_{10-2.5}$. Across studies low-to-moderate correlations (i.e., $r < 0.7$) were often observed between copollutants and $PM_{2.5}$. Collectively, studies that examined the potential confounding effects of copollutants on the $PM_{2.5}$ association with respiratory (i.e., lung function and asthma development) and cardiovascular effects (i.e., cardiovascular mortality), along with lung cancer incidence and mortality, reported associations that were relatively unchanged in copollutant models, but these assessments were conducted in a limited number of studies.

Compared to other health effects, several studies of long-term $PM_{2.5}$ exposure and mortality examine potential copollutant confounding. Within studies that examined the potential confounding effects of copollutants on the relationship between long-term $PM_{2.5}$ exposure and mortality, the most extensive analyses occurred for O_3, with a limited number of studies examining NO_2, SO_2, $PM_{10-2.5}$, and

the air toxic, benzene. Studies that examined O_3 reported correlations that were generally moderate (ranging from $r = 0.49–0.73$), with a few studies reporting weak correlations ($r < 0.4$). Overall, associations remained relatively unchanged in copollutant models for total (nonaccidental) mortality, cardiovascular, and respiratory mortality (Figure 11-18). Studies focusing on copollutant models with NO_2, $PM_{10–2.5}$, SO_2 and benzene were examined in individual studies, and across these studies the $PM_{2.5}$-mortality association was relatively unchanged (Figure 11-19).

1.5.2 Timing of Effects

An important question to address when evaluating the scientific evidence demonstrating health effects due to short-term $PM_{2.5}$ exposure is the timing of observed effects. Studies have attempted to address this question through two primary avenues: (1) examining various averaging times of the exposure metric used to represent short-term exposure to $PM_{2.5}$ to determine whether PM averaged over time periods other than 24-hours are more closely associated with health effects; and (2) assessing whether the relationship between exposure and effect is biologically plausible by examining the lag days over which associations are observed.

1.5.2.1 Averaging Time

Most epidemiologic studies that examine the relationship between short-term $PM_{2.5}$ exposures and health effects rely primarily on an exposure metric that is averaged over 24-hours. Some recent studies, focusing on respiratory and cardiovascular effects and mortality, have examined whether there is evidence that subdaily exposure metrics are more closely related to health effects than the traditional 24-hour average metric.

Epidemiologic studies that examined both respiratory-related emergency department visits and hospital admissions as well as subclinical markers of respiratory effects explored associations with subdaily exposure metrics (Section 5.1.10.5). In studies of respiratory-related emergency department visits and hospital admissions, positive associations were not consistently observed with subdaily exposure metrics, and often there was no information on spatiotemporal variability of the subdaily metrics. Additionally, in a study that examined multiple subdaily averaging times and compared them to the 24-hour average exposure metric there was no difference in associations across metrics, but this was limited to a single study location. Panel studies also examined subdaily exposure metrics through personal monitoring, but associations were not consistently observed at these shorter averaging times for markers of pulmonary inflammation and changes in lung function.

A more limited number of studies examined subdaily exposure metrics and cardiovascular effects (Section 6.1.14.3). Studies of ST-elevation, myocardial infarction, out-of-hospital cardiac arrest, and cerebrovascular disease emergency department visits and hospital admissions reported positive

associations with subdaily exposure metrics, but the magnitude of the association tended to be larger when averaging over multiple hours up to one day (i.e., 24-hour average). These studies provide evidence that continues to support the use of a 24-hour average exposure metric.

A few studies examined subdaily $PM_{2.5}$ exposure metrics and associations with mortality, focusing on comparisons between the 24-hour average and an hourly peak exposure metric (Section 11.1.8.2). In these studies, positive associations were reported for both the 24-hour average and hourly peak exposure metric with the association often slightly larger in magnitude for the 24-hour average metric. Collectively, the available evidence does not indicate that subdaily averaging periods for $PM_{2.5}$ are more closely associated with health effects than the 24-hour average exposure metric.

1.5.2.2 Lag Structure of Associations

Often epidemiologic studies have examined associations between short-term $PM_{2.5}$ exposure and health effects over a series of single-day lags, multi-day lags, or by selecting lags *a priori*. Recent studies have expanded the assessment of examining the timing of effects by systematically examining lag days by focusing on whether there is evidence of an immediate (e.g., lag 0−1 days), delayed (e.g., lag 2−5 days), or prolonged (e.g., lag 0−5 days) effect of PM on health.

Epidemiologic studies of respiratory effects have primarily focused on examining the lag structure of associations for respiratory-related emergency department visits and hospital admissions, with most studies examining asthma with a more limited assessment for COPD and respiratory infection (Section 5.1.10.3). Across the studies that examined asthma, COPD, respiratory infections and combinations of respiratory-related diseases, the strongest association reported, in terms of magnitude and precision, is generally within a few days after exposure, but there is some evidence demonstrating the potential for a prolonged effect of $PM_{2.5}$ (i.e., lags ranging from 0−5 days). Recent studies of respiratory mortality provide additional insight on the lag structure of associations for respiratory-related effects due to short-term $PM_{2.5}$ exposure. Studies of respiratory mortality tend to support more immediate $PM_{2.5}$ effects (i.e., lags of 0 to 2 days), but initial evidence of stronger associations, in terms of magnitude and precision, at lags of 0−5 days. Collectively, the studies of respiratory morbidity and mortality that conducted systematic evaluations of $PM_{2.5}$ associations across a range of lags, provide evidence of effects within the range of 0–5 days after exposure.

Similar to respiratory effects, the majority of epidemiologic studies examining the lag structure of associations for cardiovascular effects focus on cardiovascular-related emergency department visits and hospital admissions. Studies of IHD, MI and cardiovascular-related outcomes emergency department visits and hospital admissions reported stronger associations for multi-day lags, but these effects tended to be in the range of 0−1 or 0−2 days. When examining cerebrovascular disease there was no evidence of an association at any of the lag days examined; however, when focusing on specific stroke types, particularly ischemic stroke there was evidence of immediate effects at lags of 0 and 1 day, which is consistent with

other cardiovascular outcomes. The immediate effects of $PM_{2.5}$ on cardiovascular morbidity outcomes, specifically those related to ischemic events, are consistent with the lag structure of associations observed in studies of cardiovascular mortality that report immediate effects (i.e., lag 0−1 day). There is some evidence indicating $PM_{2.5}$-cardviovascular mortality associations with exposures over longer durations, but this is not supported by studies examining single-day lags that encompass the same number of days.

An evaluation of recent epidemiologic studies of short-term $PM_{2.5}$ exposure and mortality found that studies either conducted analyses of single-day lags over many days or various iterations of multi-day lags (e.g., 0−1, 0−2, 0−3, etc.) (Section 11.1.8.1). Across studies, associations were largest in terms of magnitude and precision for total (nonaccidental) mortality at lags of 0 to 1 day, but there is some evidence that associations remain positive at multi-day lags up to 0−4 days. The combination of the multi- and single-day lag analyses provides further support of an immediate effect of short-term $PM_{2.5}$ exposure on mortality.

1.5.3 Concentration-Response (C-R) Relationship

In assessing the relationship-between short- and long-term PM exposure and health effects, an important consideration is whether the relationship is linear across the full range of ambient concentrations and whether there is a threshold concentration below which there is no evidence of an effect. As detailed in the 2004 AQCD and 2009 PM ISA, conducting C-R and threshold analyses is challenging due to the "(1) limited range of available concentration levels (i.e., sparse data at the low and high end); (2) heterogeneity of (at-risk) populations (between cities); and (3) influence of measurement error" (U.S. EPA, 2004). Recent studies that focus on the shape of the C-R curve expand upon the health effects evaluated in previous reviews and continue to provide evidence of a linear, no threshold, relationship between both short- and long-term $PM_{2.5}$ exposure and several respiratory and cardiovascular effects, and mortality, with some recent evidence indicating a steeper slope (i.e., supralinear curve) at lower concentrations for some outcomes (i.e., long-term $PM_{2.5}$ exposure and mortality). However, cut-point analyses that focus on whether risk changes at different concentration ranges provide some evidence of nonlinearity, specifically in the relationship between short-term $PM_{2.5}$ exposure and respiratory-related emergency department visits and hospital admissions. It is important to note that although recent studies have used many different statistical methods to examine the shape of the C-R relationship and generally provide evidence for a linear, no-threshold relationship, many of these studies have not systematically evaluated alternatives to a linear relationship.

1.5.3.1 Short-Term Exposure

Recent epidemiologic studies that examined the C-R relationship between short-term $PM_{2.5}$ exposure and health are limited to studies of respiratory-related emergency department visits and hospital

admissions (Section 5.1.10.6), and mortality (Section 11.1.10). Across studies that examined respiratory effects, different analytical methods have been employed to examine the C-R relationship, either explicitly examining the shape of the C-R curve and whether there is evidence of linearity across the full range of $PM_{2.5}$ concentrations, or through cut-point analyses that examine whether the risk of a $PM_{2.5}$-related respiratory effect changes within specified ranges of $PM_{2.5}$ concentrations. These studies primarily focused on asthma emergency department visits and hospital admissions, with some studies examining combinations of respiratory emergency department visits and hospital admissions. Studies that focused on the shape of the C-R curve provide initial evidence of a linear relationship for short-term $PM_{2.5}$ exposure and both respiratory disease and asthma hospital admissions and emergency department visits, with less certainty at concentrations below 10 $\mu g/m^3$. However, cut-point analyses provide some initial evidence indicating nonlinearity in the relationship (i.e., larger risk estimates at various quintiles when compared to the lowest quintile) between short-term $PM_{2.5}$ exposure and asthma emergency department visits and hospital admissions.

The examination of the C-R relationship for short-term PM exposure and mortality was initially limited to studies of PM_{10}. Recent epidemiologic studies focus on $PM_{2.5}$ and specifically the shape of the C-R curve at the low end of the $PM_{2.5}$ concentration distribution. Evidence from U.S. studies, which can examine the shape of the C-R curve at lower $PM_{2.5}$ concentrations compared to other countries, provide evidence indicating a linear relationship at concentrations as low as 5 $\mu g/m^3$. The observations from C-R analyses are further supported by cut-point analyses examining associations at different $PM_{2.5}$ concentrations as well as analyses that reported no evidence of a threshold. Overall, recent studies focusing on short-term $PM_{2.5}$ exposure and mortality support a linear, no threshold relationship at ambient $PM_{2.5}$ concentrations lower than those evaluated in the 2009 PM ISA.

1.5.3.2 Long-Term Exposure

The most extensive analyses of the C-R relationship between long-term PM exposure and a health outcome traditionally has been for $PM_{2.5}$ and mortality. Recent studies further expand and provide new insights on the relationship between long-term $PM_{2.5}$ exposure and mortality, and provide initial examinations of the C-R relationship for respiratory and cardiovascular effects, as well as lung cancer mortality and incidence.

While the assessment of the C-R relationship for long-term $PM_{2.5}$ exposure is more limited for most health outcomes, it has been extensively examined in studies of mortality (Section 11.2.4). Across studies a variety of statistical methods have been examined to assess whether there is evidence of deviations in linearity as well as cut point analysis that focus on examining risk at specific ambient concentrations (Table 11-7). These studies report results that generally support a linear, no-threshold relationship for total (nonaccidental) mortality, especially at lower ambient $PM_{2.5}$ concentrations, with confidence in some studies in the range of 5−8 $\mu g/m^3$. Additionally, there is initial evidence indicating

that the slope of the C-R curve may be steeper (supralinear) at lower concentrations for cardiovascular mortality.

Epidemiologic studies examining the C-R relationship for long-term $PM_{2.5}$ exposure and respiratory effects (Section 5.3.2.1.1) are limited in number and focus on asthma incidence and childhood wheeze. Studies of asthma incidence that examine the shape of the C-R curve and whether risk changes at different quartiles of $PM_{2.5}$ concentrations do not find any evidence for deviations in linearity and evidence of monotonically increasing risk, respectively. In an initial study of childhood wheeze, specifically repeated wheeze events, there is evidence of a linear C-R relationship with the greatest confidence at long-term $PM_{2.5}$ concentrations ranging from 10 to 12 $\mu g/m^3$.

A limited number of studies report initial assessments of the C-R relationship for long-term $PM_{2.5}$ concentrations and cardiovascular effects, specifically IHD incidence, coronary artery calcification (CAC), and hypertension (Section 6.2.16). For IHD incidence, there was evidence of a linear C-R relationship at concentrations below 15 $\mu g/m^3$, which is consistent with the shape of the curve when compared to the full range of $PM_{2.5}$ concentrations. Analyses of the relationship between long-term $PM_{2.5}$ exposure and CAC indicated both linear and nonlinear relationships, while there is initial evidence of a linear relationship between long-term $PM_{2.5}$ exposure and incidence of hypertension. A few studies that examined the relationship between long-term $PM_{2.5}$ exposure and lung cancer incidence and mortality also examined the shape of the C-R curve through assessments of linearity, and cut-point and threshold analyses (Section 10.2.5.1.4). These collective assessments provide initial evidence supporting a no-threshold, linear relationship across the range of $PM_{2.5}$ concentrations observed in the U.S., with confidence in some studies in the range of 5−10 $\mu g/m^3$.

1.5.4 PM Components and Sources

Building upon the initial evaluation conducted in the 2004 PM AQCD, the 2009 PM ISA conducted a formal evaluation of the relationship between exposures to PM components and sources and health effects. Through the evaluation of experimental and epidemiologic studies that focused on individual PM components as well as studies that used quantitative approaches aimed at reducing the correlation between components it was identified that many components and sources representative of combustion-related activities (e.g., motor vehicle emissions, coal combustion, oil burning, vegetative burning) are associated with a range of health effects. This assessment led to the 2009 PM ISA concluding that "many [components] of PM can be linked with differing health effects and the evidence is not yet sufficient to allow differentiation of those components or sources that are more closely related to specific health outcomes".

Building upon the evaluation of PM sources and components in the 2009 PM ISA, and as detailed in the Preface , this PM ISA systematically evaluated whether there was evidence that specific PM components or sources are more strongly associated with health effects than PM mass by focusing on

those studies that: (1) included a composite metric of PM (e.g., mass of $PM_{2.5}$ and/or $PM_{10–2.5}$, or in the case of ultrafine particles [UFP] mass, particle number, etc.) and PM components; (2) applied some approach to assess the particle effect (e.g., particle trap) of a mixture; or (3) conducted formal statistical analyses using source-based exposures that were not defined a priori (see Preface). Overall, these criteria allow for a thorough evaluation of whether there is evidence that an individual component(s) and/or source(s) is more closely related to health effects than PM mass. Across the health effects categories evaluated in this ISA, most studies that examine PM sources and components focus on $PM_{2.5}$. As such, the following sections summarize the current state of the science on $PM_{2.5}$ components and sources for those health effects categories where it was concluded that a "causal" or "likely to be causal" relationship exists, with details on the $PM_{2.5}$ components and sources evidence for the other health effects categories (e.g., Reproductive and Developmental Effects) in subsequent health chapters of this ISA.

Overall, recent studies continue to demonstrate that many $PM_{2.5}$ components and sources are associated with health effects ranging from subclinical (e.g., changes in heart function, such as HRV, or circulating biomarkers) to the more overt (i.e., emergency department visits, hospital admissions, and mortality). The results of these studies confirm and further support the conclusion of the 2009 PM ISA, i.e., that many $PM_{2.5}$ components and sources are associated with many health effects, and the evidence does not indicate that any one source or component is consistently more strongly related with health effects than $PM_{2.5}$ mass.

1.5.4.1 Respiratory Effects

The examination of $PM_{2.5}$ components and sources and respiratory effects was limited to epidemiologic studies (Section 5.1.11). Epidemiologic studies that examined associations between short-term $PM_{2.5}$ components and respiratory health effects and examined associations with $PM_{2.5}$ mass (n = 113), primarily focus on the components nitrate (n = 29), sulfate (n = 40), OC (n = 50), and EC/BC (n = 95). Across these studies the health effects examined range from inflammation and changes in lung function to respiratory-related emergency department visits and hospital admissions. When examining the pattern of associations for individual $PM_{2.5}$ components with those observed for $PM_{2.5}$ mass, all the components examined (i.e., evaluated in at least three studies) were positively associated with a respiratory effect in at least a few studies (Section 5.1.11.7). For EC/BC, the most extensively examined $PM_{2.5}$ component, many studies reported positive associations, but some studies also reported results indicating no association, which is consistent with the pattern of associations for $PM_{2.5}$ mass.

A more limited number of studies examined associations between long-term $PM_{2.5}$ components and respiratory effects (Section 5.2.12). Similar to short-term exposure studies, the majority of studies focus on EC/BC, and did not observe a different pattern of associations with respiratory effects than what was observed for $PM_{2.5}$ mass. Collectively, positive associations were observed in studies examining

short- and long-term $PM_{2.5}$ component exposure and respiratory effects, but there is no evidence that any one component is more strongly associated with respiratory effects than $PM_{2.5}$ mass.

Few studies examined the relationship between $PM_{2.5}$ sources and respiratory health effects. Through analyses where $PM_{2.5}$ components were apportioned into source factors, positive associations were reported for several respiratory effects, particularly asthma exacerbation, and sources representative of combustion-related activities, such as traffic and biomass burning. There were no recent studies that examined long-term exposure to $PM_{2.5}$ sources and respiratory effects.

1.5.4.2 Cardiovascular Effects

Both epidemiologic and experimental studies examined the relationship between $PM_{2.5}$ component and sources exposures and cardiovascular effects (Section 6.1.15). In short-term exposure studies, the epidemiologic evidence focuses on studies examining cardiovascular-related emergency department visits and hospital admissions with only a few studies examining other cardiovascular effects. Similar to studies examining respiratory effects and $PM_{2.5}$ components, of the studies that examined both $PM_{2.5}$ mass and components (n = 14), the most extensively examined components include EC (n = 12), OC (n = 10), sulfate (N = 9), and nitrate (n = 9). Across all components examined, most were positively associated with cardiovascular-related emergency department visits and hospital admissions in at least one study (Section 6.1.15). Although EC was positively associated with cardiovascular-related emergency department visits and hospital admissions in many of the studies evaluated, it was not possible to decipher if EC was independently associated or a marker of exposure to $PM_{2.5}$ mass.

Studies examining long-term exposure to $PM_{2.5}$ components and cardiovascular effects were few, and consistent with the long-term exposure and respiratory effects studies primarily focus on EC/BC (Section 6.2.17). These studies did not provide evidence that any one component is more strongly associated with a cardiovascular effect. Collectively, studies examining short- and long-term $PM_{2.5}$ components exposure continue to support there is not one component that is more strongly associated with a cardiovascular effect than $PM_{2.5}$ mass.

Epidemiologic and animal toxicological studies conducted source based analyses using mathematical methods to apportion $PM_{2.5}$ components into source factors (Section 6.1.15.6 and Section 6.1.15.8). Epidemiologic studies focused on cardiovascular-related emergency department visits and hospital admissions and reported positive associations with sources representative of combustion-related activities (e.g., industrial combustion, traffic), with more limited evidence for wildfires. Animal toxicological studies, which focused on markers of heart function (e.g., HR, HRV), reported associations with a variety of source categories, but the associations were dependent on the location of the study (i.e., where the $PM_{2.5}$ CAPS were collected). Additional studies focusing on long-term exposures to $PM_{2.5}$ sources were fewer in number, with epidemiologic studies only examining traffic

sources and animal toxicological studies reporting associations with a number of sources and various cardiovascular effects.

1.5.4.3 Mortality

Epidemiologic studies that examined associations with $PM_{2.5}$ components and sources and mortality have primarily focused on examining short- and long-term exposures to components (Section 11.1.11 and Section 11.2.6). Both short- and long-term exposure studies reported consistent, positive associations with $PM_{2.5}$ mass across all studies that also examined a component. While for respiratory and cardiovascular effects most studies focused on EC/BC, for studies of mortality no one component was disproportionally examined compared to the rest. Of the $PM_{2.5}$ components examined, each were found to be positively associated with mortality in at least a few studies, but overall one component was not found to be as consistently associated with mortality as $PM_{2.5}$ mass.

Compared to the 2009 PM ISA, where most epidemiologic studies of mortality conducted formal source apportionment analyses, recent studies focus more exclusively on $PM_{2.5}$ components. Of the limited number of studies that examined associations between short- and long-term source exposures and mortality, positive associations were observed for those sources representative of combustion-related activities including traffic, coal, and vegetative fires.

1.5.5 Populations and Lifestages at Potentially Increased Risk of a PM-related Health Effect

An important consideration in the evaluation of the scientific evidence for PM, and in the consideration of the extent to which the NAAQS provides public health protection with an adequate margin of safety, is whether specific populations or lifestages are at increased risk of a PM-related health effect. As detailed in the preceding sections of this chapter and subsequent chapters of this ISA, a large body of evidence demonstrates health effects related to PM exposure, particularly $PM_{2.5}$ exposure, across populations with diverse characteristics (e.g., children, older adults, people with pre-existing cardiovascular diseases, etc.). While this larger body of evidence informs the causal nature of the relationship between PM exposure and health effects, this section focuses on answering the question:

Are there specific populations and lifestages at increased risk of a PM-related health effect, compared to a reference population? That is, is the magnitude of effect or exposure greater for some populations or lifestages compared to a reference population, where applicable, or are health effects observed at lower PM concentrations for some populations or lifestages compared to others?

The evaluation of populations and lifestages potentially at increased risk builds off the approach used in the 2009 PM ISA and includes the application of a framework to characterize the evidence

informing increased risk detailed in the 2013 O_3 ISA (U.S. EPA, 2013). The focus of this evaluation is on determining the extent to which specific factors may increase the risk of a PM-related health effect in a population or lifestage relative to a reference population, where applicable. Importantly, this builds on the conclusions drawn elsewhere in the ISA, taking into consideration the relationship between exposure to PM and health effects. As detailed in the Preamble to the ISAs (U.S. EPA, 2015), the evaluation of the evidence includes (1) epidemiologic studies that conducted stratified analyses, (2) evidence from animal toxicological studies using animal models of disease and epidemiologic or controlled human exposure studies conducted in specific populations (e.g., lung function growth in children, people with mild asthma), (3) information on the dosimetry of PM within the body, and (4) consideration of information on differential exposure to PM within a population or lifestage. Overall, the framework allows for a transparent characterization of the collective body of evidence in order to draw conclusions on the degree to which the scientific evidence indicates that a specific population or lifestage is at increased risk of a PM-related health effect (Table 12-1).

Based on the causality determinations briefly summarized within this chapter, and more fully detailed in subsequent chapters, the strongest evidence indicating an effect of short- and long-term PM exposure on health is for $PM_{2.5}$ and the broad health categories of respiratory and cardiovascular effects, cancer, and mortality. As a result, the assessment of populations and lifestages potentially at increased risk of a $PM_{2.5}$-related health effect primarily focuses on studies that form the basis of these causality determinations that also conducted analyses to inform whether there is differential risk in a specific population or lifestage. It is important to note that in the evaluation of studies a number of factors can influence the ability to observe an association including, but not limited to, publication bias (i.e., not reporting null findings when examining evidence of differential risk), variability in how indicators or metrics are defined across studies (e.g., socioeconomic status, obesity, age), and variability in the population as a whole, particularly with respect to behavioral differences, biological differences (e.g., obese vs. nonobese), and adherence to treatment for pre-existing diseases.

Of the factors evaluated (see Table 12-18 for a full list), children and race were the only factors for which it was concluded that "*adequate evidence*" was available indicating that people of a specific lifestage and race are at increased risk of $PM_{2.5}$-related health effects (Section 12.5.1.1 and Section 12.5.4). For children, although stratified analyses do not indicate a difference in the risk of PM-related health effects between children and adults, there is strong evidence from studies focusing on children demonstrating health effects that are only observable in growing children, attributed to $PM_{2.5}$ exposure. Particularly recent epidemiologic studies of long-term $PM_{2.5}$ exposure have provided strong evidence of impaired lung function growth with additional evidence of decrements in lung function and asthma development. These longitudinal epidemiologic studies are consistent with and extend the evidence that was available in the 2009 PM ISA demonstrating health effects in children due to long-term $PM_{2.5}$ exposure. For race, this conclusion was based on studies that examined whether there was evidence of increased risk for $PM_{2.5}$-related health effects as well as studies focusing on whether there was evidence of differential exposure by race. Multiple studies reported that nonwhite populations across

different geographical regions are exposed to higher $PM_{2.5}$ concentrations and at increased risk for $PM_{2.5}$-related mortality, particularly due to long-term exposure. Collectively, the combination of evidence demonstrated that nonwhite populations are at increased risk for both $PM_{2.5}$-related health effects and $PM_{2.5}$ exposure compared to whites.

It was concluded that there is "*suggestive evidence"* that populations with pre-existing cardiovascular (Section 12.3.1) or respiratory (Section 12.3.5) disease, that are overweight or obese (Section 12.3.3), with particular genetic variants (Section 12.4), or that are of low SES (Section 12.5.3) are at increased risk for $PM_{2.5}$-related health effects. Epidemiologic studies that conducted analyses stratified by pre-existing cardiovascular disease tended to focus on hypertension, one of the most easily measurable cardiovascular conditions, and did not consistently indicate increased risk for several outcomes examined (e.g., mortality, stroke, blood pressure). However, the strong evidence supporting a "*causal relationship*" between short- and long-term $PM_{2.5}$ exposure cardiovascular-related mortality and ischemic heart disease (Section 6.1.16 and Section 6.2.18) indicates that individuals with underlying cardiovascular conditions related to these serious outcomes may be at increased risk of a $PM_{2.5}$-related health effect. Similarly, when evaluating pre-existing respiratory diseases, including asthma (Section 12.3.5) and COPD (Section 12.3.5), there are a limited number of studies evaluating whether there is evidence of increased risk between people with pre-existing asthma and COPD and those that do not have a pre-existing respiratory disease. However, it is important to note that epidemiologic studies, particularly those studies examining short-term $PM_{2.5}$ exposure and asthma or COPD emergency department visits and hospital admissions report generally consistent positive associations (Section 5.1.2.1 and Section 5.1.4.1), which represent exacerbations that are only possible in people with asthma or COPD. Therefore, there is limited evidence to support that people with pre-existing respiratory diseases, specifically asthma or COPD, are at increased risk for a $PM_{2.5}$-related health effect, but there is generally consistent evidence demonstrating these populations experience health effects due to a $PM_{2.5}$ exposure. Studies that examined the role of being obese or overweight on the risk of a $PM_{2.5}$-related health effect, reported evidence of increased risk for mortality associated with long-term exposures to $PM_{2.5}$, but inconsistent evidence for subclinical cardiovascular outcomes, when comparing obese or overweight individuals to normal weight individuals. However, the evaluation of studies focusing on differences in risk by weight were complicated by the different definitions of obesity used across studies. The examination of whether specific genetic characteristics dictate increased risk of a $PM_{2.5}$-related health effect is based on studies of a variety of genetic variants. Across the large number of genetic variants examined there is a consistent trend for increased risk of respiratory and cardiovascular effects associated with $PM_{2.5}$ exposure across gene variants involved in the glutathione pathway. These results are consistent with underlying mechanisms that provide biological plausibility for $PM_{2.5}$-related health effects and have shown that oxidative stress is an early response to $PM_{2.5}$ exposure. Lastly, epidemiologic studies have examined several measures of SES (e.g., income level, educational attainment, etc.) in assessing whether populations are at increased risk of a $PM_{2.5}$-related health effect. In studies examining both differential exposure as well as increased risk of health effects, there is some evidence that low SES populations are more likely to have higher $PM_{2.5}$ exposures and that low SES populations, as measured by metrics for

income, are at increased risk of $PM_{2.5}$-related mortality when compared to populations defined as higher SES.

For the remaining factors evaluated, "*inadequate evidence*" exists to determine whether having diabetes (Section 12.3.2), being in an older lifestage (i.e. older adults) (Section 12.5.1.2), residential location (including proximity to source and urban residence; Section 12.5.5), sex (Section 12.5.2), or diet (Section 12.6.2) increase the risk of $PM_{2.5}$-related health effects. Across these factors there is either limited assessment of differential risk or exposure (i.e., residential location, diet), or inconsistency in results across studies to support evidence of increased risk of a $PM_{2.5}$-related health effect (i.e., diabetes and sex). However, as stated previously this does not indicate there is no evidence of a $PM_{2.5}$-related health effect for these populations and lifestages, but limits the assessment of determining whether a specific population is at disproportionately increased risk of a health effect. For example, for older adults (Section 12.5.1.2) there is a relatively small number of studies that examined whether there is evidence of differential risk between age groups. In the evaluation of these studies there is limited evidence indicating that older adults are at increased risk of $PM_{2.5}$-related health effects when compared to other age ranges; however, epidemiologic studies focusing only on older adults demonstrate associations with respiratory-related emergency department visits and hospital admissions with additional, but more limited, evidence from epidemiologic panel studies and controlled human exposure studies that observed associations between $PM_{2.5}$ exposure and subclinical cardiovascular effects.

1.6 Welfare Effects of PM

Whereas the evaluation of the evidence for PM exposures and health effects are specific to exposure duration (i.e., short- and long-term) and PM size fraction (i.e., $PM_{2.5}$, $PM_{10–2.5}$, and UFP), the evaluation of the evidence for welfare effects focuses generally on whether there is a causal relationship between PM and visibility impairment, climate effects, and effects on materials. As detailed below, the evidence continues to support a "*causal relationship*" between PM and visibility impairment (Section 1.6.1), climate effects (Section 1.6.2), and materials effects (Section 1.6.3).

1.6.1 Visibility Impairment

It has been well characterized that light extinction from pollution is primarily due to $PM_{2.5}$, resulting in the conclusion that there is a "*causal relationship*" between PM and visibility impairment, which is consistent with the conclusions of the 2009 PM ISA (Table 1-4). This conclusion is based on additional characterization of the impact of PM size and composition on light extinction.

The relationship between PM and light extinction has been well documented (Section 13.2.2). Although reconstruction of light extinction is best achieved with detailed information on the size and

composition of PM measurements, empirical relationships between light extinction of PM components are more practical and have been successfully evaluated and widely used (Section 13.2.3). Light extinction has been found to vary depending on the available PM species monitoring data, with light extinction efficiencies varying by a factor of 10 between species. Additionally, the variation in PM species by region and season as well as urban and rural location can impact light extinction. The steep decline in $PM_{2.5}$ sulfate of −4.6% per year in rural areas and −6.2% per year in urban areas from 2002−2012 (Section 1.2.1) has impacted the apportionment of light extinction among $PM_{2.5}$ species. Although $PM_{2.5}$ sulfate is still responsible for more light extinction than any other single species, visibility in many areas has improved, and a smaller and less seasonally variable fraction of light extinction can be attributed to $PM_{2.5}$ sulfate, and an increasing share is due to nitrate and organic matter (Section 13.2.4).

1.6.2 Climate Effects

Substantial evidence indicates that PM affects the radiative forcing of the climate system, both through direct scattering and absorption of radiation, and indirectly, by altering cloud properties, resulting in the conclusion that there is a "*causal relationship*" between PM and climate effects, which is consistent with the conclusions of the 2009 PM ISA (Table 1-4). This conclusion is based on multiple recent studies that have strengthened the evidence for the effects of PM on radiative forcing and have improved the characterization of major sources of uncertainty in estimating PM climate effects, including the indirect radiative forcing effects associated with PM-cloud interactions, and the additional climate impacts and feedbacks involving atmospheric circulation and the hydrologic cycle resulting from PM effects on radiative forcing.

Due to these radiative effects, the net effect of PM has been to cool the planet over the last century, masking some of the effects of greenhouse gases on warming (Section 13.3.3). The decrease in PM concentrations in many developed countries over the last few decades has likely contributed to the recent shift toward "global brightening," which may in turn have helped drive rapid warming in North American and Europe as this greenhouse-gas warming was unmasked (Section 13.3.6). In developing countries in Asia, by contrast, there has been an increase in PM concentrations over the last several decades, but the associated radiative forcing effects are highly uncertain, due to uncertainties in emissions estimates and the lack of accurate information on the proportion of reflecting versus absorbing species. Although uncertainties in the relationship between PM and climate effects have been further elucidated since the 2009 PM ISA, there are still substantial uncertainties with respect to key processes linking PM and climate, specifically clouds and aerosols. This is because of the small scale of PM-relevant cloud microphysical processes compared to the resolution of state-of-the-art models, and because of the complex cascade of indirect impacts and feedbacks in the climate system that result from a given initial radiative perturbation caused by PM.

1.6.3 Materials Effects

Multiple recent studies further characterize soiling and corrosion processes associated with PM and add to the body of evidence of PM damage to materials. Approaches to quantify pollutant exposure corresponding to perceived soiling and damage continue to indicate that deposition can result in increased cleaning and maintenance costs and reduced usefulness of soiled material. The combination of this evidence results in the conclusion that there is a "*causal relationship*" between PM and effects on materials, which is consistent with the conclusions of the 2009 PM ISA (Table 1-4).

Assessments of the relationship between PM and effects on materials have often focused on quantitative assessments including the development of dose-response relationships and application of damage functions to stone used for historic monuments and buildings. Recent studies provide additional information on understanding soiling and corrosion process for glass and metals, and allowed for the development of new dose-response curves (Section 13.4.3), particularly for glass as well as new damage functions for materials (Section 13.4.4). Additional evidence demonstrates that atmospheric soiling can impact energy costs and climate control, energy consumption of large buildings, and efficiency of photovoltaic systems (Section 13.4.2).

Table 1-4 Key Evidence contributing to a "causal" causality determination for PM exposure and welfare effects evaluated in the current draft Integrated Science Assessment for Particulate Matter.

Key Evidence	Welfare Effect Category[a] and Causality Determination
Visibility Impairment and PM Exposure (Section 13.2): Causal Relationship	
No change in causality determination from the 2009 PM ISA; new evidence further supports the previous determination.	
Section 13.2.6	Visibility impairment by atmospheric PM with the strongest effects in the size range from 0.1 to 1.0 µm, is supported by numerous studies summarized in the 1969 PM AQCD (NAPCA, 1969), although the relationship between PM and atmospheric visibility impairment was well-established decades earlier. Additional studies supporting the relationship have been described in subsequent documents, and additional new evidence is based on extensive simultaneous network measurements of $PM_{2.5}$ and light extinction.
Climate Effects and PM Exposure (Section 13.3): Causal Relationship	
No change in causality determination from the 2009 PM ISA; new evidence further supports the previous determination.	
Section 13.3.9	Effects of PM on radiative forcing of the climate system through both absorption and scattering of radiation directly, as well as through indirect effects involving interactions between PM and cloud droplets, with corresponding impacts on temperature, precipitation, and atmospheric circulation, is supported by numerous observational and modeling studies. Research since the 2009 ISA (U.S. EPA, 2009) has improved understanding of climate-relevant aerosol properties and processes, as well as characterization of key sources of uncertainty in estimating PM climate effects, particularly with respect to PM-cloud interactions.
Materials Effects and PM Exposure (Section 13.4): Causal Relationship	
No change in causality determination from the 2009 PM ISA; new evidence further supports the previous determination.	
Section 13.4.5	Both soiling and corrosion associated with PM contribute to materials damage (U.S. EPA, 2009, 2004, 1982). Deposition of PM can physically affect materials by promoting or accelerating the corrosion of metals, by degrading paints and by deteriorating building materials such as stone, concrete and marble. Further characterization of PM effects on glass and metals along with quantitative dose-response relationships and damage functions for stone and other materials lend additional support to the causal relationship in the 2009 ISA. Recent evidence shows that deposition of PM reduces energy efficiency of photovoltaic systems.

[a]The sections referenced include a detailed discussion of the available evidence that informed the causality determinations.

1.7 Summary of Causality Determinations for All Health and Welfare Effects

The preceding sections of this chapter focused on summarizing the key evidence that formed the basis for causality determinations within this ISA. Table 1-5 and Table 1-6 detail the causality determinations for each of the exposure duration and health or welfare effects categories evaluated in this ISA and note whether these conclusions differ from those presented in the 2009 PM ISA.

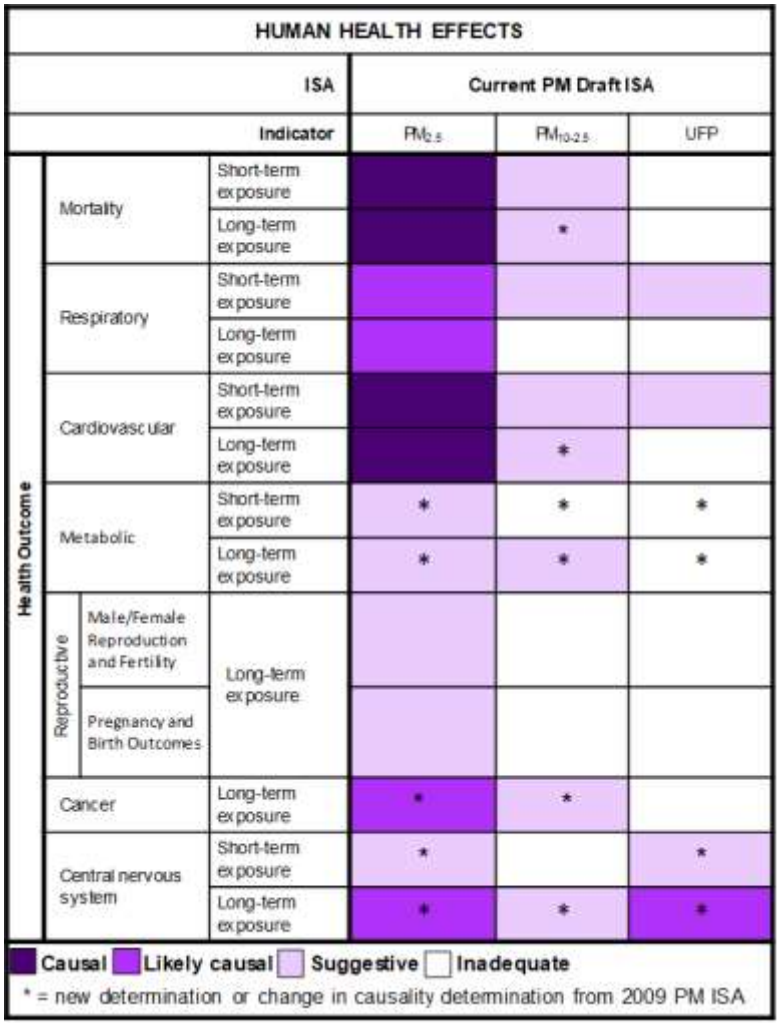
There is extensive scientific evidence that demonstrates health and welfare effects from exposure to PM. In assessing the older and more recent evidence, the U.S. EPA characterizes the key strengths and remaining limitations of this evidence. In the process of assessing the evidence across studies and scientific disciplines and ultimately forming causality determinations, the U.S. EPA takes into consideration multiple aspects that build upon the Hill Criteria (Hill, 1965) and include, but are not limited to consistency in findings, coherence of findings, and evidence of biological plausibility [see U.S. EPA (2015)]. As documented by the extensive evaluation of evidence throughout the subsequent chapters of this ISA, the U.S. EPA carefully considers uncertainties in the evidence, and the extent to which recent studies have addressed or reduced uncertainties from previous assessments, as well as the strengths of the evidence. Uncertainties considered in the epidemiologic evidence, for example, include the potential for confounding by copollutants or covarying factors and exposure error. The U.S. EPA evaluates many other important considerations (not uncertainties) such as coherence of evidence from animal and human studies, evaluation of different PM components, heterogeneity of risk estimates, and the shape of concentration-response relationships. All aspects are evaluated along with the degree to which chance, confounding, and other biases affect interpretation of the scientific evidence in the process of drawing scientific conclusions and making causality determinations. Where there is clear evidence linking PM with health and welfare effects with minimal remaining uncertainties, the U.S. EPA makes a determination of a *causal* or *likely to be causal* relationship (Section P.3, Table P-2).

1.7.1 Health Effects Evidence: Key Findings

A large body of scientific evidence spanning many decades clearly demonstrates there are health effects attributed to both short- and long-term PM exposure, with the strongest evidence for a relationship between some health effects and $PM_{2.5}$. Generally, for most health effects and exposures to $PM_{10-2.5}$ and UFPs, there are more limitations and uncertainties across scientific disciplines (i.e., atmospheric chemistry, exposure science, and both epidemiology and experimental sciences), complicating the interpretation of the evidence. The collective body of evidence for each of the PM size fraction, exposure, and health outcome category combinations evaluated in this ISA was carefully considered and assessed, including the inherent strengths, limitations, and uncertainties in the overall body of evidence such as the

available methods, models and data used within and across studies, resulting in the causality determinations detailed in Table 1-5. Through identification of the strengths and limitations in the evidence this ISA may help in the prioritization of research efforts to support future PM NAAQS reviews. Examples of the key findings that support the health effects causality determinations include:

Table 1-5. Summary of causality determinations for health outcome categories for first draft PM ISA.



Causal and Likely to be Causal Relationship

Epidemiologic evidence:

$PM_{2.5}$

- There are many epidemiologic studies conducted in diverse geographic locations, encompassing different population demographics, and using a variety of exposure assignment techniques, that continue to report consistent positive associations between short- and long-term $PM_{2.5}$ exposure and various health effects. This evidence continues to support the large body of epidemiologic studies reporting positive $PM_{2.5}$ associations with respiratory and cardiovascular effects, and mortality and in some cases strengthens and extends the evidence base.
- Recent epidemiology studies incorporate new $PM_{2.5}$ exposure assignment methods that utilize several sources of available data (i.e., satellite observations, model predictions, and ambient monitors). These methods are well validated by $PM_{2.5}$ monitors in areas with moderate-to-high population density and better allow for the inclusion of less urban areas. Although fewer monitors are available for model validation in sparsely populated rural areas compared with urban areas, $PM_{2.5}$ concentrations are typically lower and more spatially homogeneous in rural areas, resulting in the need for fewer validation sites.
- Each of the exposure assignment methods used in short- and long-term $PM_{2.5}$ exposure epidemiologic studies have inherent strengths and limitations, and vary in the degree they contribute bias and uncertainty to health effects estimates. Exposure errors most often result in the underestimation of health effects associations in short- and long-term $PM_{2.5}$ exposure studies (i.e., health effect associations are even larger than estimated). However, in long-term $PM_{2.5}$ exposure studies health effects associations can be overestimated, specifically when the exposure model has low spatial resolution and underestimates $PM_{2.5}$ exposures.

Experimental evidence:

$PM_{2.5}$ and UFP

- The large number of animal toxicological and controlled human exposure studies conducted since the 2009 PM ISA provide coherence (i.e., an indication of an effect across multiple lines of evidence) and biological plausibility for effects observed in epidemiologic studies of short- or long-term $PM_{2.5}$ exposure. Although experimental studies are conducted at PM concentrations higher than those often observed in ambient environments (e.g., concentrated ambient particle [CAP] exposures 10−15-fold higher), this practice is consistent with the design of experimental studies used in chemical and pharmacological risk assessments.
- There is strong and consistent animal toxicological evidence linking long-term UFP exposure to nervous system effects. This evidence is supported by dosimetric studies in animals showing that particles can translocate out of the respiratory tract into the brain via the olfactory nerve, however, it is unclear whether this translocation occurs in humans as well as in animals. There is also uncertainty surrounding the mechanisms and degree to which particles translocate from the respiratory tract to the brain. However, translocation of particles to the brain may not be required for UFP-related nervous system effects.
- There is uncertainty in the spatial and temporal variability in UFP concentrations and subsequently population exposures to UFPs, questioning the generalizability of the animal toxicological evidence indicating nervous system effects to the population-level.

Policy-relevant considerations:

- The expansion in the number of experimental studies, both animal toxicological and controlled human exposure, using CAP exposures provides evidence of a direct effect of PM exposure on various health effects.
- The $PM_{2.5}$ experimental evidence in combination with the increased number of epidemiologic studies that conducted copollutant analyses show that associations remain relatively unchanged when adjusting for gaseous pollutants and other particle size fractions (e.g., $PM_{10–2.5}$), addressing a key uncertainty identified in the 2009 PM ISA.
- Examination of the concentration-response (C-R) relationship has primarily been conducted for short- and long-term $PM_{2.5}$ exposure and mortality, with a more limited number of analyses examining cardiovascular morbidity effects. Across recent studies that used a variety of statistical methods to examine potential deviations in linearity, evidence continues to support a linear, no-threshold C-R relationship, but with less certainty in the shape of the curve at lower concentrations, i.e., below about 8 $\mu g/m^3$. Additionally, recent evidence from studies of long-term $PM_{2.5}$ exposure and cardiovascular mortality indicate that the C-R curve may be steeper (i.e., supralinear) at lower concentrations.
- Multicity epidemiologic studies, particularly examining short-term $PM_{2.5}$ exposure and mortality, continue to report evidence of heterogeneity in the magnitude and precision of risk estimates across cities. However, recent studies indicate that the observed heterogeneity in risk estimates is not attributed solely to differences in the composition of $PM_{2.5}$, as was hypothesized in the 2009 PM ISA, but also reflects city-specific exposure conditions (e.g., housing and commuting characteristics).
- The combination of evidence spanning atmospheric chemistry, experimental, and epidemiology show that although the composition of ambient $PM_{2.5}$ has changed over time, evidence continues to support that a multitude of $PM_{2.5}$ components and a diverse array of sources are associated with a variety of health effects, and the evidence does not indicate that any one source or component is more strongly related with health effects than $PM_{2.5}$ mass.

Suggestive of, but not Sufficient to Infer, a Causal Relationship

Epidemiologic evidence:

$PM_{2.5}$

- Recent epidemiologic studies examining short- or long-term $PM_{2.5}$ exposure and various health effects report inconsistent evidence of an association or there are relatively few studies focusing on the health effect of interest.
- Additionally, recent studies conducted a limited assessment of potential copollutant confounding for some health effects.

$PM_{10–2.5}$

- Recent epidemiologic studies continue to examine associations between short- or long-term $PM_{10–2.5}$ exposure and various health effects, and report generally positive associations (i.e., not all results are positive). However, many of these studies are conducted in locations outside of the U.S. Additionally, the overall interpretation of results across studies is complicated by the use of different methods to estimate $PM_{10–2.5}$ concentrations because the design of the $PM_{10–2.5}$ FRM was not finalized until 2006 and routine $PM_{10–2.5}$ monitoring with the FRM was not instituted until 2011.

- $PM_{10–2.5}$ concentrations are more spatially and temporally variable than $PM_{2.5}$. Although some $PM_{10–2.5}$ data are available across the nation, micro-to-neighborhood scale data are not widely available, adding uncertainty to the interpretation of results from epidemiologic studies, especially for long-term exposure studies that rely on spatial contrasts to examine associations with health effects.

UFP

- There are a limited number of epidemiologic studies examining short-term UFP exposure and health effects, with some providing initial evidence of positive associations. However, it is difficult to assess the results across studies due to the different size ranges of UFPs examined and exposure metrics used (i.e., particle number concentration, surface area concentration, mass concentration).
    - There is no national monitoring network in place to measure UFP concentrations. As a result, there is limited information on the spatial and temporal variability of UFP concentrations within the U.S., but it has been reported UFPs vary more over space and time than $PM_{2.5}$. As a result, the use of one monitor in most epidemiologic studies to estimate UFP concentrations may not adequately capture population exposure to UFPs.
    - There is a difference in the size range of UFPs examined in epidemiologic studies (0.1 um and less) and experimental studies (i.e., up to 0.3 um). This difference adds uncertainty to the examination of the coherence of effects observed in experimental and epidemiologic studies. Furthermore, the spatial and temporal variability in UFP concentrations as well as population exposures to UFPs adds uncertainty to epidemiologic findings.

Experimental evidence:

$PM_{2.5}$ and $PM_{10–2.5}$

- Animal toxicological and controlled human exposure studies provide limited, and in some instances inconsistent, evidence of effects due to short- or long-term $PM_{2.5}$ and $PM_{10–2.5}$ exposure. As a result, there is limited coherence with results from epidemiologic studies and limited evidence indicating biologically plausible pathways by which effects could occur.

UFP

- For all other health effect categories besides nervous system effects, animal toxicological and controlled human exposure studies provide limited, and in some instances inconsistent, evidence of effects due to short- or long-term UFP exposure contributing to limited coherence and biological plausibility for some health effects categories.

<u>Inadequate to Infer the Presence or Absence of a Causal Relationship</u>

$PM_{10–2.5}$ and UFPs

Epidemiologic evidence:

- Depending on the health effect, few or no epidemiologic studies examined the relationship between short- and long-term $PM_{10–2.5}$ or UFP exposures and various health effects. These studies often include single-city analyses that were conducted over short study durations. As noted previously, (1) for studies examining $PM_{10–2.5}$, the methods used to estimate $PM_{10–2.5}$

concentrations across studies varies and it is unclear how well correlated concentrations are across methods; and (2) for UFP studies, this includes inconsistency in the size ranges examined across studies and the exposure metric used, which prevents a thorough comparison of results across studies.

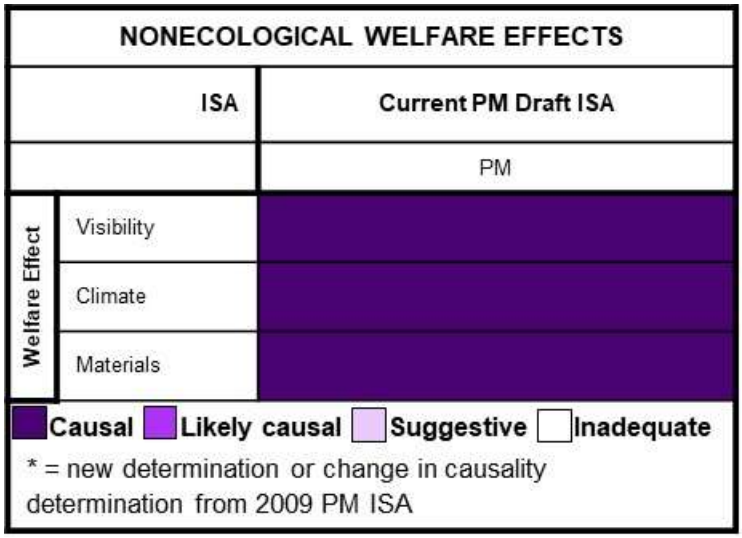
Experimental evidence:

- Depending on the health effect, few or no experimental studies examined the relationship between short- and long-term $PM_{10-2.5}$ or UFP exposures and various health effects. The few studies conducted provide inconsistent evidence of effects due to $PM_{10-2.5}$ or UFP exposures. As a result, there is limited to no evidence to support coherence of effects across multiple lines of evidence and limited to no evidence of biologically plausible pathways that could elicit an effect.

1.7.2 Welfare Effects Evidence: Key Findings

A large body of scientific evidence spanning many decades also demonstrates there are welfare effects attributed to PM. Examples of the key findings that support the welfare effects causality determinations detailed in Table 1-6 include:

Table 1-6. Summary of causality determinations for welfare effects for first draft PM ISA.



- Recent studies further confirm evidence from previous assessments supporting the strong relationship between PM and the nonecological welfare effects of visibility impairment, effects on the climate, and materials damage.

- For visibility impairment and materials damage there is extensive evidence demonstrating the relationship between PM and light extinction and PM impacts on stone, respectively.
- While there is substantial evidence indicating that PM affects the climate system, specifically through radiative forcing, there are still substantial uncertainties in key processes, such as the relationship between clouds and aerosols and the indirect impacts and feedbacks in the climate system due to the radiative effect of PM.

Table 1-7 below presents a side-by-side comparison of all causality determinations presented in this ISA and the 2009 PM ISA for each of the health and welfare effects categories evaluated in subsequent chapters.

Table 1-7 Causality determinations from the 2009 PM ISA and the current PM ISA for the health and welfare effects categories evaluated.

Summary of Causality Determinations		
CHAPTER 5. Respiratory Effects

CHAPTER 2 SOURCES, ATMOSPHERIC CHEMISTRY, AND AMBIENT CONCENTRATIONS

Summary of Sources, Atmospheric Chemistry, and Ambient Concentrations of Particulate Matter (PM)

- National 3-year average $PM_{2.5}$ concentrations decreased from 12 µg/m^3 to 8.6 µg/m^3 between the 3-year periods 2005−2007 and 2013−2015.
- SO_2 emissions decreased from 13.9 million metric tons in 2006 to 4.8 million metric tons in 2014. This decrease led to large decreases in the sulfate contribution to $PM_{2.5}$ and contributed to the decrease in $PM_{2.5}$ concentration. Emissions of NO_X and primary $PM_{2.5}$ have also decreased, but not NH_3.
- Seasonal patterns of $PM_{2.5}$ concentrations have changed from summer as the season with highest national average $PM_{2.5}$ concentration to rough equivalence in national average concentration between summer and winter. Sulfate concentrations have been historically highest in summer.
- The relative $PM_{2.5}$ contribution to PM_{10} has decreased and the relative $PM_{10-2.5}$ contribution to PM_{10} has increased since 2004.
- Extensive research has led to advances in understanding the formation of secondary organic aerosols, in particular with regard to biogenic precursor reactions, heterogeneous reactions, and production of organonitrates and organosulfates.
- For the first time, a national multipollutant monitoring network was implemented, and it includes simultaneous measurements for $PM_{2.5}$ and $PM_{10-2.5}$ using a Federal Reference Method at 78 monitoring sites.
- For the first time, a national near road $PM_{2.5}$ monitoring method was implemented, and it includes 36 monitoring sites.
- For the first time, routine monitoring of particle number count was implemented at 23 monitoring sites.

2.1 Summary Overview

This chapter presents basic concepts and new research in atmospheric sciences relevant for understanding exposure, health effects, and welfare effects discussed throughout this document. It builds on information presented in the 2009 Integrated Science Assessment for Particulate Matter (hereafter referred to as the 2009 PM ISA) (U.S. EPA, 2009) and earlier PM Air Quality Criteria Documents (AQCDs) by reviewing recent research on PM sources, chemistry, composition, measurement, monitoring, modeling, and atmospheric concentrations. Among the new results and observations are some fundamental changes in PM in the Eastern U.S. over the past decade, including a sharp decrease in the contribution of sulfate to PM, a shift in particle size distribution toward particles in 2.5 to 10 µm diameter size range, and a shift in seasonal maximum concentrations from summer to winter. These changes likely resulted from a recent sharp decline in SO_2 emissions due to stronger emission controls, as well as fuel switching and closures of coal-fired power plants. The highest $PM_{2.5}$ and PM_{10} concentrations continue to

persist in some areas in the Western U.S. Recent progress in PM measurement includes network implementation of improved methodologies for accurate measurement of particulate mass in the size range between 2.5 and 10 µm diameter, initiation of near road monitoring of $PM_{2.5}$, initiation of routine monitoring of particle number counts at a small number of near road and remote locations, and advancement of methods for retrieval and application of satellite data for estimating $PM_{2.5}$.

This chapter is organized into sections by major topic (sources, measurements, etc.) and where appropriate, content in each section is divided into subsections by size range and other subtopics such as PM composition. Section 2.2 contains a basic description of ambient PM size distributions and typical particle size characteristics to set the stage for this organization. Section 2.3 discusses sources and emissions of PM and its major precursors as well as atmospheric chemistry of PM. Section 2.4 addresses advances in measurement and modeling of PM and describes PM monitoring networks. Section 2.5 summarizes recent concentration trends, including spatial and temporal variability on national and local scales. Section 2.6 provides an overall synthesis of the chapter highlighting major new findings.

2.2 Atmospheric Size Distributions

Airborne particulate matter is a mixture of substances suspended in air as small liquid and/or solid particles. These individual particles range in size from less than 0.01 µm to more than 10 µm. Particle size is an important characteristic for health effects because different size particles penetrate into different regions of the human respiratory tract, potentially leading to distinctive health consequences for various particle size ranges (U.S. EPA, 2009). The effect of particle size on particle behavior in the respiratory system is described in Section 4.1.6. Particle size also plays an important role in welfare effects covered in CHAPTER 13, particularly for effects on radiative forcing and visibility. Properties and effects of various particle size ranges are considered separately in this document, and particle size is used as an important organizing framework for the various sections both in this chapter and in the entire document.

PM subscripts refer to the aerodynamic diameter in micrometers (µm) of 50% cut points of sampling devices. For example, U.S. EPA defines $PM_{2.5}$ as particles collected by a sampler with an upper 50% cut point of 2.5 µm aerodynamic diameter and a specific, sharp penetration curve as defined in the Code of Federal Regulations (40 CFR Part 58) (U.S. EPA, 2009). Similarly, $PM_{10–2.5}$ is the PM mass collected with an upper 50% cut point of 10 µm and a lower 50% cut point of 2.5 µm. Ultrafine particles (UFP) are often defined as particles with a diameter of <0.1 µm based on physical size, thermal diffusivity or electrical mobility (U.S. EPA, 2009). By definition, UFP encompass all particles smaller than the defined upper diameter limit. However, in practice UFP measurement methods (Section 2.4.3) have varying lower and upper size limits and measured concentration is instrument-dependent (see Preface).

Material presented in this and following chapters will focus on particles in the fine ($PM_{2.5}$), coarse ($PM_{10-2.5}$), and ultrafine particle (UFP) size ranges as shown in Figure 2-1. There is also some limited discussion of PM_{10}. This is because longer term monitoring data exist for PM_{10} than for either $PM_{2.5}$ or $PM_{10-2.5}$, and occasionally PM_{10} data are available when $PM_{2.5}$ or $PM_{10-2.5}$ data are lacking. Each of these size ranges were described in detail in the 2009 PM ISA (U.S. EPA, 2009).

Atmospheric particle size distributions usually exhibit distinct size modes which roughly align with the above PM size ranges. An example particle size distribution, showing a nucleation mode, accumulation mode, and coarse mode, is illustrated in Figure 2-1 (Kittelson and Kraft, 2015; Kittelson, 1998). Both number of particles and particulate mass are unevenly distributed in a typical atmospheric particle size distribution, forming distinct lognormal size modes in the atmospheric particle size distribution, each with different local maxima and measurable variance (Whitby, 1978). The nucleation mode is generally made up of freshly generated particles, formed either during combustion or by atmospheric reactions of precursor gases. The nucleation mode is especially prominent near sources like heavy traffic, industrial emissions, biomass burning, or cooking (Vu et al., 2015). Particle size is not static and nucleation mode particles grow rapidly through coagulation of particles or uptake of gases by particle surfaces, giving rise to the accumulation mode. Particle size in the accumulation mode is limited by removal from the atmosphere (Friedlander, 1977) through wet and dry deposition. Coarse mode particles are formed by mechanical generation, and through processes like dust resuspension and sea spray formation (Whitby et al., 1972). Usually, the accumulation mode is the predominant contributor to PM mass and surface area, but only a minor contributor to particle number. Conversely, nucleation mode particles are only a minor contributor to PM mass and surface area, but the main contributor to particle number.

In principle, PM measurement methods are designed to correspond to one or more of the PM size modes in Figure 2-1. In practice, they are restricted to fixed particle size ranges while PM size modes are dynamic and continually changing. As a result, the subscripted PM size ranges (i.e., $PM_{2.5}$, $PM_{10-2.5}$) may not exactly match up with distinct PM size modes. However, there is a rough correspondence that can be useful for interpreting PM measurements. By number, most nucleation mode particles usually fall into the UFP range, but it is possible some fraction of the nucleation mode number distribution extends beyond above 0.1 μm in diameter. By surface area or mass, the peak of the nucleation mode corresponds to a greater diameter than for particle number, and it is more likely that a substantial fraction of particle surface area or mass is due to nucleation mode particles larger than the UFP upper limit. Most of the nucleation and accumulation mode mass is captured by $PM_{2.5}$ sampling, although a small fraction of particles that make up the accumulation mode are greater than 2.5 μm in diameter. Most coarse mode mass is captured by $PM_{10-2.5}$ sampling, but small fractions of coarse mode mass are usually smaller than 2.5 μm or greater than 10 μm in diameter.

Particles of different sizes differ in their sources, composition, chemical properties, atmospheric lifetimes, transport distances, and removal processes (U.S. EPA, 2009). Typical differences in particle

characteristics for different particle size ranges are described in Table 2-1. Although atmospheric lifetime depends on atmospheric conditions, usually UFP are transformed into the accumulation mode and $PM_{10-2.5}$ are removed from the atmosphere more rapidly than accumulation mode particles are transformed or removed, leading to shorter average atmospheric lifetimes and transport distances for particles in the UFP and $PM_{10-2.5}$ size ranges than for particles in the $PM_{2.5}$ size range (U.S. EPA, 2009). Differences in transport and atmospheric wet and dry deposition processes between different size particles were discussed in detail in the 2009 PM ISA (U.S. EPA, 2009).

2.3 Primary Sources and Atmospheric Formation

Particulate matter is composed of both primary and secondary chemical components. Primary PM is derived from particle emissions from a specific source. Secondary PM originates from gas-phase chemical compounds present in the ambient atmosphere that have participated in new particle formation or condensed onto existing particles. Primary particles, and the gas-phase compounds that ultimately contribute to PM, are emitted by both natural and anthropogenic sources. Earlier assessments have described, in detail, the important sources of primary and secondary atmospheric particles (U.S. EPA, 2009, 2004). Table 2-2 summarizes the anthropogenic and natural sources for the major primary and secondary constituents of $PM_{2.5}$ and $PM_{10-2.5}$.

Anthropogenic sources can be divided into stationary and mobile sources. Stationary sources include fuel combustion for electricity production and other purposes, industrial processes, agricultural activities, road and building construction and demolition, and biomass combustion. Mobile sources include diesel- and gasoline-powered highway vehicles and other engine-driven sources such as locomotives, ships, aircraft, and construction and agricultural equipment. These sources directly emit combustion-derived primary PM, as well as secondary PM precursors (discussed below), and generate particles during vehicle braking, as well as fugitive dust from paved and unpaved roads.

Table 2-2 Particle formation, composition and sources.

	UFP	$PM_{2.5}$	$PM_{10-2.5}$
Formation processes	Combustion Pyrogenesis Homogeneous and/or heterogeneous nucleation Condensation and adsorption (gas-particle partitioning)	Gas-particle partitioning Particle agglomeration Reactions of gases in or on particles Cloud droplet evaporation	Mechanical degradation of solid materials (crushing, grinding, abrasion of surfaces) Evaporation of sea spray Suspension of dust
Typical chemical/material components	Sulfate Elemental carbon Metal compounds Low volatility organic compounds	Sulfate, nitrate, ammonium, and hydrogen ions Elemental carbon Low and moderate volatility organic compounds Metals: compounds of Pb, Cd, V, Ni, Cu, Zn, Mn, Fe, etc. Water	Suspended soil or street dust Fly ash from coal, oil, and wood combustion Nitrates/chlorides/sulfates from HNO^3/HCl/SO_2 reactions with coarse particles Oxides of crustal elements (Si, Al, Ti, Fe) Sea salt (Na, K, Ca, carbonate, sulfate and chloride) Pollen, mold, fungal spores Plant and animal detritus Tire, brake pad, and road wear debris
Dominant[1] primary particle sources	Combustion of fossil fuels and biomass High temperature processes (i.e., smelters, steel mills, etc.)	Combustion of fossil fuels and biomass High temperature processes	Resuspension of industrial dust and soil tracked on to roads and streets Suspension from disturbed soil (e.g., farming, mining, unpaved roads) Construction and demolition Coal and oil combustion Sea spray Biological sources
Secondary particle formation processes	Particle formation and growth due to oxidation of gas-phase anthropogenic, biogenic and geogenic precursors (NO_X, SO_2, and organic compounds)	Partitioning of gas phase products of precursor oxidation; aqueous oxidation of dissolved precursors with evaporation and growth cycling	

[1]All source-specific particles are produced in a distribution of sizes, with usually one major mode. This means that all sources will generate small quantities of particles that are both much larger and much smaller than the main size mode. For example, particles generated by construction activities generally fall into the $PM_{10-2.5}$ size fraction. However, the distribution extends into the UFP size range.

Ambient PM also forms in the atmosphere from photochemical oxidation of precursor gases. This material is referred to as secondary PM. The large, semi- and nonvolatile reaction products of these oxidation reactions may condense to form new particles or onto existing particles. Table 2-2 includes sources for several PM precursor gases. Discussion of the photochemical reactions that transform these precursor gases into secondary PM can also be found in earlier assessments (U.S. EPA, 2009, 2004). An overview of estimates of emissions of primary PM and precursors to secondary PM from major sources is given in this section.

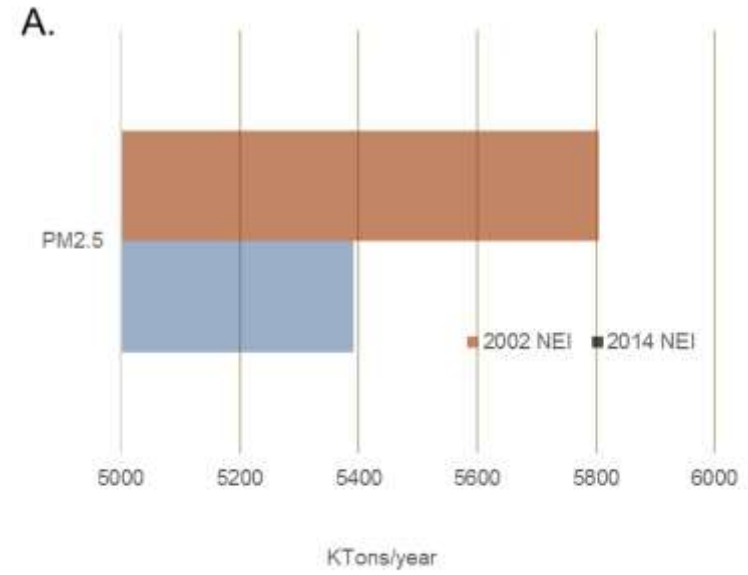
In general, the sources of $PM_{2.5}$ are very different from those of $PM_{10-2.5}$. $PM_{10-2.5}$ is almost entirely primary in origin, as described in Section 2.2, and is produced by surface abrasion or by suspension of sea spray or biological material (e.g., microorganisms, pollen, plant and insect debris).

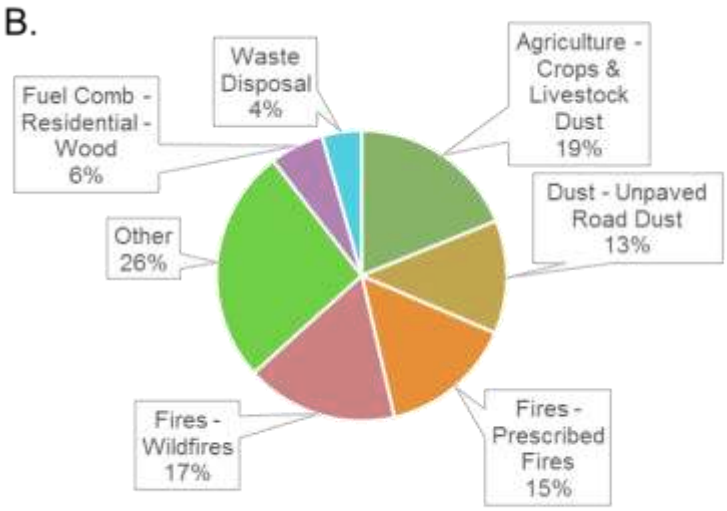
2.3.1 Primary $PM_{2.5}$ Emissions

2.3.1.1 National Scale Emissions

The relative contributions of specific sources to national emissions of primary $PM_{2.5}$ are similar to those reported in the 2009 PM ISA (U.S. EPA, 2009). Figure 2-2 shows the U.S. national average emissions of primary $PM_{2.5}$ from the 2002 National Emissions Inventory (NEI) described in the 2009 PM ISA (U.S. EPA, 2009), and the 2014 NEI, Version 2 (U.S. EPA, 2018). The NEI is a national compilation of emissions information provided by state, local, and tribal air agencies as well as source sector emission estimates developed by the U.S. Environmental Protection Agency (U.S. EPA). It focuses largely on anthropogenic sources, with information about natural sources where available. Emissions composition and mass estimates undergo continual revision as better information becomes available but are subject to varying degrees of uncertainty. For these and other reasons, ambient PM mass and composition can be quite different from what might be inferred by examining emission inventories alone (U.S. EPA, 2009).

Dust and fire each account for approximately 36% of total $PM_{2.5}$ emissions included in the 2014 NEI. Dust includes agricultural, construction, and road dust. Of these, agricultural dust and road dust make the greatest contributions to $PM_{2.5}$ mass on a national scale. Fires include wildfires, prescribed fires, and agricultural fires, with wildfires and prescribed fires accounting for most of the $PM_{2.5}$ fire emissions on a national scale.





Source Permission pending: U.S. EPA (2018) and U.S. EPA (2009).

Figure 2-2 **Primary $PM_{2.5}$ emissions at the U.S. national scale. (A) $PM_{2.5}$ emissions from the 2002 U.S. EPA National Emissions Inventory versus the 2014 U.S. EPA National Emissions Inventory. (B) Largest, national-scale sources of $PM_{2.5}$. "Other" includes all remaining source sectors, all of which are emitting 2% or less of the national $PM_{2.5}$ emissions total.**

2.3.1.2 Urban Scale Emissions

The sources and relative annual average emissions of primary $PM_{2.5}$ at the urban scale can vary substantially from city to city. Figure 2-3 shows five U.S. counties containing large cities that were selected from the 2014 NEI to illustrate the variation in primary $PM_{2.5}$ source composition. In urban settings, the majority of primary $PM_{2.5}$ emissions estimated in the NEI include some combination of industrial activities, motor vehicles, cooking, and fuel combustion, and often include wood smoke. Dust accounts for a large fraction of primary $PM_{2.5}$ emissions in several of the counties, due to construction and entrainment of paved road dust, in contrast to the national scale where the largest emissions are attributed to agricultural processes and vehicular traffic on unpaved roads. While fire emissions comprise a large fraction of annual average emissions at the national scale, they represent a much smaller fraction with respect to other sources for the urban counties shown.

Mobile sources, as noted in the 2009 PM ISA, are a major source of primary PM at urban scales, especially light-duty gasoline and heavy duty diesel vehicles (U.S. EPA, 2009). They are discussed in further detail here because they represent a consistently large fraction of total $PM_{2.5}$ emissions in all urban areas (Section 2.3.1.2), and several important advances in engine and pollution control technology have occurred in recent years. For the example counties shown in Figure 2-3, mobile sources account for an estimated 13−23% of the NEI's total primary $PM_{2.5}$ emissions. Primary $PM_{2.5}$ emitted by mobile sources is due to direct tailpipe emissions, brake, clutch and tire wear. Significant changes in both gasoline and diesel emissions controls have led to reductions in primary $PM_{2.5}$ emitted from newer vehicles. Light-duty vehicles in the U.S. (i.e., passenger cars and light-trucks under 8,500 lbs. gross vehicle weight rating) are rapidly transitioning from port fuel injection (PFI) with fuel injected upstream of the exhaust valve to direct, in-cylinder fuel injection systems, also known as gasoline direct injection (GDI). In 2007, a new U.S. EPA PM emissions standard required reduction of diesel PM emissions by 90% to 0.01 g/bhp-hour (U.S. EPA, 2009). Their impact on UFP are discussed in Section 2.3.4. Mobile sources are also responsible for $PM_{2.5}$ dust suspension on and off-road. (Note: dust is also present in the coarse mode and is discussed further in Section 2.3.3 as it pertains to primary $PM_{10-2.5}$ emissions).

2.3.2 Secondary $PM_{2.5}$ Formation

After emission, primary particles transform in size and chemical composition due to coagulation with other particles, gas-to-particle condensation of semivolatile gases, and photochemical aging processes that oxidize particle components or generate oligomers. Particle dynamics, gas-particle partitioning, aging and other heterogeneous chemical processes have been discussed in earlier PM assessments (U.S. EPA, 2009, 2004). Much is understood about the physical processes that lead to the growth of particles in the atmosphere, but the reaction mechanisms that contribute to these processes as well as to the formation and chemical transformation of particles with time remains an area of active research.

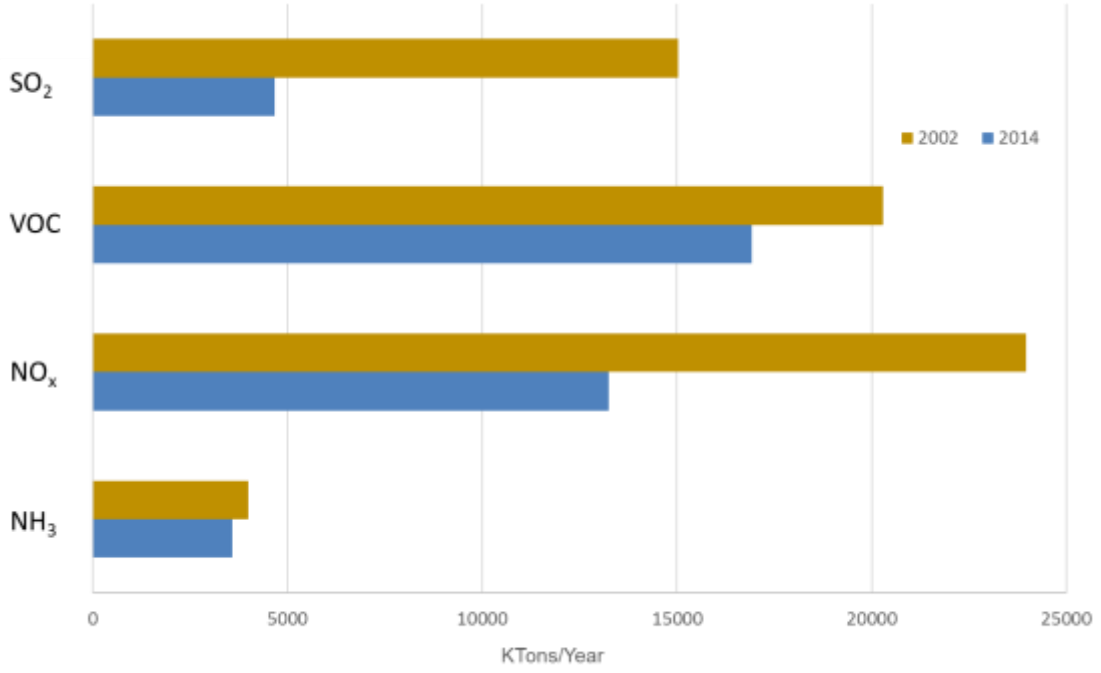
Secondary $PM_{2.5}$ accounts for a substantial fraction of the $PM_{2.5}$ mass with both natural and anthropogenic sources (U.S. EPA, 2009). It forms by way of atmospheric photochemical oxidation reactions of both inorganic and organic gas-phase precursors. Reactions leading to sulfate production from SO_2, nitrate production from NO_X (i.e., NO + NO_2) and the gas-to-particle equilibrium between NH_3 and NH_4^+ are relatively well understood. As noted, above, formation of secondary PM, often referred to as secondary organic aerosol (SOA) in the atmospheric chemistry literature, is less well resolved. Considerable recent research on mechanisms, kinetic details, and secondary organic component identification has been reported in the literature since the 2009 PM ISA. The following sections will briefly summarize the important developments in new secondary organic PM formation, including the identification of previously unknown precursors, interactions among biogenic and anthropogenic reactants, and the role of aqueous-phase chemistry.

2.3.2.1 Precursor Emissions

Secondary PM is derived from the oxidation of a range of organic and inorganic gases of anthropogenic and natural origin. Figure 2-4 shows relative source contributions to emissions of major $PM_{2.5}$ precursors from the 2014 NEI. Anthropogenic SO_2 and NO_X are the predominant precursor gases in the formation of secondary $PM_{2.5}$. Ammonia plays an important role in the formation of sulfate and nitrate PM by neutralizing sulfuric and nitric acid, leading to more stable PM with lower volatility (i.e., ammonium nitrate). The oxidation of volatile organic compounds (VOCs) may also yield semi- and nonvolatile compounds that contribute to PM and the formation of new particles.

The relative proportions of the various anthropogenic source categories (i.e., as fractions of the total emissions inventory) are very similar to those presented in the 2009 PM ISA (U.S. EPA, 2009). Sulfur dioxide emissions are mainly from electricity generating units (fuel combustion used in electricity generation (66%). NO_X is emitted by a range of combustion sources, including various mobile sources (54%). Ammonia emissions are primarily emitted by livestock waste from animal husbandry operations (55%) and fertilizer application (22%). Estimates of biogenic emissions were provided in the 2014 NEI and appear as the predominant organic precursor on the national scale (71%).

The greatest change in precursor emissions since the publication of the 2009 PM ISA (U.S. EPA, 2009) is the reduction in SO_2 emissions.



SO2 = sulfur dioxide; VOC = volatile organic compounds; NOX = nitrogen oxides; NH3 = ammonia; KTons = kilotons.

Source Permission pending: U.S. EPA (2018) and U.S. EPA (2009).

Figure 2-5 shows the difference in NEI national emission estimates for SO_2, NO_X, and NH_3 between the 2006 NEI and the 2014 NEI, showing SO_2 decreasing from 13.9 million metric tons (MMT) in 2006 to 4.8 MMT in 2014, a 65% decrease. NO_X also exhibited a substantial decrease over this period while NH_3 emissions are similar. VOC's cannot be compared because biogenics were not included in the 2006 NEI.

Anthropogenic emissions of SO_2 in the U.S. have shown dramatic declines since the implementation of the 1990 amendments to the Clean Air Act (USC Title 42 Chapter 85). Annual SO_2 emissions from electric utilities declined by 79% in the 2004−2016 time frame (U.S. EPA, 2017). In the same period, SO_2 emissions by highway and nonhighway vehicles declined by 84% and 90%, respectively. Hand et al. (2012b) studied reductions in EGU-related annual SO_2 emissions during the 2001−2010 period. They found that emissions decreased throughout the U.S. by 6.2% per year, with the largest reductions in the western U.S. at 20.1% per year. The smallest reduction (1.3% per year) occurred in the Great Plains states. These trends, and emissions of sulfide gases that serve as precursors to ambient SO_2, are discussed in detail in the 2017 Integrated Science Assessment for the Sulfur Oxides (U.S. EPA, 2017).

2.3.2.2 Secondary Inorganic Aerosols

Particulate sulfate, nitrate, and ammonium formation processes were summarized in the 2009 PM ISA (U.S. EPA, 2009) and presented in more detail in the 2004 PM AQCD (U.S. EPA, 2004) and ISAs for oxides of sulfur and nitrogen (U.S. EPA, 2008b). Together, these $PM_{2.5}$ components produced by secondary formation often account for the majority of $PM_{2.5}$ mass (see Section 2.5.2.1.4).

SO_2 reacts in both the gas phase and in aqueous solution in clouds and particles to form sulfate. Dissolved SO_2 rapidly partitions into four forms with the same oxidation state, with their relative concentrations dependent on pH:

$$S(IV) = SO_2(aq) + H_2SO_3(aq) + HSO_3^-(aq) + SO_3^{2-}(aq)$$

Equation 2-1

S(IV) is then oxidized to sulfuric acid in cloud water by H_2O_2, O_3, or O_2 in the presence of Fe(III). Reaction with H_2O_2 dominates at pH values below 5.3. Reaction with either dissolved O_3 or O_2 catalyzed by Fe(III) becomes most important at pH values greater than about 5.3 (U.S. EPA, 2008a). SO_2

is also oxidized to H_2SO_4 in the gas phase by hydroxyl radical or organic radicals formed in atmospheric photochemical processes (Berndt et al., 2012; Mauldin et al., 2012; Welz et al., 2012) with a characteristic time scale of about 10 days (Sander et al., 2011).

NO_2 can be converted to gaseous HNO_3 by reaction with OH radicals during the day. At night, NO_2 is also oxidized to HNO_3 by a sequence of reactions initiated by O_3 that produce nitrate radicals and dinitrogen pentoxide as intermediates. Both processes are important in the atmosphere.

Both H_2SO_4 and HNO_3 react with atmospheric ammonia (NH_3). Atmospheric particulate NH_4NO_3 is in equilibrium with gas-phase NH_3 and HNO_3. Lower temperature and higher relative humidity shifts the equilibrium towards particulate NH_4NO_3 because of the large sensitivity of the equilibrium constant to temperature. This results in a strong seasonal dependence in particulate nitrate concentrations, with much higher winter than summer concentrations in many locations (see Section 2.5.2.2.4). In aqueous aerosols, sulfuric acid can be partly or totally neutralized by NH_3. At low atmospheric NH_3 concentrations, equilibrium formation of ammonium sulfate is favored over ammonium nitrate; any nitrate remains in the gas phase as nitric acid. When NH_3 concentration exceeds SO_4^{2-} concentration, excess NH_3 can react with HNO_3 to form NH_4NO_3. (U.S. EPA, 2008a).

Ambient particle acidity is a difficult property to measure and is usually estimated by models. Recent measurement attempts in the U.S. Southeast have led to questions concerning the predictability of particle acidity on the basis of relative atmospheric NH_3, H_2SO_4 and HNO_3 concentrations—species which would otherwise be expected to quickly react and achieve thermodynamic equilibrium. For example, Weber et al. (2016), after evaluating the observational record, suggested that pH buffering by partitioning of ammonia between the gas and particle phases produced a relatively constant particle pH of 0−2 throughout the 15 years of decreasing atmospheric sulfate concentrations. They saw little change in particle ammonium nitrate concentrations that would have been expected, had particle pH values increased with decreasing sulfuric acid concentrations. They concluded that fairly constant emissions of semivolatile NH_3 related to agriculture ensures that the acid/base gas-particle system in the southeastern U.S. remains insensitive to changing SO_2 concentrations. Other observations indicated that the extent of neutralization of sulfuric acid and bisulfate by ammonium can be incomplete even in the presence of excess atmospheric NH_3 and proposed that uptake of NH_3 is inhibited by organic compounds coating particle surfaces (Kim et al., 2015), in accord with laboratory studies (Liggio et al., 2011). Pye et al. (2018), in their combined modeling study and evaluation of available measurements, suggest that the inconsistencies among the different measurements of particle composition, especially concerning to the fraction of condensed-phase organosulfate, must be resolved before conclusions can be drawn concerning the validity of current approaches to modeling particle acidity.

2.3.2.3 Secondary Organic Aerosols

As discussed in the 2004 PM AQCD (U.S. EPA, 2004) the study of the chemical mechanisms responsible for the formation of secondary PM related to VOC precursor oxidation has been the subject of active research. Oxygenated organic compounds appeared, based on observations, to be the dominant form of organic PM in Northern Hemisphere midlatitudes (Zhang et al., 2007). However, the mechanism(s) responsible for their formation were not well resolved, as evidenced by the persistent underprediction of observed OC concentrations by chemical transport models. This underprediction was significant for summertime PM (Wyat Appel et al., 2008; Morris et al., 2006), when biogenic precursor concentrations and photochemical reaction conditions are most favorable for SOA formation.

Substantial research on isoprene, aromatic hydrocarbons and further reaction of gas phase secondary products has been reported. Studies of isoprene as a major precursor led to identification of a number of previously unknown products as well as advances in understanding yields and mechanisms (Carlton et al., 2009). Modeling studies that included oxidation of aromatic precursors indicated that a large fraction of SOA could be derived from aromatic precursors. SOA production not only from simple aromatic compounds, but also from less volatile polycyclic aromatic compounds like naphthalene and substituted naphthalenes were reported (Kleindienst et al., 2012; Chan et al., 2009), and polycyclic aromatic hydrocarbons could account for up to 54% of total SOA from oxidation of diesel emissions (Zhao et al., 2014). Additional precursors remain possible, and the products of aromatic and biogenic compound oxidation that appear in particles may have not been fully identified.

As reported in the 2009 PM ISA (U.S. EPA, 2009), in the presence of high NO_X concentrations, the oxidation of biogenic hydrocarbons is observed to produce larger quantities of SOA. High ambient NO_X concentrations in the atmosphere are typically due to anthropogenic emissions. Mixtures, as a rule, of both biogenic and anthropogenic precursors produce greater SOA yields than mixtures dominated by just one class of precursors (Shilling et al., 2013). The presence of anthropogenic particles also enhances the formation of SOA, by providing additional volume and surface area to which semivolatile VOC oxidation products can partition or adsorb (Hoyle et al., 2011). Carlton et al. (2010) predicted that more than 50% of biogenic SOA in the Eastern U.S. could be controlled by reducing anthropogenic NO_X emissions. These findings are consistent with the satellite observations of (Goldstein et al., 2009) of a cooling haze of secondary particles over the Southeastern U.S. associated with a mixture of biogenic VOCs with anthropogenic NO_X.

Recent insight into the role of anthropogenic NO_X and SO_X in enhancing the production secondary PM include the identification of organosulfates and organonitrates among particle-phase organic compounds. The 2009 PM ISA discussed the early indications that SOA chemistry with anthropogenic SO_X yielded compounds with oxidized sulfur functional groups (U.S. EPA, 2009). Organosulfates had been observed as products of isoprene (Surratt et al., 2007), and monoterpenes (Surratt et al., 2008). Subsequently, oxidation of sesquiterpenes (Chan et al., 2011), and glyoxal (Lim et al., 2016) were also found to yield organosulfates under similar conditions. These products have been

estimated to account for 40% of PM sulfate (Vogel et al., 2016), 30% of PM organic matter (Surratt et al., 2008), 6−14% of total atmospheric sulfur concentration (Lukacs et al., 2009), and 5−10% of $PM_{2.5}$ organic mass (Tolocka and Turpin, 2012). The chemical mechanism that may explain the formation of organosulfate compounds is described in the ISA for Sulfur Oxides (U.S. EPA, 2017).

Substantial SOA mass from highly functionalized nitrate products of isoprene and monoterpenes were observed in several studies (Fisher et al., 2016; Lee et al., 2016; Kourtchev et al., 2014; Nguyen et al., 2011), accounting for as much as 10−20% of carbonaceous aerosol mass in urban locations (Day et al., 2010; Holzinger et al., 2010). In flow reactor experiments, organic nitrates accounted for up to 40% of SOA mass (Berkemeier et al., 2016). O'Brien et al. (2013), in their study of SOA collected during the CalNex 2010 field study, found that the identities of nitrogen-containing organics and total proportion of OC varied as a function of time-of-day. These differences could be explained by multiple reaction mechanisms, including one that relies upon the nitrate radical as a reactant. In the presence of both NO_X, SO_X and O_3, Lim et al. (2016) identified organonitrates, organosulfates, and organic compounds containing both nitrogen and sulfur, in their smog chamber study of the photochemistry of glyoxal in the presence of sulfate or sulfuric acid particles at high and low relative humidities.

Aqueous particle reactions and cloud processing as well as repeated cycles of volatilization and condensation of semivolatile reaction products have been shown to be important processes for SOA evolution. Production of OH in cloud water was described by Hallquist et al. (2009) and estimates of the magnitude of in-cloud formation of SOA comparable to that of gas phase formation were reported (Liu et al., 2012). High molecular weight organic compounds appear to increase with decreasing cloud water pH (Cook et al., 2017). Cloud water has been shown to provide a medium for oligomer formation involving methylglyoxal (Cook et al., 2017; Yasmeen et al., 2010), syringol and guaiacol (Cook et al., 2017; Yu et al., 2016; Yu et al., 2014a) when influenced by wildfire emissions (Cook et al., 2017; Yasmeen et al., 2010).

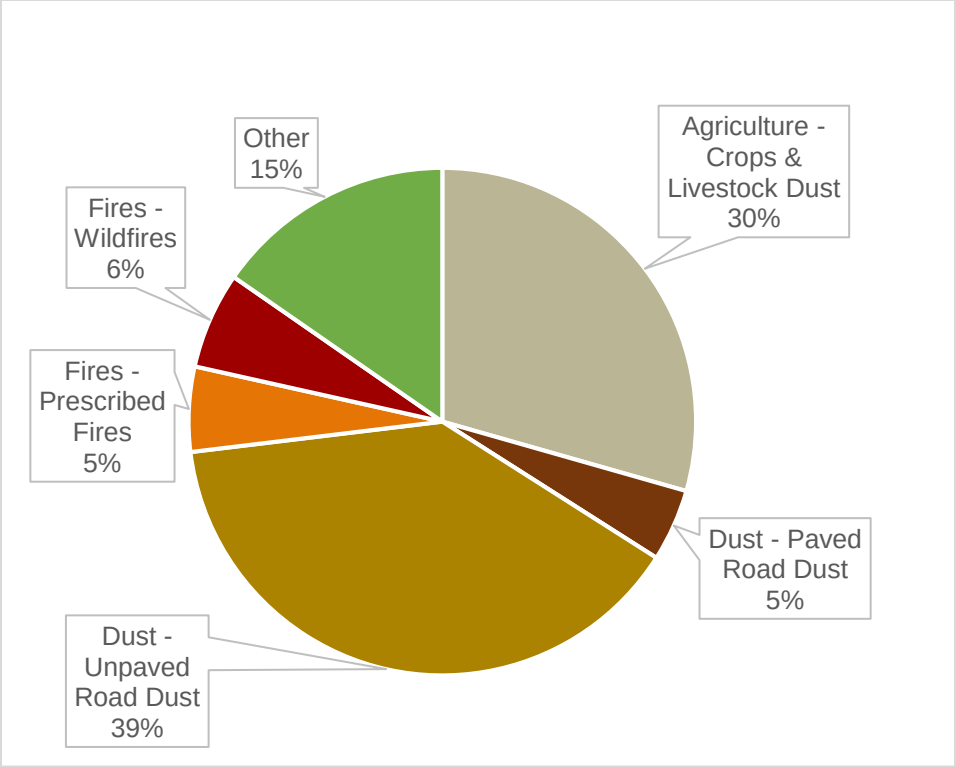
In summary, consistently higher-than-predicted measured OC concentrations, along with the observations of unexpectedly large fractions of secondary-to-total organic $PM_{2.5}$, motivated an intensive research effort to identify additional chemical processes that could explain these differences. This effort has yielded new observations of high SOA yields from isoprene and intermediate volatility organic compounds; identification of new sulfur and nitrogen containing products that account for a substantial fraction of SOA mass; identification of cloud water and aqueous aerosols as reaction media potentially as productive as the gas phase; and enhancement of SOA yields from biogenic precursors when anthropogenic reactants are also present. Given the rapid discovery of new precursors, products, and even reaction media, a high degree of uncertainty remains regarding the contribution of SOA to organic aerosol.

2.3.3 Primary $PM_{10-2.5}$ Emissions

As described in the 2004 PM AQCD (U.S. EPA, 2004), crustal materials dominate the $PM_{10-2.5}$ fraction throughout the U.S. and fugitive dust has been identified as the largest source of measured PM_{10} in many locations in the western U.S. Mineral dust, organic debris, and sea spray have also been identified as mainly in the coarse fraction (U.S. EPA, 2004). Road and construction dust represent a mechanism for suspension of crustal material on paved and unpaved roads. Wildfire plumes are now known to entrain soil representing another potential source of ambient $PM_{10-2.5}$ (Kavouras et al., 2012). Estimates of $PM_{10-2.5}$ sources from the 2014 NEI are summarized in Figure 2-6, and are very similar to those reported in the 2009 PM ISA (U.S. EPA, 2009).

Quantification of dust emissions is highly uncertain. Dust storms, like wildfires, are common but intermittent emissions sources. The suspension and resuspension of dust by any mechanism is difficult to quantify. Current NEI estimates of dust emissions across the U.S. are based on limited emissions profile and activity information. Dust injected into the upper troposphere is also transported from other continents into the U.S. by strong atmospheric currents, notably from the African and Asian deserts. Some of these particles fall into the $PM_{10-2.5}$ size range. These particles are considered to be part of the "background" component of PM, discussed in Section 2.5.4.

As discussed in the 2004 PM AQCD (U.S. EPA, 2004) and the 2009 PM ISA (U.S. EPA, 2009), primary biological aerosol particles (PBAP) contribute to coarse PM. However, estimating emissions is highly problematic. No emission rates have yet been reported, though Despres et al. (2012) described the occurrence, sources and measurement methods for different categories of PBAP. Barberán et al. (2015) characterized the distribution of airborne microbes in settled dust from ~1,200 locations in the continental U.S. They found substantial variability in the composition of microbial communities that could be related largely to climatic factors (mean annual temperature and precipitation) and soil composition (soil pH and net primary productivity). No estimates were given of the rates at which these particles are emitted into the atmosphere.



Source Permission pending: 2014 U.S. EPA National Emissions Inventory, Version 2 (U.S. EPA, 2018).

Figure 2-6 National emissions of PM_{10}.

2.3.4 Ultrafine Particles

UFP primary sources were not treated separately in the 2009 PM ISA because there is almost complete overlap between UFP and $PM_{2.5}$ sources. Particles in the $PM_{2.5}$ size range typically begin as primary UFP, or are formed through secondary particle formation, and grow through coagulation or gas-to-particle condensation (see Section 2.2). However, UFP sources are addressed independently in this ISA with a focus on sources for which near-source human exposure is substantial, such as roads and airports, as well as on new particle formation, for which a substantial amount of new research has recently been conducted.

Ambient UFPs originate from two distinct processes: primary emissions and new particle formation (NPF). Primary UFP originate from a large variety of sources, such as transportation (road traffic, ships and aircraft), power plants, municipal waste incineration, construction and demolition, vegetation fires, domestic biomass burning, cooking and cigarette smoke (Kumar et al., 2013; Janhaell et al., 2010; Langmann et al., 2009; Morawska et al., 2008). Primary sources of UFP are largely the same as $PM_{2.5}$, and much of $PM_{2.5}$ mass is initially emitted as UFP before atmospheric coagulation and growth (see Section 2.2). Atmospheric NPF involves the production of very small, molecular clusters and

subsequent growth of these clusters to larger sizes, typically a few tens of nm in particle diameter (Kulmala et al., 2014; Zhang et al., 2012b). As described in Section 2.2, UFP consists mainly of nucleation mode particles, but nucleation mode aerosols often have short atmospheric lifetimes as particles coagulate into the accumulation mode.

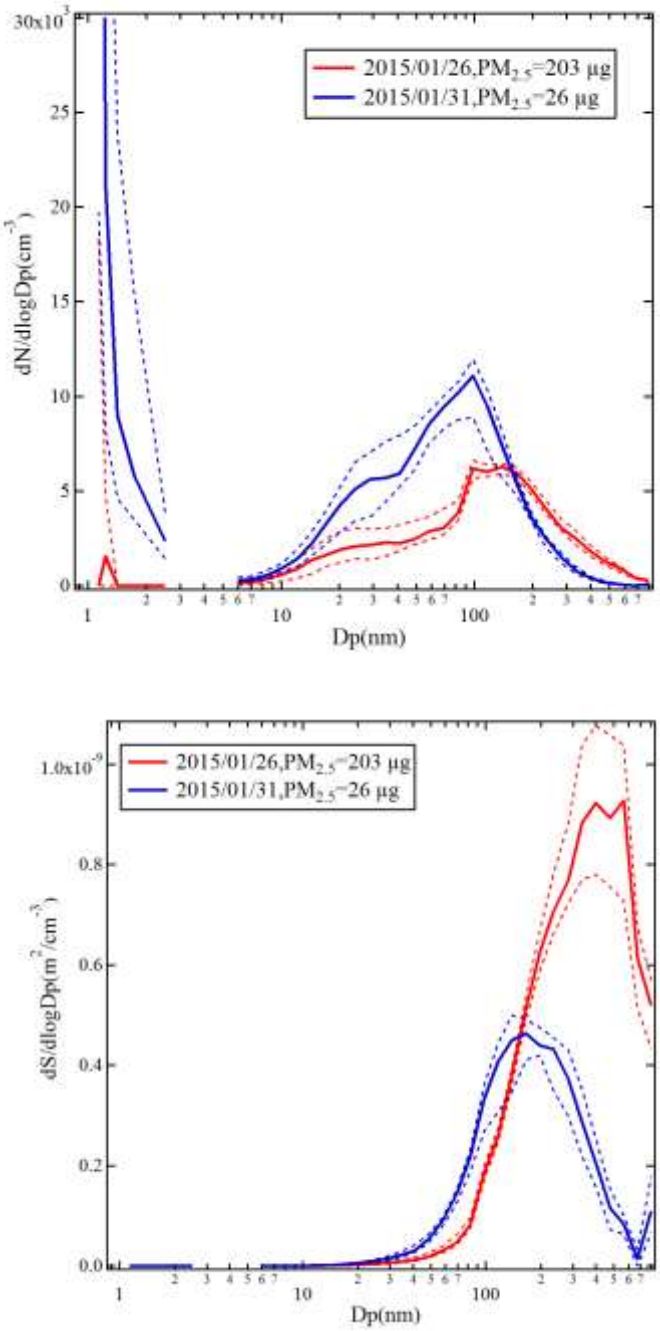
As Table 2-3 shows, UFP can be subdivided into a cluster mode, nucleation mode, Aitken mode, and a portion of the accumulation mode in order of increasing size, although a naming convention for primary ultrafine particles has not been established (Giechaskiel et al., 2014; Kumar et al., 2010). The size ranges refer to the particle diameter, encompassing the disparate definitions found in the scientific literature.

Table 2-3 Modes of atmospheric particle populations.

Mode	Size Range	Sources[a]	Main Components
Cluster mode	<3 nm	NPF	Secondary compounds capable of forming extremely low volatility complexes
Nucleation mode	<30 nm	NPF, COM	Secondary compounds of very low volatility, nonvolatile additives in fuels, lubricants
Aitken mode	10−100 nm	NPF, COM	Soot, secondary compounds of very low volatility, semivolatile compounds
Accumulation mode	30−1,000 nm	NPF, COM, OTH	Soot, secondary semi- and low-volatility organic and inorganic compounds

[a]NPF = atmospheric new particle formation and growth, COM = combustion, OTH = other primary sources.

In the atmosphere, the cluster mode is usually well separated from the other modes and has a relatively high number concentration (Figure 2-7 and Figure 2-8), even though only few atmospheric measurements on the character of this mode currently exist. The relative magnitudes and mean diameters of the nucleation, Aitken and accumulation modes vary with the time of day and location depending on the dominant particle sources and aging processes. As a result, these three modes are often not distinguishable in individual particle number distributions. Even when cluster mode or sub-0.01 µm size particles are not considered, ultrafine particles tend to dominate the total particle number concentration. Contrary to this, accumulation mode particles dominate the submicron particulate mass concentration, as explained in Section 2.2.



[a]The cluster mode, along with overlapping nucleation, Aitken and accumulation modes can be seen in the particle number distribution.

2.3.4.1 Primary Sources

Motor vehicles are a major, if not the most important, source of UFP in urban environments (Morawska et al., 2008). Their role as a major source of $PM_{2.5}$ mass and impacts of new engines and control technologies were discussed in Section 2.3.1.2. Here, these new engine and control technology advances are discussed with a focus on their impact on UFP emissions.

The number concentration, size distribution, morphology and chemical composition of mobile source-derived primary UFP are determined by the composition of the fuel used and lubricating oil, driving conditions, engine after-treatment system, as well as environmental conditions (Karjalainen et al., 2014; Rönkkö et al., 2014; Fushimi et al., 2011; Gidney et al., 2010; Heikkilä et al., 2009; Johnson, 2009). As discussed in Section 2.3.2.1, recent changes in engine and emissions control technology have influenced PM emissions from both gasoline and diesel vehicles, with light duty vehicles rapidly transitioning from port fuel injection (PFI) to gasoline direct injection (GDI), and heavy-duty diesel vehicles complying with a new U.S. EPA PM emission standard requiring reduction of diesel PM emissions by 90% to 0.01 g/bhp-hour (U.S. EPA, 2009).

The number of particles emitted by GDI vehicles can be one to two orders of magnitude higher than for PFI vehicles (Fushimi et al., 2016; Mamakos et al., 2012). For both GDI and PFI vehicles, the largest number of particles are sub-200 nm, with a more distinctly bimodal distribution characterized by a larger contribution to particle number from a sub-30 nm nucleation-mode particles for PFI (Karavalakis et al., 2013; Kittelson et al., 2006), and somewhat larger particles generally observed for GDI (Fushimi et al., 2016; Myung et al., 2015; Choi et al., 2014; Myung et al., 2014).

The new heavy-duty diesel PM emissions requirements as well as additional required reductions in NO_X emissions phased in by 2010 led to UFP emissions reduction of more than 90% compared to earlier diesels. However, CDPF regeneration resulted in approximately one order of magnitude increase in particle number. As a result, in spite of much lower average UFP emissions, there can still be discrete periods of extremely high UFP formation that do not reflect the overall reduction in UFP emissions. These UFP releases may have been due to thermal desorption of adsorbed sulfates stored within the exhaust catalyst system (Khalek et al., 2015; Ruehl et al., 2015).

Most of the particles emitted by marine and aircraft engines are in the ultrafine size range (Moldanova et al., 2013; Jonsson et al., 2011; Lack et al., 2009; Whitefield et al., 2008). Emissions of UFPs appears to be a strong function of fuel sulfur content, with reduced emissions for lower sulfur fuels (Lack et al., 2009). The size distribution of UFP produced by marine ships is usually bimodal with a nucleation mode below 30 nm and another mode between about 30 and 100 nm (Pirjola et al., 2014; Hallquist et al., 2013; Petzold et al., 2010).

Biomass burning is also a major source of UFP. The mean particle number diameter produced by burning fresh vegetation varies usually from a few tens of nm up to about 150−200 nm (Maruf Hossain et al., 2012; Zhang et al., 2011a; Janhaell et al., 2010).

2.3.4.2 New Particle Formation

New particle formation (NPF) was described in the 2009 PM ISA (U.S. EPA, 2009) as an important atmospheric process responsible for the formation of UFP, especially in remote continental areas but also in urban environments under certain conditions. Particle nucleation rates are observed to be higher in summer than in winter, and during daytime as compared to nighttime, consistent with photochemical processes. While sulfuric acid and water vapor had been identified as the major nucleating species, research was proceeding on nucleation mechanisms involving other chemical species. Numerous subsequent advances in our understanding of these mechanisms have occurred since the 2009 PM ISA (U.S. EPA, 2009).

Atmospheric NPF starts with the formation of molecular clusters. Subsequent growth via the uptake (condensation) of low volatility gas molecules occurs for some of these clusters, while others dissociate (Vehkamaki and Riipinen, 2012; Zhang et al., 2012b). If growing clusters reach the size threshold of 1.5−2 nm in diameter, they are more likely to grow further by additional vapor uptake (Kulmala et al., 2014). The processes involved in the initial steps of atmospheric NPF are collectively referred to as nucleation (Kulmala et al., 2013).

Key constituents in the initial steps of atmospheric NPF are (1) gaseous compounds of very low volatility, mainly sulfuric acid and highly oxidized organic compounds, (2) compounds which can facilitate the formation of low volatility complexes, such as gaseous ammonia or amines that form acid-base complexes with inorganic or organic acids, (3) water molecules which cluster through hydrogen-bonding, and (4) possibly ions that can form clusters through electrostatic interactions. Low-volatility compounds capable of initiating NPF primarily originate from photochemical oxidation reactions in the gas phase. As noted, above, the most important compound in this respect is sulfuric acid (Kulmala et al., 2014; Kerminen et al., 2010; Sipila et al., 2010). Other low-volatility compounds that play important roles in the early steps of NPF, at least in continental boundary layers, are extremely low volatility organic compounds (ELVOC) (Krechmer et al., 2015; Ehn et al., 2014; Riccobono et al., 2014; Donahue et al., 2013; Kulmala et al., 2013). Gas-phase ammonia and amines form acid-base complexes with inorganic or organic acids, facilitating cluster formation and subsequent NPF (Kürten et al., 2014; Almeida et al., 2013). Ions originating from radon decay and external radiation (cosmic rays and gamma radiation from soils) participate actively in the formation of clusters in the atmosphere, having the potential to affect nucleation rates (Kirkby et al., 2011) and ion-induced, or ion-mediated, particle formation mechanisms are expected to be important in locations with low temperatures and pre-existing aerosol surface areas, and high ion and sulfuric acid concentrations (Yu, 2010). Measurements conducted at a few continental locations suggest that ion-mediated pathways typically contribute a few percent to the total new particle formation rate, with slightly higher contributions estimated for some elevated sites and in Antarctica (Hirsikko et al., 2011; Manninen et al., 2010).

Averaged over a large-scale (~100 mile^2) NPF event, observed particle formation rates varied mostly in the range 0.01−10 cm^{-3} s^{-1} (Kulmala and Kerminen, 2008). Higher formation rates, up to about

100 cm^{-3} s^{-1} have been reported in some urban areas, and especially in heavily-polluted environments (Salma et al., 2011; Shen et al., 2011; Yue et al., 2009; Iida et al., 2008). The vast majority of particle growth rates associated with large-scale NPF events lie in the range 1−10 nm/hour (Kulmala and Kerminen, 2008) and increase with particle size (Hakkinen et al., 2013; Kuang et al., 2012b; Yli-Juuti et al., 2011). These findings indicate that it typically takes a few hours for newly-formed particles to grow into the 25−100 nm size range and between about half a day and 3 days before newly-formed particles grow larger than 100 nm in diameter. The main sink for molecular clusters and new particles is their coagulation with larger pre-existing particles and, in cases where their number concentration is very large, also by their coagulation with each other (Westervelt et al., 2014).

Direct observations show that secondary particles (i.e., those originating from NPF) are usually composed primarily of organic compounds, especially in forests (Han et al., 2014; Pennington et al., 2013; Pierce et al., 2012; Pierce et al., 2011), but also in many rural or urban environments (Bzdek et al., 2014; Setyan et al., 2014; Bzdek et al., 2013; Ahlm et al., 2012; Smith et al., 2008). Exceptions for this pattern are areas near large sulfur emissions sources, in which sulfate may comprise up to about half of the ultrafine particle (Crilley et al., 2014; Bzdek et al., 2012; Zhang et al., 2011b; Wiedensohler et al., 2009).

Pre-existing particles serve as an important sink for low-volatility vapors, clusters, and growing UFPs. Therefore, primary ultrafine particles tend to decrease both new particle formation and growth rates (Kulmala et al., 2014). It is because of this competition that particle number concentrations are expected to be governed by primary particle emissions in highly polluted settings and by nucleation in remote continental sites, although nucleation still occurs in urban environments and can still be the major source (U.S. EPA, 2009).

2.4 Measurement, Monitoring and Modeling

2.4.1 $PM_{2.5}$ and PM_{10}

PM Federal Reference Method (FRM) samplers and Federal Equivalence Method (FEM) monitors are designed to measure the mass concentrations of ambient particulate matter. An FRM is a method that has been approved (40 CFR Part53) for use by states and other monitoring organizations to assess NAAQS compliance and implementation. The FRMs for $PM_{2.5}$, $PM_{10-2.5}$, and PM_{10} measurement are specified in CFR 40 Part 50, Appendices L, O, and J, respectively. A FEM is based on different sampling or analytical technology from the FRM but provides the same decision-making quality for making NAAQS attainment determinations. In practice, a large fraction of the FEM monitors in operation for PM are automated and designed to provide hourly data, while the FRMs for $PM_{2.5}$, PM_{10}, and $PM_{10-2.5}$ require sampling for 24-hours and provide a daily average $PM_{2.5}$ concentration, including pre- and

post-sampling gravimetric laboratory analysis. $PM_{2.5}$ FEMs, their performance criteria, and evaluation of their performance were described in detail in the 2009 PM ISA (U.S. EPA, 2009).

Operating principles and performance of FRMs and FEMs for PM were discussed in detail in the 2004 PM AQCD (U.S. EPA, 2004) and 2009 PM ISA (U.S. EPA, 2009). The FRMs for PM are based on gravimetric measurement of mass concentration after collection on filters. There are two broad categories of FEMs for PM measurement, those that are filter-based and designed for collection of 24-hour samples, of which very few are in use, and automated monitors designed for quantification of PM on hourly or shorter time scales, of which there are several hundred in operation. Filter-based FEMs include virtual impactor/dichotomous sampler techniques, in which a sampler is designed to separate particles by their inertia into separate flow streams, in this case $PM_{2.5}$ and $PM_{10–2.5}$. There are three widely used short time resolution automated FEMs: (1) beta attenuation monitors which measures absorption of beta radiation by PM, which is proportional to PM mass; (2) Tapered Element Oscillating Microbalance (TEOM), monitors, which continuously records the mass of particles collected on a filter substrate and are typically configured with the Filter Dynamics Measurement System (FDMS), which is designed to ensure the sample is appropriately conditioned and that volatile aerosols are measured; and (3) optical methods that utilize a spectrometer, which allow calculation of aerosol mass concentrations over a wide range of cut points.

At the time of completion of both the 2004 AQCD (U.S. EPA, 2004) and 2009 PM ISA (U.S. EPA, 2009), considerable effort was still focused on improvement of measurement methods for PM mass. Examples are the development of the $PM_{10–2.5}$ FRM and the Filter Dynamics Measurement System-TEOM (FDMS-TEOM) (Grover et al., 2006), both of which are described in detail in the 2009 PM ISA (U.S. EPA, 2009). More recently, there has been little new emphasis on method development research for PM mass measurement.

2.4.2 $PM_{10–2.5}$

Although the $PM_{10–2.5}$ FRM and FEMs were already discussed in the 2009 PM ISA (U.S. EPA, 2009), the state of technology for $PM_{10–2.5}$ measurement is reviewed here because the large data set of nationwide $PM_{10–2.5}$ network measurements is reported for the first time in Section 2.5. $PM_{10–2.5}$ FRM and FEMs now used for routine network monitoring are considerably improved compared to methods used in the previous key analyses of $PM_{10–2.5}$ sampling issues (U.S. EPA, 2004; Vanderpool et al., 2004). New results reveal changing trends in $PM_{2.5}/PM_{10}$ ratios (see Section 2.5.1.1.4).

There are three categories of methods widely used for ambient sampling of $PM_{10–2.5}$. The first is the $PM_{10–2.5}$ FRM (40 CFR Part 50, Appendix O), which determines $PM_{10–2.5}$ mass as the arithmetic difference between separate, collocated, concurrent 24-hour PM_{10} and $PM_{2.5}$ measurements at local conditions of temperature and pressure. This is sometimes referred to as the difference method for $PM_{10–2.5}$ sampling. The difference method was selected as the FRM to preserve the particle size limits for

$PM_{2.5}$ and PM_{10}, which are defined by fractionation curves with characteristic shapes and cut-off sharpnesses established for the $PM_{2.5}$ and PM_{10} FRMs as well as to preserve integrated sample filter collection and gravimetric measurement technology used for all previous FRMs for PM indicators to maximize comparability between $PM_{2.5}$, PM_{10}, and $PM_{10-2.5}$ measurements. $PM_{10-2.5}$ FRMs are largely deployed as part of a multipollutant monitoring network (see Section 2.4.6).

A second category of $PM_{10-2.5}$ methods are the automated FEM monitors that utilize either a difference method or dichotomous separator in the design of the method. Automated difference method FEMs use two measurement devices similar to the FRM difference method. Automated dichotomous FEMs also rely on two measurement devices, but instead of having separate inlets, use one flow stream, that splits the particles into larger and smaller PM mass fractions to be analyzed separately. Automated $PM_{10-2.5}$ FEMs are also largely deployed at NCore stations.

The third category of $PM_{10-2.5}$ methods deployed are for the IMPROVE program. In the IMPROVE sampling methods, two of the four sampling modules operated provide data that are used to calculate a $PM_{10-2.5}$ concentration similar to how the FRM difference method is calculated. Although not an FRM or FEM, the IMPROVE program $PM_{10-2.5}$ data are included as they represent a consistent national network at over 150 locations. IMPROVE program sites are typically located in class one areas and national parks to support the Regional haze program.

There were early observations of poor precision for $PM_{10-2.5}$ mass measurements for both the difference method (Allen et al., 1999; Wilson and Suh, 1997), and dichotomous samplers (Camp, 1980), as well as discussion of the inherently lower precision of both the old difference method and dichotomous sampling compared to $PM_{2.5}$ and PM_{10} FRMs (Allen et al., 1999). The early observations of poor precision were not based on the performance of $PM_{10-2.5}$ samplers in current use in the NCore and other sampling networks, as a number of improvements have facilitated greater precision of the difference method (Allen et al., 1999) and the development of a FRM for $PM_{10-2.5}$ (40 CFR Part 50 Appendix O). Precision better than 5% was demonstrated by using identical instrumentation for both $PM_{2.5}$ and PM_{10} except for the sampler cut-point; using the same filter type, filter material, filter face velocity, and ambient-to-filter temperature difference, lowering blank variability, and increasing gravimetric analytical precision (Allen et al., 1999). These are provisions that are now specified in the FRM and used for measurements of $PM_{10-2.5}$ in national sampling networks that use the $PM_{10-2.5}$ FRM or FEM to obtain differences in PM_{10} and $PM_{2.5}$ mass. Because of these improvements, high uncertainties reported for previous measurements described in U.S. EPA (2004) no longer apply to the difference methods in use as FRMs and FEMs on which current $PM_{10-2.5}$ network measurements are based.

2.4.3 Ultrafine Particles: Number, Surface Area, Mass

In this section measurement methods for UFP are reviewed. In Section 2.4.3.1 methods for counting particle number and measuring particle number distribution are described. Because UFP mass is

usually so small, the number rather than the mass of UFP are usually reported. As this can be instrument-dependent, differences in particle number measurement methods in common use are discussed. Section 2.4.3.2 reviews surface area measurements and Section 2.4.3.3 reviews mass measurements. There are a number of reasons why measurements in the UFP size range are more challenging than mass measurements of $PM_{2.5}$ or $PM_{10–2.5}$, and these can result in differences in the upper size limit for sampling UFP mass and number. These challenges and differences are explained in Section 2.4.3.3.

2.4.3.1 Particle Number and Number Distribution

Particle number measurement is a rapidly advancing area of research, and large uncertainties and biases are likely associated with UFP measurement. The U.S. EPA has not yet established reference methods for ambient or source UFP number measurement. However, use of particle number measurements for regulatory and certification purposes has driven technological development of particle number measurements in the European Union (EU), where a network of UFP monitoring stations that uses PM electrical properties for both counting and sizing particles to measure particle number distributions are classified into six size classes every 10 minutes has been developed (Wiedensohler et al., 2012).

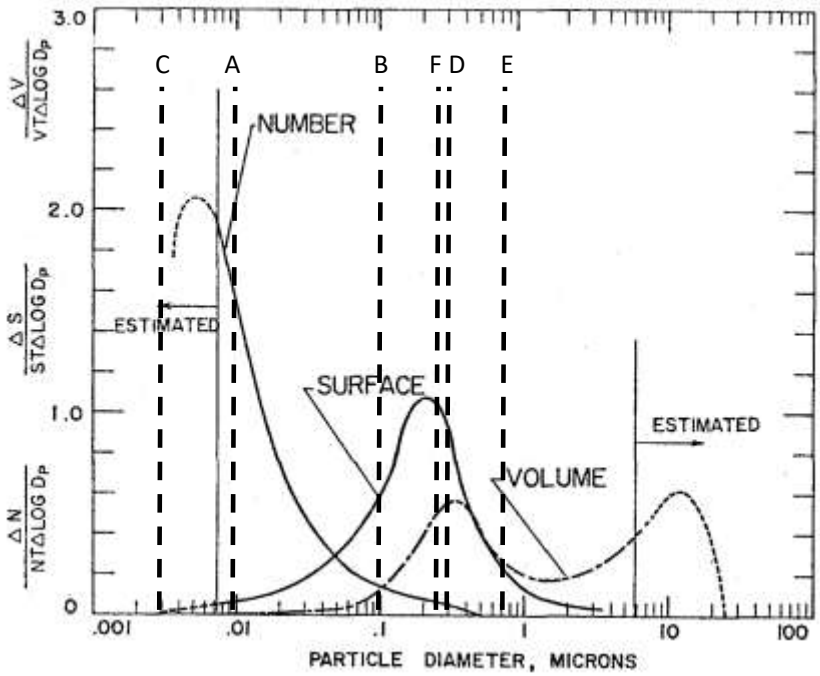
Condensation particle counters (CPC) are one of the most common means of determining total number concentration (the majority which is usually in the UFP range) for both ambient and source particle measurements. Particles enter a water or alcohol saturated vapor chamber and grow by condensation to a size that allows measurement using an optical particle counter (OPC). In some cases CPC instrumentation is used to measure UFP number without size classification under the assumption that particles with Dp > 0.1 µm do not significantly contribute to particle number measurements. The 2009 PM ISA (U.S. EPA, 2009) reported the development of a water-based CPC more suitable for long-term field studies. Before the development of this technology particle number measurements were mainly restricted to short-term, intensive field studies. Water-based CPC instruments have since found limited use in network monitoring applications (see Section 2.4.5 and Section 2.5.1.1.5).

The 2009 PM ISA also reported a reduction in detection size down to <0.002 µm in diameter with mobility particle sizers (U.S. EPA, 2009). More recently, substantial progress has been made in measuring sub-0.003 µm particles and clusters, as well as gaseous compounds involved in the initial steps of atmospheric NPF. Advances include development of particle counters (CPCs) capable of measuring particle number counts and number distributions down to about 0.001 µm in particle mobility diameter (Kangasluoma et al., 2015; Lehtipalo et al., 2014; Kuang et al., 2012a; Jiang et al., 2011; Vanhanen et al., 2011; Iida et al., 2008). These advances are especially useful for investigating atmospheric nucleation of particles (see Section 2.3.4).

Other recent advances include current efforts to develop a miniaturized CPC for use in personal monitoring applications (He et al., 2013). CPCs can be used as stand-alone instruments to measure total particle number but are often used downstream of other particle classifiers to determine UFP number or particle-number size distributions. Classification of UFP size may be via the inertial, diffusional, or electric mobility properties of the aerosol and sometimes more than one means of classification may be used. Faraday cup electrometers (FCE) can also be used downstream of other particle classifiers to determine UFP number or particle-number size distributions (Dhaniyala et al., 2011; McMurry et al., 2011; Fletcher et al., 2009). Size classification of UFP was reviewed in the 2009 PM ISA (U.S. EPA, 2009) and methods based on inertial, gravitational, centrifugal, and thermal techniques were reviewed (Marple and Olson, 2011). Advances in the development of size classification methods have mainly concerned classification by electrical mobility. A unique particle mobility within an electric field can be established relative to particle size (Hinds, 1999) and aerosols can be charged with radioactive sources such as Kr-85, Am-241, or Po-210 or using a soft-X-ray source (Jiang et al., 2014). Other instruments that classify by size using electrical mobility were described in the 2009 PM ISA (U.S. EPA, 2009).

The size ranges measured by instruments widely used in field research are superimposed on a typical particle number size distribution (Whitby et al., 1972) illustrated in Figure 2-9. The vertical lines in Figure 2-9 show the lower and upper size limits of various UFP sampling methods. In earlier literature, CPCs used for particle number measurement variable lower limit particle size detection levels were reported, but they were often near 0.01 µm (Liu and Kim, 1977), shown as Line A. In several field studies described in this ISA, particles are sized by diffusive or electrical methods before counting to limit measurements to particle number count to below 0.1 µm (Evans et al., 2014; Liu et al., 2013; Rosenthal et al., 2013), shown as Line B. In these cases, resulting particle number measurements are the number of particles between Line A and Line B in Figure 2-9. Since the number distribution continues below 0.01 µm (Line A), it is possible that some fraction of the total number of particles smaller than 0.01 µm are too small to be detected, except without specialized research methods for counting clusters, as described above.

Moreover, the peak of the number distribution can change considerably over time or over short distances. At less than 50 meters from a major highway there were more particles in the 0.006 to 0.025 µm size range than in the 0.025 to 0.05 µm size range, but at 100 meters from the highway there were more particles in the 0.025 to 0.05 µm size range than in the 0.006 to 0.025 µm size range (Zhu and Hinds, 2002). It is possible that actual particle number could decrease with distance from a busy road at the same time that the fraction of the particles is large enough to be detected may increasing, making interpretation of particle number data difficult.



Vertical lines are: (A) lower size limit from a widely used condensation particle counter (CPC) from 1977; (B) upper size limit definition of UFP; (C) lower size limit of a newer CPC; (D) and (E) upper size limits for particle number measurements from different epidemiologic studies. (Line F is not used.)

Source Permission pending: Original figure showing example particle size distribution from Whitby et al. (1972), vertical lines correspond to lower and upper size ranges for sampling procedures reported by Viana et al. (2015); Evans et al. (2014); Meier et al. (2014); Olsen et al. (2014); Liu et al. (2013); Rosenthal et al. (2013); Hampel et al. (2012); Iskandar et al. (2012); Verma et al. (2009); Liu and Kim (1977).

Figure 2-9 Size ranges collected by various UFP sampling procedures.

The development of CPCs that can detect particles as small as 0.003 µm could complicate comparison of particle number concentrations measured with different particle counters. As Figure 2-9 shows there is a difference in number of particles counted between older particle counters with size limits down to 0.010 µm (between Lines A and B) and newer particle counters with size limits down to 0.003 µm (between Lines B and C). In one study where two different particle counters were used, one with a lower size limit of 0.003 µm gave 14−16% higher number counts than one with a lower size limit of 0.007 µm (Hampel et al., 2012). In the Pittsburgh Air Quality Study, the average particle number count in the size range 0.003 to 0.010 µm was 5,600 cm^{-3} (Stanier et al., 2004), while the average particle number count for the entire 0.003 to 2.5 µm size range was 22,100 cm^{-3}. This corresponds to 25% of total particle number count accounted for by particles in the range of 0.003 to 0.010 µm.

In other studies, particle number has been counted without size classifying before counting over size ranges up to 0.3 µm (Meier et al., 2014; Olsen et al., 2014) or 0.7 µm (Iskandar et al., 2012), as shown in Lines D and E of Figure 2-9 as an indicator UFP number. Although 0.3 µm is well above the nominal UFP upper limit of 0.1 µm, the use of a larger upper size limit was more convenient and was

justified by observations that most particles are smaller than 0.1 µm. Figure 2-9 shows that the greatest number of particles are smaller than 0.1 µm, but that a part of the particle number distribution extends beyond it. Recent studies verified that 75% of particles smaller than 0.7 µm (Iskandar et al., 2012) and roughly 5/6 of particles smaller than 0.5 µm by number were smaller than 0.1 µm (Evans et al., 2014).

An additional complication for electrometer based measurements (but not for CPCs) is that the number of particles that can be detected varies with particle size. For example, an electrometer can have a size detection limit of 0.02 µm, this does not indicate that a single particle with a diameter of 0.02 µm can be detected. Instead, lower count detection varies with particle size because the amount of charge required for detection by an electrometer increases with decreasing particle size. For example, a UFP 3031 electrometer has an estimated lower detection limit of 408 cm^{-3} for 0.02−0.03 µm particles but falls off to 120 cm^{-3} for 0.07 to 0.1 µm particles (Vedantham et al., 2015). Detection of particle number using an electrometer is thus limited by a size below which no particles are counted, as well as by a minimum detectable particle number count that varies with size.

To summarize, the variety of instruments and approaches used for measuring particle number present potentially large uncertainties for use in field studies to estimate exposure and health impacts, and complicate comparison of particle number concentrations between field studies using different measurement methods. Not removing particles larger than 0.1 µm before measurement introduces a bias of greater than 10−20%. Differences in the lower size limit of detection between different particle counters could produce an even greater uncertainty that has not been fully characterized. Underlying these uncertainties is the knowledge that because there is a lower size limit for particle detection, there is inherently some unknown fraction of particle number concentration that is accounted for by particles that are too small to be detected. This is an especially important consideration for comparing recent data to older data. As particle number counting technology rapidly advances, the lower size limit of detection is decreasing and the number of particles capable of being detected is correspondingly increasing. In essence, different widely used UFP measurement methods do not measure the same particle size range, and serious biases in particle number measurements are both likely and difficult to assess.

2.4.3.2 Surface Area

Particle surface area is usually measured by radioactive or electrical labeling of particles using an electrical aerosol detector or radiation detector (U.S. EPA, 2009). There have been new advances in measurement of UFP surface area. The epiphaniometer directly measures surface area via surface deposition of Pb-211 onto sampled particles and subsequent measurement of the α-activity of particles deposited on a filter using an annular surface barrier detector (Gini et al., 2013; Gaggeler et al., 1989). Surface area may also be approximately determined via unipolar diffusion charging of particles with active surface area related to the electrical charge transferred to particles under controlled charging conditions (Jung and Kittelson, 2005). Excess ions are removed using an ion trap charge is measured via

electrometer (Geiss et al., 2016). The diffusion charge surface area relationship is only valid within a particle size range of approximately 0.02 to 0.4 µm (Geiss et al., 2016; Kaminski et al., 2012; Asbach et al., 2009). Diffusion charge surface area shows good agreement with TEM projected surface area for particle sizes of primary interest for UFP characterization (i.e., DP < 0.1 µm) but appears to underestimate surface area for larger particles (Ku and Maynard, 2005). Instrumentation and methods used to estimate "lung-deposited surface area" are described in Section 4.1.7.

2.4.3.3 Mass

Inertial classification to the most common UFP size definition (i.e., an inertial 50% cutpoint Dp less than 0.1 µm) can be accomplished for UFP mass sampling by using a low-pressure impactor as an initial scalper stage and using sample filter media in the flow exiting the impactor. In such cases, UFP mass can be designated as $PM_{0.1}$, which makes reference to the 0.1 µm 50% cutpoint in a manner analogous to nomenclature used for other size-classified particle mass measurements (e.g., $PM_{2.5}$).

Measurement of UFP mass gravimetrically can be problematic due to the small amount of collected mass, long sampling periods involved, and the potential loss of semivolatile particles. While inertial classifiers can be used to classify or determine the size distribution of UFP, the pressure drop across the sub-0.1 µm stage required for sampling UFP may present challenges with respect to evaporative loss of particulate matter (Hata et al., 2012; Furuuchi et al., 2010; Singh et al., 2003).

To address this, particles with a larger aerodynamic diameter cutpoint have been sampled using a high volume slit impactor with 50% cutpoints of 0.18 or 0.25 µm to increase the sample collected for mass determination and/or compositional analyses and to reduce the pressure drop across the inertial classification stage to reduce evaporative losses. For example, Misra et al. (2002) designed a sampler with a 0.25 µm inertial 50% cutpoint D_p to quantify $PM_{0.25}$ (Saffari et al., 2015; Misra et al., 2002), and a design by Demokritou et al. (2002) later evolved into a commercial sampler with a 0.18 µm cutpoint for sampling near the UFP range.[38] Sampling of $PM_{0.25}$ or $PM_{0.18}$ increases sampled mass over a time interval and reduces the pressure differential necessary for inertial classification relative to $PM_{0.1}$. In the available studies, the estimated upper limit of the measured PM mass that has been referred to as the ultrafine particle size range usually varies between about 0.1 and 0.3 µm of the particle aerodynamic diameter, depending on the PM sampling device used (Cheung et al., 2016; Borgie et al., 2015; Viana et al., 2015; Daher et al., 2013; Kudo et al., 2012; Mueller et al., 2012; Chen et al., 2010; Bruggemann et al., 2009).

Concentrated ambient particles (CAPs) are frequently used in controlled human exposure and animal toxicology studies. The technology that allows for CAPs is the virtual impactor with a high volume slit design (Sioutas et al., 1994c; Sioutas et al., 1994a, b). Briefly, ambient air is accelerated

[38] BGI 900 High Volume Cascade Impactor Guidance Manual, https://bgi.mesalabs.com/wp-content/uploads/sites/35/2014/10/BGI900_MANUAL_1.0.0.pdf.

through a high-volume nozzle that lets smaller particles pass through in a small fraction of the flow stream, but removes larger particles by impaction in a larger fraction of the flow stream. Classification by size has been achieved by placing two or three virtual impactors in sequence in a Versatile Aerosol Concentration Enrichment System (VACES) (Maciejczyk et al., 2005; Ghio et al., 2000; Sioutas et al., 1995b; Sioutas et al., 1995a). The Ultrafine Particle Concentrator (UPC) was developed by Sioutas et al. (1999) as a laboratory aerosol concentration device and was incorporated into a variation of the VACES by Kim et al. (2001). Ambient air is introduced in the system through three inlets: 0.18 μm impactor, 2.5 μm impactor, and ambient air with no upstream cutpoint (Kim et al., 2001). The VACES was briefly described in the 2004 PM AQCD (U.S. EPA, 2009). Because virtual impaction works best for particles much larger than 0.1 μm, UFP concentration requires supersaturation for particle growth to an optimal size for virtual impactor operation, and a subsequent drying step after separation to return particles to their original size.

The original description of the Harvard Ultrafine Concentrated Ambient Particle System (HUCAPS) includes an outlet impactor with a 0.2 μm cut point (Gupta et al., 2004). A 0.3 μm cut point using the HUCAPS has also been described (Liu et al., 2017) and the VACES, uses 0.18 μm cut point inlet impactor for its nominally ultrafine size range (Kim et al., 2001).

Other approaches to PM delivery in controlled exposure studies can result in particle size ranges up to 0.3 μm. Previously described high volume ambient samplers designed to collect a UFP fraction have also been used in controlled exposure studies with UFP, by collecting PM on a filter substrate, extracting the PM from the filter, and nebulizing and drying the extract to reconstitute the aerosol (Cheng et al., 2016; Morgan et al., 2011), (Zhang et al., 2012a), (Cacciottolo et al., 2017; Woodward et al., 2017). In other controlled clinical exposure studies PM with MMD <0.1 μm was generated by spark discharge (Schaumann et al., 2014) or sampled directly from automobile exhaust (Tyler et al., 2016).

UFP CAPS and other delivery systems for controlled exposure studies are generally not limited to the nominal UFP size limit of less than 0.1 μm. Instead, they usually involve a particle size ranging up to 0.18 to 0.3 μm without exclusion by impaction or other means of removal. Under these circumstances, a large fraction of the mass range targeted for investigation of UFP effects in controlled exposure studies can come from particles larger than the nominal size of 0.1 μm. Consequently, a difference in mass between practical mass sampling methods targeting UFP and what would be measured below 0.1 μm is likely. However, as described in Section 2.4.3.1, the difference in particle number measurements is likely to be much less.

2.4.4 Chemical Components

Measurement of PM components is potentially useful for providing insight into what sources contribute to PM mass as well as for discerning differential toxicity. Sulfate, nitrate, ammonium, organic carbon and elemental carbon as well as a suite of elements are measured in national speciation monitoring

networks (see Section 2.4.5) and intensive field studies mainly by collection on filters, using methods described in detail in the 2004 PM AQCD (U.S. EPA, 2004) and 2009 PM ISA (U.S. EPA, 2009). New advances in PM speciation analysis has included new network applications for OC analysis and better characterization of sampling errors of major PM components. Fourier Transform Infrared Spectroscopy has been applied to OC and organic functional group determination in national networks (see Section 2.4.6) for monitoring $PM_{2.5}$ species (Weakley et al., 2016). Characterization of sampling errors due to loss of ammonium nitrate and semivolatile organic material during sampling, adsorption of organic vapors during sampling, and generation of elemental carbon during analysis of organic carbon have emerged as the main sources of measurement error and considerable effort has been devoted to their minimization or correction (U.S. EPA, 2009, 2004).

New research has focused on seasonal differences in the impacts of these errors, indicating 40−50% loss of $PM_{2.5}$ nitrate from Teflon filters in summer and less than 10% in winter, with summer losses largely balanced out by an increase in retained water (Malm et al., 2011; Nie et al., 2010; Vecchi et al., 2009). The volatilized nitrate is minimized in network nitrate sampling methods (Solomon et al., 2014), but not with most $PM_{2.5}$ mass methods, making a negative bias in the $PM_{2.5}$ FRM possible if the nitrate contribution to $PM_{2.5}$ mass is large enough. Further research has also continued on quantification of positive OC artifacts due to vapor adsorption on filters (Vecchi et al., 2009; Watson et al., 2009), including observation of more vapor adsorption in summer than winter (Cheng et al., 2010; Vecchi et al., 2009). Minimization of sampling error has been investigated by adjusting filter deposit area, flow rate, and passive exposure time (Chow et al., 2010a); using denuders upstream of filters (Chow et al., 2010b); and characterizing backup filter correction and its influence on the split between OC and EC (Cheng et al., 2009) to reduce the positive adsorption artifact. Considerable research has also focused on measurement of particulate organic species, elemental analysis, and single particle mass spectrometric analysis, and some novel sampling and analytical approaches for measurement of PM components, but these are beyond the scope of this review because they have not been used for interpreting health and welfare impacts.

2.4.5 Satellite Remote Sensing

Instruments sensing back-scattered solar radiation on satellites have made it possible to characterize tropospheric aerosol properties on the global scale. Satellite-based measurements used for estimating $PM_{2.5}$ are becoming more widely used and have recently been combined with modeled data and ground-level measurements to extend the spatial coverage over which $PM_{2.5}$ concentrations can be estimated and to improve the spatial resolution of $PM_{2.5}$ estimates used to assign exposure in health studies. The satellite borne instruments vary in their complexity and in the aerosol properties they can measure. Satellite instruments measure radiance (electromagnetic energy flux), that can then be used to provide information on the aerosol column amount, or the aerosol optical depth (AOD). Because $PM_{2.5}$ is not directly measured, computational algorithms involving a range of assumptions must be applied to

obtain estimates of $PM_{2.5}$ concentrations from AOD. These inferred measurements involve potential errors that are not encountered with the FRM or other ground-based $PM_{2.5}$ measurements. This section focuses on the estimation of $PM_{2.5}$ concentration from AOD and its strengths and limitations. Studies involving fusion of AOD with spatiotemporal modeling for prediction of exposure concentration are discussed in Section 3.3.3.

Depending on the wavelengths sampled and the spectral resolution of the instruments, information about the composition of particles of diameter <2 μm and particles of diameter >2 μm can be obtained (Engel-Cox et al., 2004). Satellite AOD observations have extensive spatial coverage, making these data attractive for estimating surface PM concentrations. AOD is a measure of the extinction of light in the atmosphere and is directly related to the presence of particulate matter as the individual particles scatter light. A higher AOD reflects greater scattering, indicating higher PM loadings. However, this relationship is not linear due to multiple factors including atmospheric (e.g., thickness of the boundary layer, cloud presence, humidity) and particle (chemical speciation, size distribution) characteristics, and can be impacted by surface characteristics as well (Martin, 2008). Data cannot be collected when clouds and snow are present, limiting the completeness of satellite datasets (Hoff and Christopher, 2009) or from excessive amounts of smoke being mistaken for clouds when AOD > 4 (van Donkelaar et al., 2011).

Spatial and temporal resolution with which concentration can be estimated by satellite images varies with the satellite data source. Satellite/instrument retrievals, and further analyses, provide AOD at varying spatial resolutions down to 500 meters [e.g., Reid et al. (2015); Hoff and Christopher (2009)]. The Moderate Resolution Imaging Spectroradiometer (MODIS) passes the U.S. twice daily with 10 km or 1 km resolution, while the Geostationary Operational Environmental Satellite (GOES) Aerosol/Smoke Product (GASP) produces data in 30-minute intervals with 1 km resolution, and the Multiangle Imaging Spectroradiometer (MISR) produces nearly continuous AOD data but with 17.6 km resolution. Additionally, AOD can be estimated at the earth's surface by the Aerosol Robotic Network (AERONET), which measures AOD from the ground surface and has sites distributed globally. AERONET AOD measurements may provide some validation of satellite AOD measurements.

The many factors that impact the relationship between AOD and $PM_{2.5}$ concentrations lead to widely varying and sometimes relatively low, correlations when linear relationships are developed. In the Hoff and Christopher (2009) review, the correlation (R) (not specified as Spearman or Pearson) ranged from 0.4 to 0.98 across cited studies. Errors in satellite data may occur because the retrievals are sensitive to the aerosol vertical distribution and the optical properties of the particles, which in turn are determined by their morphology and composition, whether they are internally or externally mixed, and the surface contribution to satellite measured reflectance. Hu (2009) observed a Pearson $R = 0.67$ for the eastern U.S. and $R = 0.22$ for the western U.S. The authors attributed poor retrieval in the western U.S. to variation in topography and meteorology. Moreover, satellite data are obtained during brief overpass, and can't be integrated over the longer averaging times used in ground-based measurements. Satellite observations have been compared with AERONET to determine how remote sensing influences measurements of

AOD. Kim et al. (2015) compared AOD for the southeastern U.S. from AERONET with that from MODIS and MISR and found correlations of 0.83 and 0.74, respectively. Normalized mean biases were −18% for MODIS and 1.5% for MISR compared with AERONET. The amplitudes of seasonal peaks were larger in satellite observations compared with the surface data. Kim et al. (2015) suggested that two main factors contribute to this finding: in summer, the mixed layer is deeper, which allows for vertical mixing to greater heights where the sensitivity of the satellite measurements is greater, and there is biogenic SOA production from isoprene oxidation; conversely in winter, the shallower mixed layer depth restricts the extent of vertical mixing, and SOA formation is greatly reduced compared to summer.

The influence of surface reflectance on the relationship between estimated $PM_{2.5}$ and AOD depends on the wavelength range of the retrieval system. The most commonly used algorithm for retrieving AOD from MODIS uses reflected sunlight in the 470 to 2,110 nm wavelength range and is more reliable over dark surfaces than over bright surfaces, because bright surfaces typically show high reflectivity in the red and near-infrared frequencies, resulting in low signal to noise ratios over bright surfaces. However, retrievals of AOD over bright surfaces are possible by making use of reflected sunlight measured in the 412−470 nm channels (Sorek-Hamer et al., 2015). R^2 was determined between retrievals of AOD over the San Joaquin Valley using a mixed effects model. In this model fixed effects represent average relationship between AOD and $PM_{2.5}$ over all monitors in the study area for the study period (2005−2008) and random effects reflect daily variability in the relationship between $PM_{2.5}$ and AOD. R^2 was 0.69, root mean square predicted error (RMSPE) was 9.1 ± 1.2 μg/m^3 and normalized RMPSE was 0.44 ± 0.05.

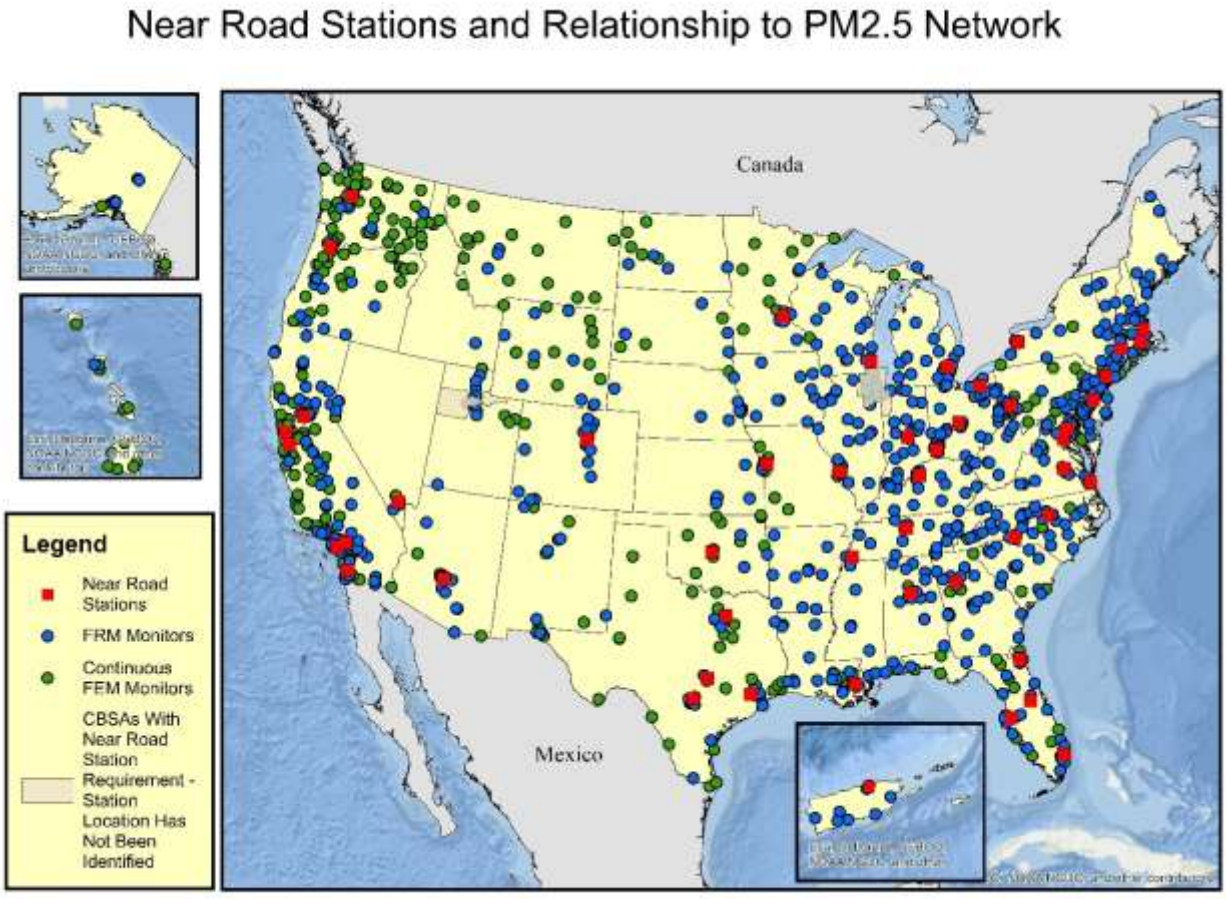
Spatial resolution of the satellite image influences the relationship between estimated $PM_{2.5}$ and AOD. More recently, Chudnovsky et al. (2013b) used the Multiangle Implementation of Atmospheric Correction (MAIAC) AOD, derived from MODIS radiances with a 1 km resolution over New England from 2002 to 2008 to assess how AOD resolution impacted the coefficient of determination with $PM_{2.5}$ using a simple linear fit. The 1 km resolution retrievals displayed greater spatial variability over New England than did the 10 km resolution with an increase in the sample of cloud free cells. They found that, in their application, the R^2 decreased as the resolution was decreased (from a median of about 0.5 at 1 km resolution to about 0.2 at 10 km), suggesting that higher resolution AOD products can provide increased spatial detail and higher accuracy. Using the same data from New England from 2002 to 2008, Chudnovsky et al. (2013a) also compared the correlation between AOD and fixed-site $PM_{2.5}$ concentration derived from 10 km resolution MODIS data and 1 km resolution MAIAC data with concentration from 84 fixed-site $PM_{2.5}$ monitors. Correlations (not stated whether Pearson or Spearman) were similar (R = 0.62 for MODIS and 0.65 for MAIAC) across all data and when broken down by region and season. The 1 km resolution MAIAC data were found to have valid AOD measures for a larger fraction of the monitoring sites compared with 10 km MODIS data. Chudnovsky et al. (2013a) noted that comparisons between AOD and fixed-site monitor $PM_{2.5}$ concentration data can sometimes produce inverse relationships. The AOD averaged over an area can be lower or higher than the $PM_{2.5}$

concentration measured at a fixed-site monitor depending on the spatial distribution of primary $PM_{2.5}$ sources.

To summarize, satellite-based measurements are becoming more widely used for estimating $PM_{2.5}$ to provide more extensive spatial coverage than can be obtained with $PM_{2.5}$ monitoring network data. The satellite based instruments measure radiance to provide information on AOD, and computational algorithms are then used to estimate $PM_{2.5}$ from AOD. These algorithms can be complex, and there is considerable uncertainty in the $PM_{2.5}$ estimated from AOD. This is because of the many factors that influence the relationship between $PM_{2.5}$ and AOD, including boundary layer thickness, cloud presence, humidity, PM composition and size distribution, and ground reflectivity. Satellite based $PM_{2.5}$ estimates are more accurate over dark surfaces on days without clouds than over bright surfaces or with clouds present, but they can also be used effectively in hybrid models that may incorporate other data sources, including CMAQ model output, surface measurements, and land use variables (Section 3.3.3).

2.4.6 Monitoring Networks

Objectives for PM monitoring include: (1) supporting air quality analyses used to conduct assessments of exposure, health risks, and welfare effects, (2) characterizing air quality status, including providing the public with timely reports and forecasts of the air quality index (AQI), (3) determining compliance with the NAAQS, (4) developing and evaluating air pollution control strategies, and (5) measuring trends and overall progress for air pollution control programs. Federal rules that regulate monitoring programs and details of the various sampling networks relevant for PM measurement are described in the 2009 PM ISA (U.S. EPA, 2009) and updated in the 2016 PM IRP (U.S. EPA, 2016b). Data from U.S. EPA's ambient air monitoring network are available from two national databases. The AirNow database provides data used in public reporting and forecasting of the AQI and the Air Quality System (AQS) database is the U.S. EPA's long-term repository of ambient air monitoring data. The current $PM_{2.5}$ network as of May 2018 is shown in Figure 2-10. As of May 2018, there are 738 FRM monitors and 839 continuous mass FEM monitors.



Source Permission pending: U.S. Environmental Protection Agency 2016 analysis of data from monitoring networks.

Figure 2-10 $PM_{2.5}$ Network Including Near Road Monitors.

There are a number of other major national monitoring networks for PM that have been in place for multiple decades. PM_{10} is also monitored in a national network for comparison of PM_{10} data to the NAAQS. As of May 2018, there are 420 FRM monitors and 351 continuous FEM monitors in the PM_{10} network. $PM_{2.5}$ components are measured in two monitoring networks, the Chemical Speciation Network (CSN), and the Interagency Monitoring of Protected Visual Environments (IMPROVE) network, which was implemented to better understand the relationship between PM composition and properties with atmospheric visibility (U.S. EPA, 2016b). As of May 2018, there are 153 CSN stations and 152 IMPROVE stations. The field and laboratory approaches used in the CSN and IMPROVE network as well as their historical evolution, measurement errors and uncertainties, and differences between them have been thoroughly reviewed (Solomon et al., 2014). Monitor locations and number of monitors required for the $PM_{2.5}$, PM_{10}, CSN, and IMPROVE networks are discussed in the 2016 PM IRP (U.S. EPA, 2016b) and monitor siting criteria are described in CFR 40 Part 58 Appendix D and the

SLAMS/NAMS/PAMS Network Review Guidance (U.S. EPA, 1998). Maps of these other national monitoring networks are not included in this ISA, but have been presented along with extensive discussion of PM monitoring networks in the 2009 PM ISA (U.S. EPA, 2009).

Extensive new PM monitoring efforts now complement these long-standing networks by providing additional data supporting multiple objectives, including for PM research. These new monitoring efforts include near road monitoring for $PM_{2.5}$, and the National Core (NCore) network for multipollutant measurement, as well as monitoring of additional PM measurements that are associated with special projects or are complementary to other networks, including particle number, black carbon, and continuous component monitoring (U.S. EPA, 2016b).

$PM_{2.5}$ near road monitors located within 50 meters of roads with heavy traffic are identified in Figure 2-10. By January 1, 2015 22 core based statistical areas (CBSAs) with a population of 2.5 million or more were to have a $PM_{2.5}$ monitor operating at a near road location and by January 1, 2017 30 CBSAs with a population between 1 million and 2.5 million were to have a $PM_{2.5}$ monitor at a near road location.

The NCore network in Figure 2-11 is a relatively new national air quality monitoring network that has been operating since January 1, 2011 and has 78 monitoring sites designed for measurement of multiple pollutants, including $PM_{10-2.5}$ (Weinstock, 2012). The purpose of the NCore network is to support long-term science and policy objectives by contributing data from the latest monitoring technology over a wide range of representative urban and rural locations (Weinstock, 2012). $PM_{10-2.5}$ is measured nationwide in both the NCore and IMPROVE networks. The number of monitoring locations for $PM_{10-2.5}$ is considerably smaller than the number of $PM_{2.5}$ or PM_{10} monitors. As of May 2018, $PM_{10-2.5}$ was being monitored at 140 IMPROVE stations in addition to the 78 NCore monitoring sites.

Another new development is the routine monitoring of particle number at several sites in the U.S. Hourly particle number monitoring data over a period of several years has been reported to AQS from an urban and a rural site in New York state, and additional monitors reported data for shorter periods. At least three near road network monitoring sites will also include particle number measurements (U.S. EPA, 2016b).

Figure 2-11 National Core (NCore) Multipollutant Monitoring Network.

2.4.7 Chemistry-Transport Models

This section briefly reviews scientific advances in chemistry-transport models (CTMs)—numerical models of atmospheric transport, chemistry, and deposition of PM. The 2009 PM ISA (U.S. EPA, 2009) provided a description of the relevant processes and numerical methods. Key observations were that the largest errors in photochemical modeling were still thought to arise from the meteorological and emissions inputs to the model (Russell and Dennis, 2000) and that additional uncertainty was introduced by the parameterization of meteorological and chemical processes (U.S. EPA, 2009). Alternative approaches to modeling these processes were discussed and compared (U.S. EPA, 2009). Most major regional-scale air-related modeling efforts at U.S. EPA use the Community Multiscale Air Quality modeling system (CMAQ) (Byun and Schere, 2006; Byun and Ching, 1999). Recent updates to CTM model design, and in particular to CMAQ, are described below. Use of CTMs for exposure assessment studies, including combination of CTMs with other models or data to increase spatial resolution of the concentration field, are described in Section 3.3.2.4.

Numerous advances in atmospheric science have been codified in CTMs, including improved algorithms that better simulate long-chain alkanes important for urban aerosol (Woody et al., 2016), biogenic secondary organic aerosol from isoprene and terpenes (Pye et al., 2017), aging of organic aerosols from combustion (Ciarelli et al., 2017), chemistry within cloud droplets and aerosol water (Fahey et al., 2017), gas-phase oxidant chemistry relevant for the formation of aerosol precursors, and dry deposition by gravitational settling (Nolte et al., 2015). Many processes that influence $PM_{2.5}$ are strongly affected by the weather, and accordingly considerable scientific effort has focused on improving the representation of meteorological processes in CTMs and interactions with aerosols (Tuccella et al., 2015). Improved algorithms for understanding the influence of weather on emissions of $PM_{2.5}$ from sources such as sea spray (Grythe et al., 2014), wind-blown dust (Foroutan et al., 2017), and emissions of precursors such as VOCs from plants (Bash et al., 2016) and ammonia from agricultural lands (Bash et al., 2013; Flechard et al., 2013; Pleim et al., 2013), have also advanced the capabilities of CTMs.

All of these improvements in specific processes work in concert to improve the CTM's performance at quantifying the spatial and temporal distribution of $PM_{2.5}$. CTMs are rigorously evaluated using $PM_{2.5}$ observations from extensive monitoring networks. Figure 2-12 shows the pattern of seasonal mean bias in $PM_{2.5}$ in CMAQ Version 5.1, which is the most recently published in the peer-reviewed literature (Appel et al., 2017). Compared to the prior version of CMAQ (v. 5.02), seasonal variability is generally improved as simulated concentrations decrease during winter and increase during summer, especially for organic carbon. Other CTMs that have reported comparisons between $PM_{2.5}$ simulated over North America and measurements of ambient $PM_{2.5}$, updated since the previous review, include the Comprehensive Air-quality Model with Extensions (Koo et al., 2014) and the Weather Research and Forecasting model coupled with Chemistry (Crippa et al., 2016).

A number of chemical transport models have been configured to conduct their simulations online with the meteorological model. This may include feedbacks between the physical and optical properties of aerosols, solar radiation, and clouds (Forkel et al., 2015; Gan et al., 2015; Yu et al., 2014b; Wong et al., 2012). The modeling community has sought to evaluate these models as part of the Air Quality Model Evaluation International Initiative (AQMEII-2)—an effort "to promote policy-relevant research on regional air quality model evaluation across the atmospheric modeling communities" (Im et al., 2015b). Five modeling groups submitted results for North America which were compared against observations of $PM_{2.5}$ at 659 stations (Im et al., 2015a). The study reported the root mean squared error for WRF-CMAQ v5.0.1 simulations of 24-hour averaged $PM_{2.5}$ as 3.08 $\mu g/m^3$ at urban monitoring sites, although another study reported larger errors for individual seasons (Hogrefe et al., 2015).

Since CTMs are often used to estimate the impact of a change in emissions, it is also important to evaluate the ability of the modeling system to respond correctly to emission perturbations. While it is challenging to isolate the impact of a single emission change in ambient observations, a few studies have conducted decade-long simulations to examine the modeling system's (both the model and the inputs) ability to capture long-term trends. Over the U.S. and Europe, substantial reductions in sulfur dioxide and

nitrogen oxides have created an opportunity to compare the model results with the trends in ambient observations (Banzhaf et al., 2015; Xing et al., 2015; Cohan and Chen, 2014; Civerolo et al., 2010). Studies have shown that CMAQ is skilled at capturing the seasonal and long-term trends in sulfate $PM_{2.5}$, in part because the emission changes are large and well quantified. CMAQ also captures the long-term trend in nitrate $PM_{2.5}$; however, the model has less skill for seasonal variability in nitrate $PM_{2.5}$, owing to uncertainties in ammonia emission trends (Banzhaf et al., 2015; Xing et al., 2015).

2.5 Ambient Concentrations

2.5.1 Spatial Distribution

This section focuses on two spatial scales, the regional scale and urban/neighborhood scale. The regional scale is useful for understanding geographic differences between regions, especially with respect to PM concentrations, composition, and size. The urban and neighborhood scales are useful for understanding primary $PM_{2.5}$, $PM_{10-2.5}$, and UFP, because there are usually numerous sources, and PM concentrations can decrease steeply with distance from sources, resulting in considerable variation in PM concentrations over relatively short distances. The urban scale refers to citywide conditions with dimensions on the order of 4 to 50 km. The neighborhood scale refers to an extended area of a city with dimensions on the order of 0.5 to 4 km (CFR 40 Part 58 Appendix E, 2018).

Much of our understanding of spatial and temporal variation in PM concentrations is based on observations from PM monitoring networks. Spatial and temporal differences in $PM_{2.5}$ concentrations have also been predicted from models based on covariate data for both fine and large spatial scales (Yanosky et al., 2014; Paciorek and Liu, 2009; Yanosky et al., 2009). In general, stronger cross-validation agreement and greater precision for $PM_{2.5}$ than for PM_{10} or $PM_{10-2.5}$ have been observed for predictive models of PM concentration, probably because $PM_{10-2.5}$ concentrations exhibited greater spatial variability (Yanosky et al., 2014; Yanosky et al., 2009). Regionally predictive capability in one study was best for the Northeast and Midwest and poorest in the Northwest and Central Plains, with intermediate performance in the Southeast, South Central and Southwest (Yanosky et al., 2014). Pang et al. (2010) compared two computational estimation methods, Bayesian maximum entropy and ordinary kriging, and concluded that lower $PM_{2.5}$ estimation errors and error variances were obtained with a Bayesian maximum entropy approach.

2.5.1.1 Variability Across the U.S.

2.5.1.1.1 $PM_{2.5}$

$PM_{2.5}$ concentrations have decreased considerably compared to those reported in the 2009 PM ISA (U.S. EPA, 2009). Figure 2-13 shows the 3-year mean of the 24-hour $PM_{2.5}$ concentrations for network monitoring sites across the U.S. from 2013−2015. Figure 2-14 shows the 98th percentile $PM_{2.5}$ concentrations over the 3-year period from 2013−2015 at monitors across the U.S. Although concentrations have decreased, the geographic distribution of average concentrations is similar to the period 2005−2007 reported in the 2009 PM ISA (U.S. EPA, 2009). Some of the highest 3-year average 24-hour $PM_{2.5}$ concentrations are in the San Joaquin Valley and the Los Angeles-South Coast Air Basin of California. Many sites in the Northwest, including Oregon, Idaho, Western Montana, and Utah

experienced 98th percentile $PM_{2.5}$ concentrations greater than 40 µg/m^3. Numerous sites in the Central Valley of California also reported 98th percentile $PM_{2.5}$ concentrations above 40 µg/m^3. In the Eastern U.S. there is a zone of elevated $PM_{2.5}$ with annual average concentrations greater than 10 µg/m^3 and 98th percentile concentrations greater than 25 µg/m^3 in the Ohio Valley, and stretching into to Eastern Pennsylvania. Both annual average and 98th percentile concentrations are generally lower than what was observed in the 2005−2007 period as reported in the 2009 PM ISA, continuing the downward trend reported there (U.S. EPA, 2009).

Figure 2-14 98th percentile 24-hour $PM_{2.5}$ concentrations 2013−2015.

Specific regional concentration patterns are also evident from $PM_{2.5}$ data derived from satellites (see Section 2.4.5), including the higher average abundance in the eastern half than in the western half of the U.S., with especially high concentrations in the Ohio Valley; the Sonoran desert region, which extends from Mexico into Arizona and inland areas of Southern California and is subject to frequent dust storms; the Los Angeles urban area; the San Joaquin Valley; and the Big Bend area of Texas, which is also subject to dust storms (Lary et al., 2014).

Table 2-4 contains summary statistics for $PM_{2.5}$ reported to AQS for the period 2013−2015. The table provides a distributional comparison between annual, 24-hour and 1-hour averaging times, as well as between quarters. The mean of annual average concentrations based on 24-hour samples across all sites during the 3-year period was 8.6 µg/m^3. This compares to a mean of annual average concentrations of 12 µg/m^3 for 2005 to 2007 (U.S. EPA, 2009), a substantial decrease.

Table 2-4 Summary statistics for $PM_{2.5}$ 2013−2015 (concentrations in µg/m^3).

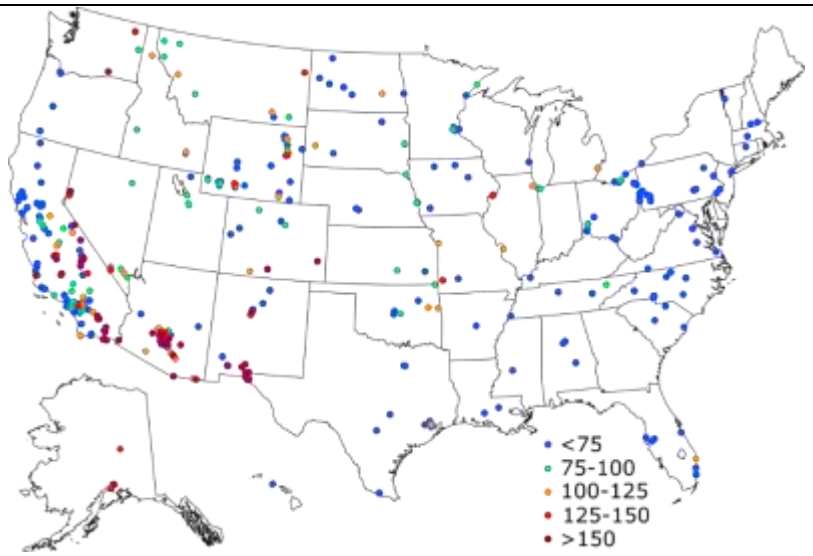
1

Average $PM_{2.5}$ concentrations were somewhat higher in winter (January−March) than in other seasons. The higher winter average contrasts with results from the 2009 PM ISA, in which slightly higher concentrations in summer were reported (U.S. EPA, 2009). This replacement of summer with winter as the season with the highest national average concentration is analyzed in more detail in Section 2.5.2.2. Table 2-4 still shows higher average $PM_{2.5}$ concentrations in summer than in fall or spring. This pattern of elevated summer and winter average $PM_{2.5}$ concentrations with lower concentrations in fall and spring has been observed since the initiation of the $PM_{2.5}$ monitoring network, and is also explored in detail in Section 2.5.2.2. The 99th percentile $PM_{2.5}$ concentration was considerably higher in winter than other seasons. This observation was consistent with trends reported in the 2009 PM ISA, which were attributed to wintertime stagnation events (U.S. EPA, 2009). The impact of meteorology on seasonal $PM_{2.5}$ concentrations is discussed in Section 2.5.2.2.

The distribution of 24-hour and 1-hour average FEM data are comparable up to the 90th percentile. At the 95th percentile, the 1-hour average is about 3 $\mu g/m^3$ higher than the 24-hour average, and at the 98th percentile it is 6 $\mu g/m^3$ higher. These concentration differences are consistent with those observed in 2005−2007 data reported in the 2009 PM ISA, although actual concentrations are 4−5 $\mu g/m^3$ lower in 2013−2015 than for 2005−2007. The deviation between 1-hour and 24-hour averaging times results from short duration spikes in $PM_{2.5}$ that have more influence on the 1-hour distribution, than the 24-hour average distribution (U.S. EPA, 2009).

2.5.1.1.2 PM_{10}

PM_{10} mass includes all of the other PM mass size fractions considered in this chapter, i.e., $PM_{2.5}$, $PM_{10-2.5}$, and UFP. Like $PM_{2.5}$, geographic trends are very similar to those reported in the 2009 PM ISA (U.S. EPA, 2009). Figure 2-15 shows the 98th percentile of PM_{10} concentration at monitors across the U.S. The highest concentrations were observed in the Western U.S., including the San Joaquin Valley, Imperial Valley, and other areas of California, as well as the Southwest, including Arizona, New Mexico, Colorado, and El Paso, TX. In contrast, throughout the Northeast and Southern U.S. 98th percentile PM_{10} concentrations are generally below 100 $\mu g/m^3$. In the Midwest, Oklahoma, Texas, and Florida, concentrations between these extremes were generally observed for 98th percentile PM_{10}.



Source Permission pending: U.S. EPA 2016 analysis of Air Quality System network data 2013−2015.

Figure 2-15 98th percentile PM_{10} concentrations (2013−2015).

Table 2-5 gives summary statistics for PM_{10} for the period 2013−2015. The national average concentration based on FRM was 21.1 µg/m^3, which is 15% lower than the average for 2005−2007 reported in the 2009 PM ISA (U.S. EPA, 2009). However, at the 99th percentile, PM_{10} concentrations were almost identical to 2005−2007 data, with a FRM 99th percentile concentration of 91 µg/m^3 in 2005−2007 and 92 µg/m^3 in 2013−2015. Table 2-5 does not exclude any data for exceptional events and many of the areas with increasing trends are in California (fires) and Arizona (dust). These sporadic natural events could have a more important impact on the trends of the upper percentiles than the average.

While some concentrations exceeded 150 µg/m^3, 99th percentile concentration was well below this concentration for all monitor types and averaging periods, and 98th percentile concentrations were below 100 µg/m^3. Summer concentrations appear to be typically higher than other seasons, with the highest average concentration as well as the highest concentration at all percentiles up to the 95th percentile for summer. However, the most extreme events appear to be more likely in the spring, as indicated by the highest 98th and 99th percentile concentrations. Winter concentrations are the lowest at all percentiles, with average concentrations 6 µg/m^3 lower in winter than in summer.

Table 2-5 Summary statistics for PM_{10} 2013−2015 (concentrations in µg/m^3).

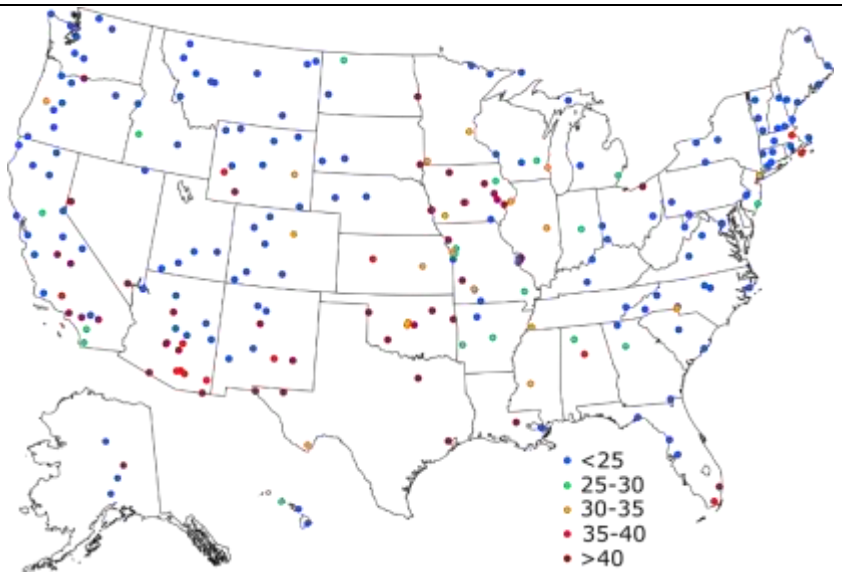
2.5.1.1.3 $PM_{10-2.5}$

As described in Section 2.4.2 and Section 2.4.6, $PM_{10-2.5}$ measurement capabilities and availability of $PM_{10-2.5}$ ambient concentration data have greatly increased since the 2009 PM ISA. At that time $PM_{10-2.5}$ concentrations were not routinely monitored, other than in the IMPROVE program, and $PM_{2.5}$ and PM_{10} measurements could only be compared between different types of samplers with different designs and flow rates (U.S. EPA, 2009).

Figure 2-16 shows the 98th percentile concentrations for $PM_{10-2.5}$ between 2013−2015. 98th percentile concentrations greater than 40 µg/m^3 were observed in multiple locations, not only in California and the Southwestern states of Nevada, Arizona, and New Mexico, but also in Texas, Oklahoma, Missouri, Iowa, and Alaska. St. Louis, Cleveland, south Florida also stand out as urban areas with some of the highest $PM_{10-2.5}$ concentrations.



Source Permission pending: U.S. EPA 2016 analysis of Air Quality System network data 2013−2015.

Figure 2-16 98th percentile concentrations for $PM_{10-2.5}$ between 2013−2015.

Table 2-6 shows summary statistics on national $PM_{10-2.5}$ concentrations from 2013−2015. Data for FRMs and IMPROVE national mean and percentile concentrations are quite different than FEM, typically a factor of 2 or more higher for FEM data than the filter-based FRM and IMPROVE data, probably because of differences in site locations such as the urban-rural mix. Concentrations of several hundred micrograms per cubic meter were occasionally observed, but 98th percentile concentrations were

under 50 µg/m^3 regardless of method or averaging period. Concentrations were typically higher in summer than in other seasons on average, and at all percentiles up to the 95th percentile. However, 98th and 99th percentile concentrations for $PM_{10–2.5}$ are highest in the fall rather than the spring, although the very highest concentration was observed in the spring.

These observations are supported by additional studies showing that the highest concentrations of $PM_{10–2.5}$ were generally observed in the Southwestern U.S. (Li et al., 2013). They are also consistent with urban data from the 2009 PM ISA (U.S. EPA, 2009)showing $PM_{10–2.5}$ comprised most of PM_{10} in Denver and Phoenix, but not in other major cities (U.S. EPA, 2009). At two urban sites in Denver and two comparatively rural sites in Greeley, CO, average $PM_{10–2.5}$ concentrations over the course of a year averaged 9.0 to 15.5 µg/m^3, with the highest values in Northeast Denver (Clements et al., 2012). $PM_{10–2.5}$ concentrations up to 5 times higher than $PM_{2.5}$ concentrations were reported (Clements et al., 2014b). $PM_{10–2.5}$ concentrations in Denver were highest when winds were coming from the urban core, and highest in Greeley when winds were coming from Denver and other large communities (Clements et al., 2012).

2.5.1.1.4 $PM_{2.5}/PM_{10}$

In numerous earlier studies summarized in the 2009 PM ISA (U.S. EPA, 2009) as well as in an extensive analysis of data reported in the 1996 PM AQCD (U.S. EPA, 1996), the ratio of $PM_{2.5}$ to PM_{10} was higher in the East than in the West in general. Crude estimates of the fraction of PM_{10} accounted for by $PM_{2.5}$ were obtained by dividing the 3-year average $PM_{2.5}$ concentration by the 3-year average PM_{10} concentration for 15 cities in the 2009 PM ISA (U.S. EPA, 2009, 179916}. PM_{10} was estimated to contain less $PM_{2.5}$ than $PM_{10-2.5}$ in Phoenix and Denver (3-year mean $PM_{2.5}/PM_{10}$ ratios of 0.19 and 0.32, respectively), but more $PM_{2.5}$ than $PM_{10-2.5}$ in Philadelphia ($PM_{2.5}/PM_{10}$ = 0.74), New York ($PM_{2.5}/PM_{10}$ = 0.68) and Pittsburgh ($PM_{2.5}/PM_{10}$ = 0.67) (U.S. EPA, 2009). By comparison, in Europe $PM_{2.5}$ usually accounts for 50 to 90% of PM_{10} and ratios are fairly constant for individual sites, but vary between sites (Putaud et al., 2010).

A more current and comprehensive comparison of the relative contributions of $PM_{2.5}$ and $PM_{10-2.5}$ to PM_{10} by region and season using data from the NCore Network is now possible. Figure 2-11 (Section 2.4.6) shows a map of NCore monitors in operation on a routine basis. Table 2-7 provides average $PM_{2.5}/PM_{10}$ ratios from the NCore network based on a FRM designed specifically for $PM_{10-2.5}$ (see Section 3.4.3) averaged over the entire period of monitoring site operation at 28 locations distributed throughout the U.S. The data indicate roughly equivalent amounts of $PM_{2.5}$ and $PM_{10-2.5}$ at most urban sites, with $PM_{2.5}/PM_{10}$ ratios ranging from 41 to 61% for all urban sites except Dayton, OH and Columbia, SC, and from 61 to 66% for rural sites in the Northeast. Although the Dayton, OH monitor is located within a defined CBSA, it is on the property of a rural county high school. In general, the $PM_{2.5}/PM_{10}$ ratios observed from the new NCore data are considerably lower than the $PM_{2.5}/PM_{10}$ ratios for Eastern U.S. sites reported in the 2009 PM ISA (U.S. EPA, 2009) and other earlier studies.

The lower $PM_{2.5}/PM_{10}$ ratios indicate a generally higher fraction of $PM_{10-2.5}$ in the Eastern U.S. than was reported in the 2009 PM ISA. The trend of a greater $PM_{2.5}$ fraction in the East and greater $PM_{10-2.5}$ fraction in the West (U.S. EPA, 2009) is generally preserved, but the data in Table 2-7 show $PM_{2.5}$ contributing only slightly more to PM_{10} mass than $PM_{10-2.5}$ in urban sites of the Northeast. $PM_{10-2.5}$ made a greater contribution to PM_{10} not only at most western sites, but also in the Midwest (Cleveland, Detroit). Important exceptions to lower $PM_{2.5}/PM_{10}$ ratios in the Western U.S. were the major cities of the Pacific Northwest (Seattle, Portland), where $PM_{2.5}$ accounted for most of PM_{10} and $PM_{2.5}/PM_{10}$ ratios were similar to Eastern locations. $PM_{2.5}$ was 60% or more of PM_{10} at only 9 of 33 NCore stations. All of these were either rural Northeastern (Litchfield, CT, Peterborough, NH, Beltsville, MD, McFarland Hill, ME, Londonderry, NH) or urban Southeastern (Charlotte, NC, Raleigh, NC, Columbia, SC) sites. It appears that PM_{10} in the U.S. has become considerably coarser than observed in the 2009 PM ISA (U.S. EPA, 2009), and that in many urban areas $PM_{10-2.5}$ mass makes a similar or greater contribution to PM_{10} mass than does $PM_{2.5}$ mass.

2.5.1.1.5 Ultrafine Particles

Key atmospheric science related uncertainties identified in the 2009 PM ISA for linking measurable particle number concentration with adverse UFP effects were the lack of data on UFP concentrations, lack of data on UFP composition, lack of data on spatial and temporal evolution of UFP size distribution and chemical composition, the lack of a UFP network in the U.S., and the lack of information on spatial and temporal variability in UFP concentration. There are few long-term average data on particle number concentrations in the U.S. Annual average particle number concentrations reaching 22,000 cm^{-3} for particles from 0.003 to 0.5 µm in Pittsburgh (Stanier et al., 2004) and monthly

average concentrations exceeding 30,000 cm^{-3} for particles from 0.017 to 0.1 µm (Hughes et al., 1998) and from 0.014 to 0.7 µm (Singh et al., 2006) in Los Angeles have been reported. The 2009 PM ISA (U.S. EPA, 2009) described several ambient UFP characteristics. Number concentrations dropped off quickly with distance from a road, and greater spatial variability occurred for UFP than $PM_{2.5}$ on an urban scale. Traffic was described as a major source, but high number concentrations during new particle formation events were also described. OC was identified as the major UFP component in several studies, along with substantial contributions from EC and sulfate. Higher winter than summer concentrations were reported in several northern locations. UFP concentration peaks during rush hour in urban areas were described, and broad midday peaks in summer were also noted in some instances, possibly due to NPF after photochemical reactions (U.S. EPA, 2009).

Results from a number of field studies reported in the 2009 PM ISA (U.S. EPA, 2009) described spatial and temporal variations in total particle number concentrations used as an estimate of UFP number concentration. In general, spatial variability of total particle number concentration increased with increasing distance between measurements, increasing source variation in the area studied, and increasing particle size within the UFP size range. Figure 2-17 shows three sites in the state of New York where UFP measurements have been initiated. Hourly results over several years from these sites are presented in Figure 2-18 and provide a much larger data set for comparing spatial and temporal variability than has been previously available (NYDEC, 2016). Figure 2-18 shows the average particle count of each location at each hour of the day, beginning and ending at midnight. The Buffalo data are averaged over three sites. There is a pronounced difference in particle number concentration between locations, with urban particle number counts several times higher than the background site. Not shown in Figure 2-18, the highest particle number counts at three sites in Buffalo were observed at a near road site.

The particle numbers remain fairly constant throughout the day at the Steuben County background site, although particle number counts are slightly elevated on average during the midday hours. In contrast, particle numbers display daily trends, peaking around 8:00 a.m. in Buffalo and New York City (NYC), and remain high into the evening hours, with distinct rush hour and early afternoon peaks. These results are consistent with spatial and temporal results reported in the 2009 PM ISA, but are based on a much larger data set. The state of New York is continuing to analyze the data for seasonal differences in the frequency of high particle number counts and nucleation events, and neighborhood scale differences in a near road environment (NYDEC, 2016).

Figure 2-18 Average hourly particle number concentrations from three locations in New York state for 2014−2015.[39]

Routine monitoring to obtain long-term average particle number distributions is a relatively recent development (Wiedensohler et al., 2012) using electromobility and electrometer based methods developed for the European UFP monitoring network (Section 2.3.4.1). Average particle concentrations classified by size from 24 European monitoring sites over a period of 2 years were recently described (Asmi et al., 2011). As one example, at the Ispra, Italy site number concentrations averaged 1,341 cm^{-3} for 0.03 to 0.05 µm, 4,448 cm^{-3} for 0.05 to 0.1 µm, and 2,129 cm^{-3} for 0.1 to 0.5 µm, corresponding to an average of 73% of airborne particles smaller than 0.1 µm (Asmi et al., 2011). This is an upper limit value because a substantial number of particles can be smaller than the 0.03 µm lower size limit for these data

[39] NYC and Steuben County also include 6 months in 2012. Buffalo data are from three different sites, with the sampler moved between sites over the 2-year period. Data for the orange line depicting Buffalo are all from Buffalo, but not all from the same site within Buffalo.

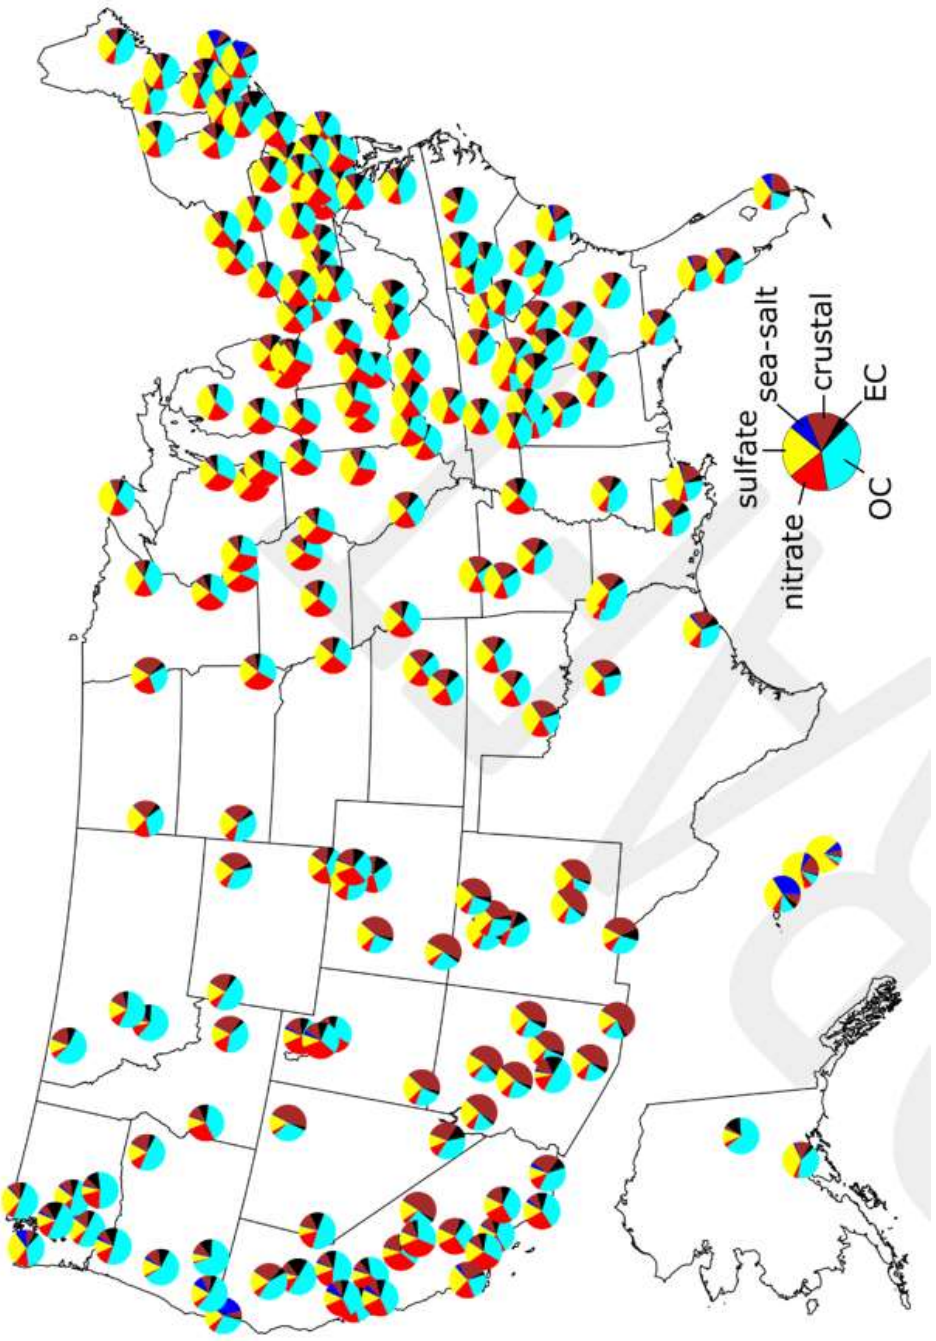
(Stanier et al., 2004). For all 24 European locations, the average upper limit percentage of particles smaller than 0.1 µm ranged from 67 to 85%.

No such large-scale summary of U.S. data is possible, because there are few long-term data on number size distributions in the U.S. Number size distribution data have been reported for an 8-year period from 2002 to 2009 in Rochester, and number concentrations averaged 4,730 cm^{-3} for 0.01 to 0.05 µm particles, 1,838 cm^{-3} for 0.05 to 0.1 µm, and 1,033 cm^{-3} for 0.1 to 0.5 µm (Wang et al., 2011). This corresponds to 90% of total particles smaller than 0.1 µm. This is a larger fraction than the European range, but the lower size limit was 0.01 µm, compared to 0.03 µm for the European network data (Wang et al., 2011). Long-term trends for this period are summarized in Section 2.5.2.1.4. These data can also be compared to earlier observations of particle number concentrations for eight size ranges for a full year from the Pittsburgh Air Quality study (Stanier et al., 2004). Using their data, it is possible to calculate that 90% of the number of particles were also smaller than 0.1 µm and that 98% were smaller than 0.2 µm.

2.5.1.1.6 $PM_{2.5}$ Components

It is useful to distinguish between bulk PM components and more finely speciated components. The term bulk component refers to a large component category like OC, sulfate, or nitrate, which is monitored in networks like CSN or IMPROVE and usually makes up a substantial portion of PM mass. It is also used to differentiate broad categories of components like OC and crustal material, which are considered bulk components, from more finely speciated components like individual organic compounds and elements, which are usually present in lower amounts.

Figure 2-19 shows contributions of sulfate, nitrate, OC, EC, crustal material, and sea salt to $PM_{2.5}$. A major change in $PM_{2.5}$ composition compared to the 2009 PM ISA (U.S. EPA, 2009) is the reduction in sulfate concentrations, resulting in a smaller sulfate contribution to $PM_{2.5}$ mass in 2013−2015 compared to what was reported for 2005−2007 in the 2009 PM ISA, especially in the Eastern U.S. As a result, at many locations sulfate has been replaced as the greatest single contributor to $PM_{2.5}$ mass by organic material or nitrate. This long-term trend demonstrating a reduction in sulfate concentrations is described in more detail in Section 2.5.2.1.4.



Source Permission pending: U.S. EPA 2016 analysis of Air Quality System network data 2013−2015.

Figure 2-19 Contributions of sulfate, nitrate, organic carbon (OC), elemental carbon (EC), crustal material, and sea salt to $PM_{2.5}$.

Regional patterns of component contributions to $PM_{2.5}$ in Figure 2-19 are similar to those reported in the 2009 PM ISA (U.S. EPA, 2009). Sulfate and OC are the species with the highest

contribution to total mass in most eastern locations and OC usually makes the greatest contribution to $PM_{2.5}$ mass in the west, although sulfate, nitrate, and crustal material can also be abundant (U.S. EPA, 2009). Urban and rural sulfate are both substantially higher in the East than in the West (Hand et al., 2012c). The highest nitrate concentrations are found in the west, particularly in California, but with some elevated concentrations in the upper Midwest. Larger contributions of OC to $PM_{2.5}$ mass observed in the Southeast and the West than in the Central and Northeastern U.S. are consistent with larger OC concentrations in those regions described in the 2009 PM ISA (U.S. EPA, 2009). The ratio of organic mass to OC mass depends on source and aerosol age, and was discussed in detail in the 2009 PM ISA (U.S. EPA, 2009). Based on speciation data from 15 cities reported in the 2009 PM ISA, EC contributed a smaller fraction of $PM_{2.5}$ mass than sulfate, nitrate, or OC, but consistently accounted for 4−11% of $PM_{2.5}$ (U.S. EPA, 2009).

Nationally, higher urban than rural OC and EC concentrations were reported by (Hand et al., 2013) and differences in urban and rural seasonal patterns for OC and EC were also observed. They also reported the highest rural OC and EC concentrations were in the Northwest and Southeast (Hand et al., 2012c). On average, OC and EC concentrations were both more uniformly distributed in the eastern U.S., but more localized in the West, with the highest urban concentrations in the West during fall and winter (Hand et al., 2013). However, EC concentrations were more consistent across cities regardless of region in the 2009 PM ISA (U.S. EPA, 2009). In the Southeastern U.S., annual average primary OC concentrations were estimated to exceed annual average secondary OC concentrations, but secondary OC could exceed primary OC at rural sites during the warmest months, and secondary OC concentration also showed little difference between urban and rural sites (Blanchard et al., 2013).

A large fraction of organic PM can be water soluble (Mwaniki et al., 2014). During the summer CalNex 2010 campaign (Kelly et al., 2014), water soluble $PM_{2.5}$ was at a maximum in the morning and in the evening in the San Joaquin Valley of California. In the same study, nitrate was present at higher concentrations than sulfate or ammonium, averaging 0.8 $\mu g/m^3$ and there were hourly average concentrations greater than 25 $\mu g/m^3$ during the winter 2013 DISCOVER-AQ campaign (Kelly et al., 2018).

Fine soil concentrations are higher in the Southwest than in other parts of the U.S., and also exhibit seasonal patterns for urban and rural sites (Hand et al., 2012c). High PM concentrations in urban desert areas were associated with a substantial contribution from crustal material from both coarse and fine PM (Wagner and Casuccio, 2014). Soil related PM also contributes substantially to $PM_{2.5}$ in populated areas of other parts of the world (Satsangi and Yadav, 2014). The pattern of higher crustal material contributions to $PM_{2.5}$ in drier areas of the Western U.S. can also be seen in Figure 2-19 with the examples of Phoenix and Denver.

There are a few new results to add to the body of literature on elemental composition, concerning both ambient observations and sources. In Southern California the most abundant elemental species was sulfur, followed by Si, Fe, Ca, and Al, with soil related elements accounting for 51% of total elemental

mass measured. New research to investigate sources further explored the importance of brake wear, lubricating oils, gasoline and diesel combustion, secondary sulfates, sea salts, and biomass burning as sources of trace elements (Na and Cocker, 2009). New research on atmospheric iron indicate that extent of aqueous solubility of iron present in PM is related to sulfur content of the PM (Oakes et al., 2012b). In Atlanta, iron concentrations exhibit considerable fluctuation, and reach up to 300 to 400 ng/m^3 for a few hours at time, (Oakes et al., 2012b). In Atlanta Fe(II) accounted for between 5 and 35%, or an average of about 25% of total soluble iron (Oakes et al., 2012a). In rural samples copper and zinc were found to be mainly present as sulfates and also nitrates in $PM_{2.5}$ in rural samples, but copper and zinc compounds found in larger particles were similar to copper and zinc compounds found in soil (Osan et al., 2010).

2.5.1.1.7 $PM_{10-2.5}$ Components

It was noted in the 2004 AQCD (U.S. EPA, 2004) that concentrations of most elements differed between $PM_{2.5}$ and $PM_{10-2.5}$, but that concentrations of some metals were similar between the two size fractions. It was also noted that this contrasted with earlier years with less controlled combustion, when Pb and other metals were much higher in $PM_{2.5}$.

Components of $PM_{10-2.5}$ are not routinely monitored like they are for $PM_{2.5}$, and information on $PM_{10-2.5}$ composition is largely limited to specific local studies. In the Southeast, OC and nitrate made similar fractional contributions to $PM_{2.5}$ and $PM_{10-2.5}$, but there was much less sulfate and EC in $PM_{10-2.5}$ than $PM_{2.5}$, and much more major metal oxides (U.S. EPA, 2009). In Los Angeles, crustal material and trace elements accounted for 47.5% of total reconstructed coarse PM mass, with secondary ions (sulfate, nitrate, ammonium, 22.6%) and organic matter (19.7%) also making important contributions, and elemental carbon was a less significant component, accounting for less than 2% of the mass (Cheung et al., 2011). Los Angeles crustal materials had low water solubility, but Ba and Cu were modestly water soluble and activity due to reactive oxygen species was most highly associated with water soluble elements, V, Pd, Cu and Rh in Los Angeles (Cheung et al., 2012a).

In the desert southwest, crustal material is the dominant component of $PM_{10-2.5}$, sometimes accounting for more than half of the mass, followed by organic matter, accounting for 15% (Clements et al., 2014a, 2013). High correlations between $PM_{2.5}$ and PM_{10} indicated that a large component of the fine fraction was derived from dust (Clements et al., 2013). In Denver and Phoenix, $PM_{10-2.5}$ made a greater contribution to total ambient PM_{10} mass than in other cities (U.S. EPA, 2009). PM in Denver has been studied in more detail since then. Coarse PM concentrations were attributed to crustal material, road salt, vehicle abrasion and sulfate (Clements et al., 2014b).

While crustal material often makes the greatest contribution to $PM_{10-2.5}$ mass, the organic fraction also makes a substantial contribution. In the Southeast, organic and elemental carbon accounted for approximately 30% of $PM_{10-2.5}$. Primary biological aerosol particles (PBAP), which consist of microorganisms and fragments of living things, can account for a large fraction of $PM_{10-2.5}$ mass (U.S.

EPA, 2009). These have been measured by treating collected PM with a dye which only reacts with protein containing material (Matthias-Maser et al., 2000). PBAP cannot be distinguished from other types of OC by methods used in monitoring networks. New research on sources of PBAP was summarized in Section 2.3.3. New information on the nature of bioaerosols and biological material associated with particles is well-described in the review by (Froehlich-Nowoisky et al., 2016). PBAP includes living and dead organisms, e.g., algae, archaea, bacteria and viruses, dispersal units, e.g., fungal spores and plant pollen, various fragments or excretions, e.g., plant debris and brochosomes. This class of material can range in size from 1 nm (individual proteins) to 5 millimeters (pollen grains). Summertime aerosols in Phoenix were abundant in biological compounds (e.g., sugars and fatty acids), present almost exclusively in the coarse size fraction (Cahill, 2013).

A pilot study on $PM_{10–2.5}$ species monitoring was carried out to develop target species, evaluate analytical methods and field performance, and to assess sampling and operational issues for routine measurement of $PM_{10–2.5}$ species (U.S. EPA, 2015). Samples collected in all seasons over a period of 1 year in both Phoenix and St. Louis indicated that soil oxides dominated $PM_{10–2.5}$ mass, with organic matter accounting for 10−20%. Sulfate and nitrate accounted for very little of the $PM_{10–2.5}$ mass, although they were substantial contributors to $PM_{2.5}$ mass. Soil oxides were by far the largest component in both locations throughout the year, except in St. Louis in winter, when soil and organic contributions were similar, but overall $PM_{10–2.5}$ concentrations were considerably lower (U.S. EPA, 2015).

2.5.1.1.8 Ultrafine Particle Components

There was little information on the composition of UFP presented in the 2009 PM ISA, although urban UFP was suspected to be rich in OC and EC, and sulfate was expected to be a substantial contributor in rural areas while new particle formation occurred (U.S. EPA, 2009). New research indicates that motor vehicles are a major, and frequently dominant, source of ultrafine particles in urban environments (Morawska et al., 2008). Chemical composition of these particles are determined by the composition of the used fuel and lubricating oil, driving conditions, and engine after-treatment system, as well as meteorological conditions, but generally PM from these sources consists mostly of agglomerates of solid-phase carbonaceous material, and can also contain metallic ash, adsorbed or condensed hydrocarbons and sulfur compounds, and liquid droplets consisting mainly of hydrocarbons and hydrated sulfuric acid that form very rapidly after the vehicle exhaust leaves a tailpipe (Liu et al., 2015; Saffaripour et al., 2015; Karjalainen et al., 2014; Rönkkö et al., 2014; Fushimi et al., 2011; Gidney et al., 2010; Heikkilä et al., 2009; Johnson, 2009).

The chemical composition of ultrafine particles originating from atmospheric NPF is tied heavily to their growth processes during their atmospheric aging. Direct observations during the period of atmospheric NPF show that the composition of particles originating from NPF is usually dominated by organic compounds, especially in forests (Han et al., 2014; Pennington et al., 2013; Pierce et al., 2012; Pierce et al., 2011), but also in many rural or urban environments (Bzdek et al., 2014; Setyan et al., 2014;

Bzdek et al., 2013; Ahlm et al., 2012; Smith et al., 2008). Exceptions for this pattern are environments exposed to major sulfur emissions, in which sulfate may explain up to about half of the ultrafine particle mass (Vakkari et al., 2015; Crilley et al., 2014; Bzdek et al., 2012; Zhang et al., 2011b; Wiedensohler et al., 2009).

2.5.1.1.9 Reactive Oxygen Species

Particle acidity, oligomer formation and the production of reactive oxygen species (ROS) are interrelated, aqueous phase processes with direct consequence for aerosol concentrations, chemical composition and toxicity (Weber et al., 2016). Polymerization reactions responsible for generating oligomers in atmospheric particles require relatively high concentrations of H^+. The reactive forms of the transition metals that play a central role in production of particle phase ROS primarily exist in low pH aqueous conditions.

Sulfate is often the main acid component of $PM_{2.5}$, and largely determines its acidity. Contrary to expectations, declining SO_2 emissions along with fairly stable NH_3 emissions (see Section 2.3.2.1), have led to little long-term change in pH of $PM_{2.5}$ (see Section 2.5.1.1.6). Low pH conditions facilitate the formation of oligomers and HULIS in aqueous particles. Upwards of 90% oligomeric/high molecular weight material has been found in SOA formed in the presence of NO_X, including a substantial fraction of organic nitrogen compounds (Nguyen et al., 2011). Humic-like substances and smaller organic compounds have been implicated in the production of particle-phase ROS, along with transition metal ions, especially Cu and Mn (Verma et al., 2015).

The 2009 PM ISA described early chamber work on identifying reactive oxygen species (ROS) in secondary organic PM by Docherty et al. (2005). Under the conditions of their experiment, they produced very high yields (47 and 85%) of organic peroxides by reacting O_3 with α- and β-pinene. Reactive oxygen species include hydroxyl radical, organic peroxides and hydroperoxides. A discussion of the role of particle-phase ROS in human health effects can be found in Section 5.1.1.

Identification of individual components that act as ROS in PM is incomplete and an active area of research. The extent to which an ambient particle can engage in oxidative reactions depends on the concentration of aqueous oxidants, such as the hydroxyl radical (OH), and whether or not reactants capable of producing additional oxidants are present within the particle. Oxidants, in addition to OH, can be taken up from the atmosphere or chemically formed from processes such as photolysis of nitrate, nitrite, or hydrogen peroxide (H_2O_2), or Fenton-type reactions between H_2O_2 and Fe(II) (McNeill, 2015; Arakaki et al., 2013; Ervens et al., 2011; Herrmann et al., 2010). Organic species, such as quinones, can act as transition ion reducing agents, which allow oxidized form of an aqueous transition metal ion to produce more ROS (Shirai et al., 2012). Tuet et al. (2017) found that the identities of available reactive precursors in the particle phase, humidity and the fate the reactive intermediate were important

determinants of particle reactivity. Atmospheric aging (oxidation) of organic aerosols has also been found to be an important indicator of ROS activity of ambient PM (Saffari et al., 2016; Verma et al., 2015).

2.5.1.2 Urban and Neighborhood Scale Variability

2.5.1.2.1 $PM_{2.5}$

Understanding spatial variation at the neighborhood and urban scale is important for interpreting data from community monitors. Because of its longer atmospheric lifetime (see Section 2.2), $PM_{2.5}$ is expected to exhibit less spatial variability on an urban scale than UFP or $PM_{10–2.5}$. In the 2004 PM AQCD (U.S. EPA, 2004) annual average $PM_{2.5}$ concentration differences between monitors within the urban area were compared for 17 urban areas. The difference in concentration between monitors with the highest and lowest concentrations ranged from less than 1 $\mu g/m^3$ (Baton Rouge, LA) to more than 8 $\mu g/m^3$ (Pittsburgh, PA). The difference exceeded 6 $\mu g/m^3$ in 6 of the 17 cities (Pittsburgh, Cleveland, Chicago, Detroit, St. Louis, Seattle), in 5 of which the highest $PM_{2.5}$ concentrations were between 20 and 22 $\mu g/m^3$. In the remaining city (Seattle) concentrations ranged from 6 to 12 $\mu g/m^3$.

The degree of spatial uniformity within urban areas also varied depending on location (U.S. EPA, 2004). Intra-urban spatial variability of $PM_{2.5}$ concentrations was discussed in considerable quantitative detail in the 2009 PM ISA, using a number of comparison statistics (U.S. EPA, 2009). In most metropolitan areas correlations between $PM_{2.5}$ monitoring sites up to a distance of 100 km from each other were greater than 0.75, with the notable exceptions of Denver, Los Angeles, and Riverside (U.S. EPA, 2009). However, while $PM_{2.5}$ concentrations at different sites within an urban area can be highly correlated, significant differences in concentration can occur on a given day (U.S. EPA, 2009).

Several recent publications have addressed urban scale spatial variability. Urban concentrations are often several $\mu g/m^3$ above regional background concentrations. For example, Indianapolis urban concentrations are on average 3.9 to 5. $\mu g/m^3$ higher than regional background (Sullivan and Pryor, 2014). Substantial spatial variation of $PM_{2.5}$ concentrations has been reported for New York City (Matte et al., 2013). Spatial variability was also demonstrated by a study indicating that $PM_{2.5}$ was present at significantly higher concentrations at urban sites than at upwind suburban sites in the greater New York area (Patel et al., 2009). Substantial differences in $PM_{2.5}$ concentrations between neighborhoods was also observed in Los Angeles (Fruin et al., 2014), but not in Boston (Patton et al., 2014). One of the contributing factors was that monitors are closer to each other in Boston, where more uniformity was observed. Sub-10 km spatial variability was identified as a contributor to poor results for satellite estimates of $PM_{2.5}$ from aerosol optical depth (AOD) using a 10 × 10 km grid (Lary et al., 2014; Chudnovsky et al., 2013b). In Indianapolis for time scales shorter than 1-day spatial variability was 2 to 3 times greater than temporal variability (Sullivan and Pryor, 2014). However, for 24-hour measurements

of PM components temporal variability accounted for 90% of the variance in Detroit (Bereznicki et al., 2012).

Spatial variability arises from source proximity, with motor vehicles accounting for 24 to 36% and secondary sulfate for 17 to 35% of $PM_{2.5}$ among different residential monitoring areas in Detroit, MI (Duvall et al., 2012). Diesel exhaust was also identified as a major and variable source of $PM_{2.5}$ in New York City (Patel et al., 2009). Land use regression modeling based on 155 city-wide street-level locations in New York City (Clougherty et al., 2013) indicated that concentrations of $PM_{2.5}$ and other pollutants varied by more than a factor of two, with highest concentrations near midtown Manhattan. They also reported that density of oil-burning boilers along with total and truck traffic density explained more than 80% of $PM_{2.5}$ spatial variability (Clougherty et al., 2013). However, in Dallas $PM_{2.5}$ exposure was only moderately associated with motor vehicles and weakly associated with industrial sources, but strongly associated with population density (Zou et al., 2009). Overall, recent observations indicate that uniform $PM_{2.5}$ concentrations can occur, but that substantial spatial variability is also common.

2.5.1.2.2 PM_{10}

PM_{10} concentrations vary by as much as a factor of five over urban scale distances of 100 km or less and by a factor of two or more over scales as small as 30 km (U.S. EPA, 2009; Alexis et al., 2001). Differences in PM_{10} measurements across 15 cities were summarized in the 2009 PM ISA (U.S. EPA, 2009). PM_{10} concentrations were less well correlated than $PM_{2.5}$, probably because of greater spatial variability of $PM_{10-2.5}$ (see Section 2.5.1.2.3). For monitors less than 4 km apart an average correlation of 0.93 between $PM_{2.5}$ monitors and 0.70 for PM_{10} monitors was observed (U.S. EPA, 2009). Spatial and temporal differences in PM_{10} concentrations have also been predicted from models based on the geographic information system; meteorological and copollutant data for both fine and large spatial scales and distance to road; elevation; and proportion of low-intensity residential, high-intensity residential, industrial, commercial, and transportation land use within 1 km have all been reported to be statistically significant predictors of measured PM_{10} (Blanchard et al., 2014; Paciorek et al., 2009; Yanosky et al., 2009); (Yanosky et al., 2014).

2.5.1.2.3 $PM_{10-2.5}$

As indicated in the 2004 PM AQCD (U.S. EPA, 2004), the shorter lifetime of $PM_{10-2.5}$ leads to lower spatial correlations for $PM_{10-2.5}$ than for either $PM_{2.5}$ or PM_{10} concentrations (U.S. EPA, 2009, 2004). Errors in measurement (see Section 2.4.4) can also contribute to lower spatial correlations of $PM_{10-2.5}$ (U.S. EPA, 2004). Recent observations from several cities indicate that there is often, but not always, considerable spatial variability in $PM_{10-2.5}$ concentrations in urban areas, that they are often related to specific industrial sources, and that concentrations of specific chemical components can be more variable than mass. In Detroit $PM_{10-2.5}$ was 5 $\mu g/m^3$ higher in two industrial areas, and 8 $\mu g/m^3$

higher in an area heavily impacted by traffic than average concentrations in other parts of the city, and not very consistent with central site monitor concentrations (Thornburg et al., 2009). Poor correlations between monitors were also observed in Los Angeles (Pakbin et al., 2010) and between industrial and suburban sites in Cleveland (Sawvel et al., 2015). In Rochester, NY, where major coarse particle sources were road dust and biological particles, considerable heterogeneity in both composition and concentrations were also observed between different sites (Lagudu et al., 2011).

2.5.1.2.4 Ultrafine Particles

As described in Section 2.5.1.1, UFP spatial variability increased with increasing distance between measurements, increasing source variation in the area studied, and increasing particle size within the UFP size range. (U.S. EPA, 2009). Particularly high spatial variabilities have been observed near roads with heavy traffic, where numerous observations of UFP number concentration declining sharply with distance from roadways have been reported (U.S. EPA, 2009).

More recently, spatial variability of UFP was compared between studies of two locations, Los Angeles, CA (Hudda et al., 2010; Krudysz et al., 2009; Moore et al., 2009) and Rochester, NY (Wang et al., 2012). These two studies provide an interesting comparison because the two studies were similar in domain size. The comparison is summarized in Table 2-8. It should be noted that the Los Angeles studies employed SMPS for particle size distribution measurements, while the Rochester study used a FMPS. Both Krudysz et al. (2009) and Hudda et al. (2010) indicated that regionally transported PM from upwind urban areas of Los Angeles lowered spatial variability by acting as a "homogenizing" factor during favorable meteorological conditions. This effect was not noticeable in Rochester, NY (Wang et al., 2012). Nevertheless, significant variability among sites was observed in both studies.

Table 2-8 Comparison between two urban-scale studies of UFP seasonal and spatial variability.

	Los Angeles, CA (Krudysz et al., 2009)	Rochester, NY (Wang et al., 2012)
Area	11 × 11 km, urban	9 × 9 km, urban
Sites	13 sites	12 sites
Instrumentation	SMPS (14−793 nm), CPC (>7 nm)	FMPS (with one SMPS in a fixed site), 5.6 to 560 nm
Levels of average total number concentrations	5,300 to 27,000 particles/cm^3	9,025 (summer), 10,939 (winter), 4,955 (spring), and 14,485 (fall) particles/cm^3
Seasonal variability	Relatively higher levels observed in the fall/winter than in the summer	Relatively higher levels observed in the fall/winter than in the spring; Relatively high 100−500 mode in the summer
Coefficient of divergence (COD)	>0.2 on average for all particles measured, 0.25 to 0.6 for size-dependent average COD	No clear overall pattern
Size-dependency	Number concentrations of smaller particles (<40 nm) differ from site to site, whereas larger particles tended to have similar concentrations at various sampling locations.	No clear overall pattern

Source: Krudysz et al. (2009).

2.5.1.2.5 Chemical Components

A detailed analysis of 15 urban locations in the 2009 PM ISA (U.S. EPA, 2009) indicated a generally fair degree of spatial uniformity in bulk $PM_{2.5}$ components. Exceptions were noted in one or two cities for crustal material, nitrate, elemental carbon, organic carbon and nickel (U.S. EPA, 2009). More recent observations have focused mainly on carbonaceous components across urban areas. Black carbon (BC) concentrations were 2 to 3 times higher at urban locations than at suburban locations in the greater New York area (Patel et al., 2009). There were several reports of higher concentrations of some PM components near roads with heavy traffic than other urban locations. For example, carbonaceous aerosols exhibited substantial intra-urban variability in Detroit, MI and Cleveland, OH that was consistent with local sources, with EC higher at sites adjacent to freeways and busy surface streets (Snyder et al., 2010). Site to site variability in OC was approximately 7% at distances from 0.5 to 4 km, but between 4−27% at distances 4 to 100 km. However, more finely speciated organic components differed by as much as 60% at the 0.5 to 4 km scale and up to 200% at the 4−100 km scale (Snyder et al., 2010). PAHs and steranes

along with OC and EC were found to be higher near roads with heavy traffic than in other urban locations (Xie et al., 2012). Differences of a factor of 2 to 3 between concentrations on major streets and at background locations in the same city in the Netherlands were also observed for chromium, copper, and iron, elements that were mainly present in the coarse fraction, as well as for black carbon and particle number count (Boogaard et al., 2011).

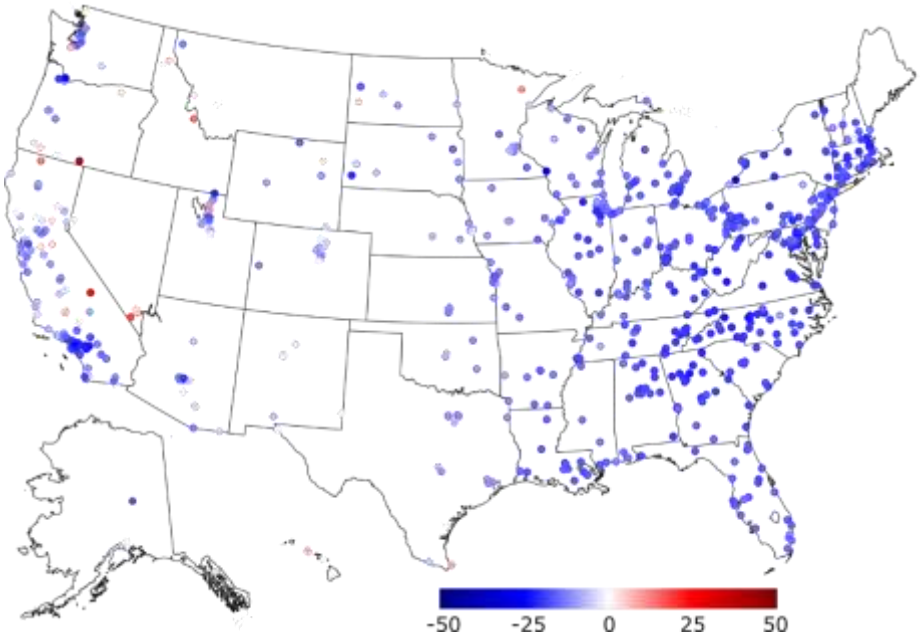
2.5.2 Temporal Variability

2.5.2.1 Regional Trends

Differences in national average concentrations and regional variability between data from immediately prior to this assessment and the 2009 PM ISA (U.S. EPA, 2009) were discussed in Section 2.5.1.1, which demonstrated substantial decreases in PM concentrations since publication of the 2009 PM ISA (U.S. EPA, 2009). This section expands on those observations by exploring long-term trends that extend back as far as 2000, when widespread network measurements of urban $PM_{2.5}$ began, in order to provide more complete assessment of trends.

2.5.2.1.1 $PM_{2.5}$

Figure 2-20 show how $PM_{2.5}$ concentrations have decreased substantially at almost all $PM_{2.5}$ monitoring sites between the periods 2003−2005 and 2013−2015, with especially large decreases in the Eastern U.S. Figure 2-21 also shows a decreasing trend of $PM_{2.5}$ concentrations as a time series using national data from network monitoring sites throughout the U.S. Overall, $PM_{2.5}$ concentrations have decreased substantially nationwide since the 2003−2005 period, especially in the Eastern U.S. $PM_{2.5}$ concentrations derived from satellite data also exhibit a decreasing trend, of $-0.39 + 0.10$ μg/m^3 per year averaged over a 1 by 1 degree grid (Boys et al., 2014).



Blue indicates a decrease and red indicates an increase. Percentage increase or decrease is indicated by color intensity of the circle.

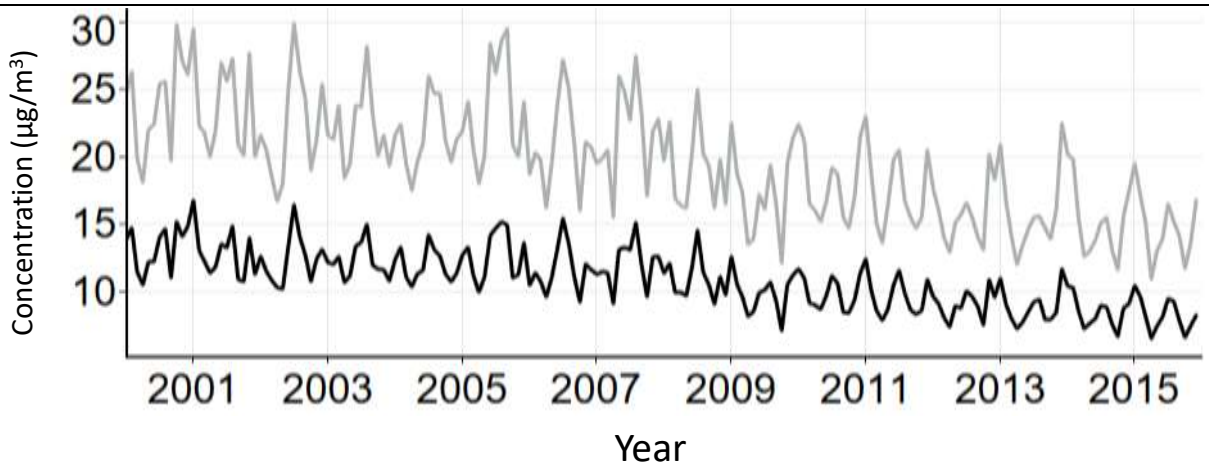
Figure 2-21 Average $PM_{2.5}$ concentration trends 2005−2014

The predominant downward trends shown in Figure 2-21 are a continuation of the decreasing trend in $PM_{2.5}$ concentration reported in the 2009 PM ISA (U.S. EPA, 2009), in which a 10% decrease in annual average $PM_{2.5}$ concentrations between the 3-year period from 1999−2001 and the 3-year period from 2005−2007 was described. Figure 2-22 shows an overall decrease in monthly and annual $PM_{2.5}$ average and 90th percentile concentrations over the 16-year period from 2000−2015, as well as a steadily shrinking summer peak, across all reporting FRM site-level monitors in the U.S. (Chan et al., 2018). Over this period $PM_{2.5}$ concentration averaged over the entire network decreased by 5 µg/m^3 and 90th percentile concentrations decreased by 9 µg/m^3 (Figure 2-22). It is evident from Figure 2-22 that the sharpest decrease occurred in 2008−2010.



Black = mean, gray = 90th percentile.

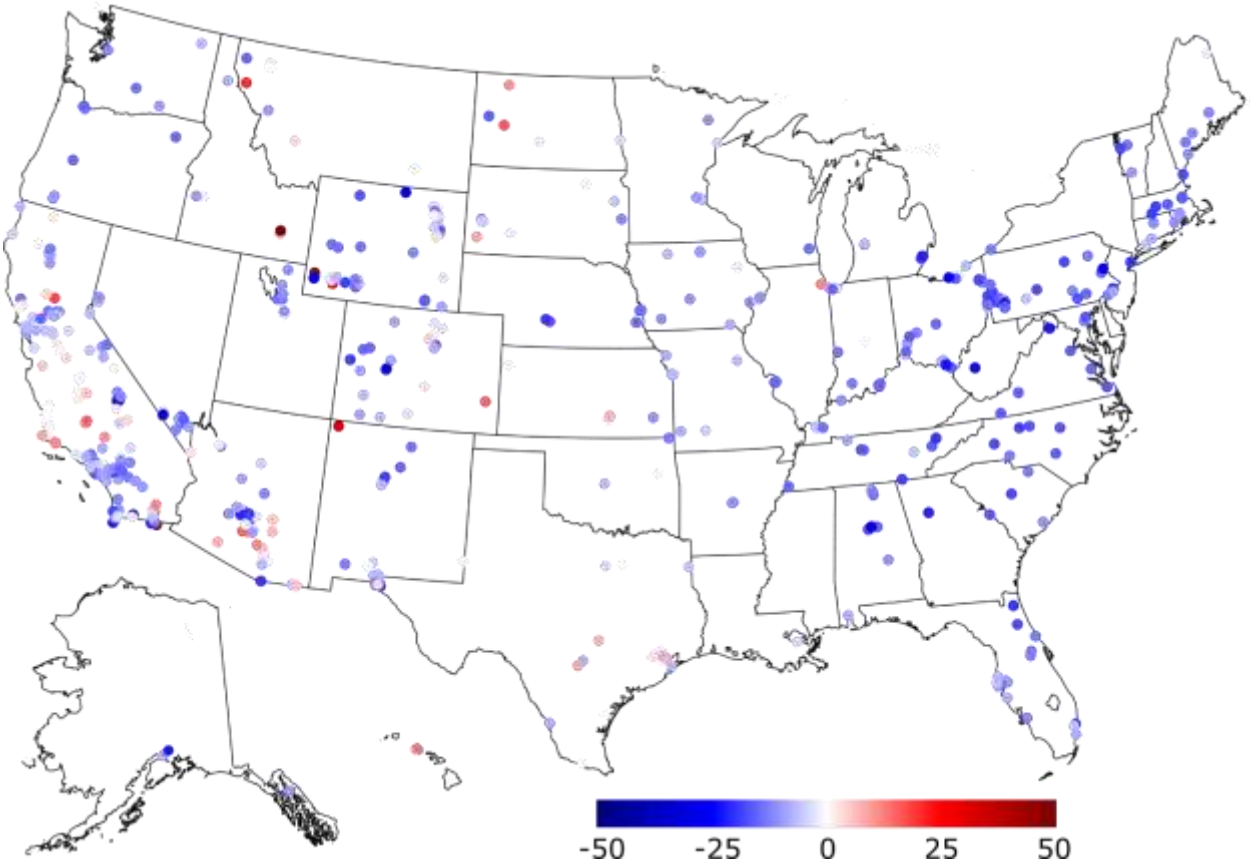
Figure 2-22 Long-term trend in national monthly and annual average $PM_{2.5}$ concentrations (µg/m³) from 2000−2015.

2.5.2.1.2 PM_{10}

Over the longer term PM_{10} has decreased steadily in several urban areas over the past several decades (U.S. EPA, 2004). Figure 2-23 shows a map of concentration trends in 98th percentile PM_{10} concentrations between 2003−2005 and 2013−2015 and Figure 2-24 shows a time series of national PM_{10} concentrations from 2005−2014. Most sites in the Eastern U.S. show decreasing concentrations over this period, consistent with the data of Table 2-5. However, there are locations in California, the Southwest, the Rocky Mountains, and the Great Plains that exhibit substantial increases in 98th percentile PM_{10} concentrations. The observed decreases in PM_{10} concentrations in many locations are consistent with similar observations for annual average $PM_{2.5}$ concentrations (see Section 2.3.4), reflecting that $PM_{2.5}$ has accounted for the majority of PM_{10} in the Eastern U.S. and a large fraction of PM_{10} throughout the U.S. over the period of decline. However, Figure 2-24 shows no evidence of a nationwide trend of decreasing PM_{10} concentrations in a time series of PM_{10} concentrations from network monitoring sites throughout the U.S.



Blue indicates a decrease and red indicates an increase. Percentage increase or decrease is indicated by color intensity of the circle.

2.5.2.1.3 $PM_{10-2.5}$

Long-term concentration trends for urban $PM_{10-2.5}$ are difficult to determine from network data because $PM_{10-2.5}$ monitoring was too recently implemented. However, some NCore stations began $PM_{10-2.5}$ measurements in the mid-2000's and IMPROVE measurements of $PM_{10-2.5}$ have been operating even longer, and although IMPROVE sites are mostly rural, some are collocated with CSN sites. These could be analyzed for long-term trends. In a Los Angeles field study $PM_{10-2.5}$ decreased by 0.39 µg/m^3 from 19 to 15 µg/m^3 for the period 1999 to 2009 compared to 0.92 µg/m^3 for $PM_{2.5}$ over the same period (Cheung et al., 2012b).

2.5.2.1.4 Ultrafine Particles

Information on UFP concentrations is very limited, confined to very few network monitors that only recently became operational. Data from field studies have been published periodically, but are generally insufficient to assess long-term trends of UFP in any location. One exception is 8 years of UFP data from Rochester, NY, the particle number characteristics of which were summarized in Section 2.5.1.1.5 (Wang et al., 2011). On average over the 8 years that UFP data were collected in Rochester, total particle number concentrations were greater before 2006 than after 2006. This trend was most evident for particles between 0.01 and 0.1 μm. The difference was described as probably due to several changes in local sources due to the 2007 Heavy Duty Highway Rule, a reduction in local industrial activity, and the closure of a nearby coal-fired power plant (Wang et al., 2011).

2.5.2.1.5 Chemical Components

Figure 2-25 and Figure 2-26 show changes in the distribution of bulk $PM_{2.5}$ components, between the 3-year period from 2003−2005 and the 3-year period from 2013−2015. The most noticeable difference is the change in sulfate contribution, which dominates $PM_{2.5}$ mass in the East during the period 2003−2005, but by 2013−2015 it has declined enough that it is no longer the most abundant component in many Eastern locations.

In the 2009 PM ISA (U.S. EPA, 2009), sulfate is described as the most abundant component of $PM_{2.5}$ on a national average, with nitrate, particulate organic matter and sometimes crustal material also contributing substantially to $PM_{2.5}$ mass. The relative abundance of major $PM_{2.5}$ components has changed since the 2009 PM ISA (U.S. EPA, 2009), with lower contributions from sulfate and greater contributions of nitrate and particulate organic matter as a result of the steep decline in SO_2 emissions (see Section 2.3.2.1). The resulting decrease in sulfate concentrations closely follows the recent long-term decrease in $PM_{2.5}$ concentrations described in Section 2.5.2.1.1, and is magnified for monitoring sites in the Eastern half of the U.S., where sulfate has until recently been the most abundant $PM_{2.5}$ components, and where SO_2 emissions have declined the most.

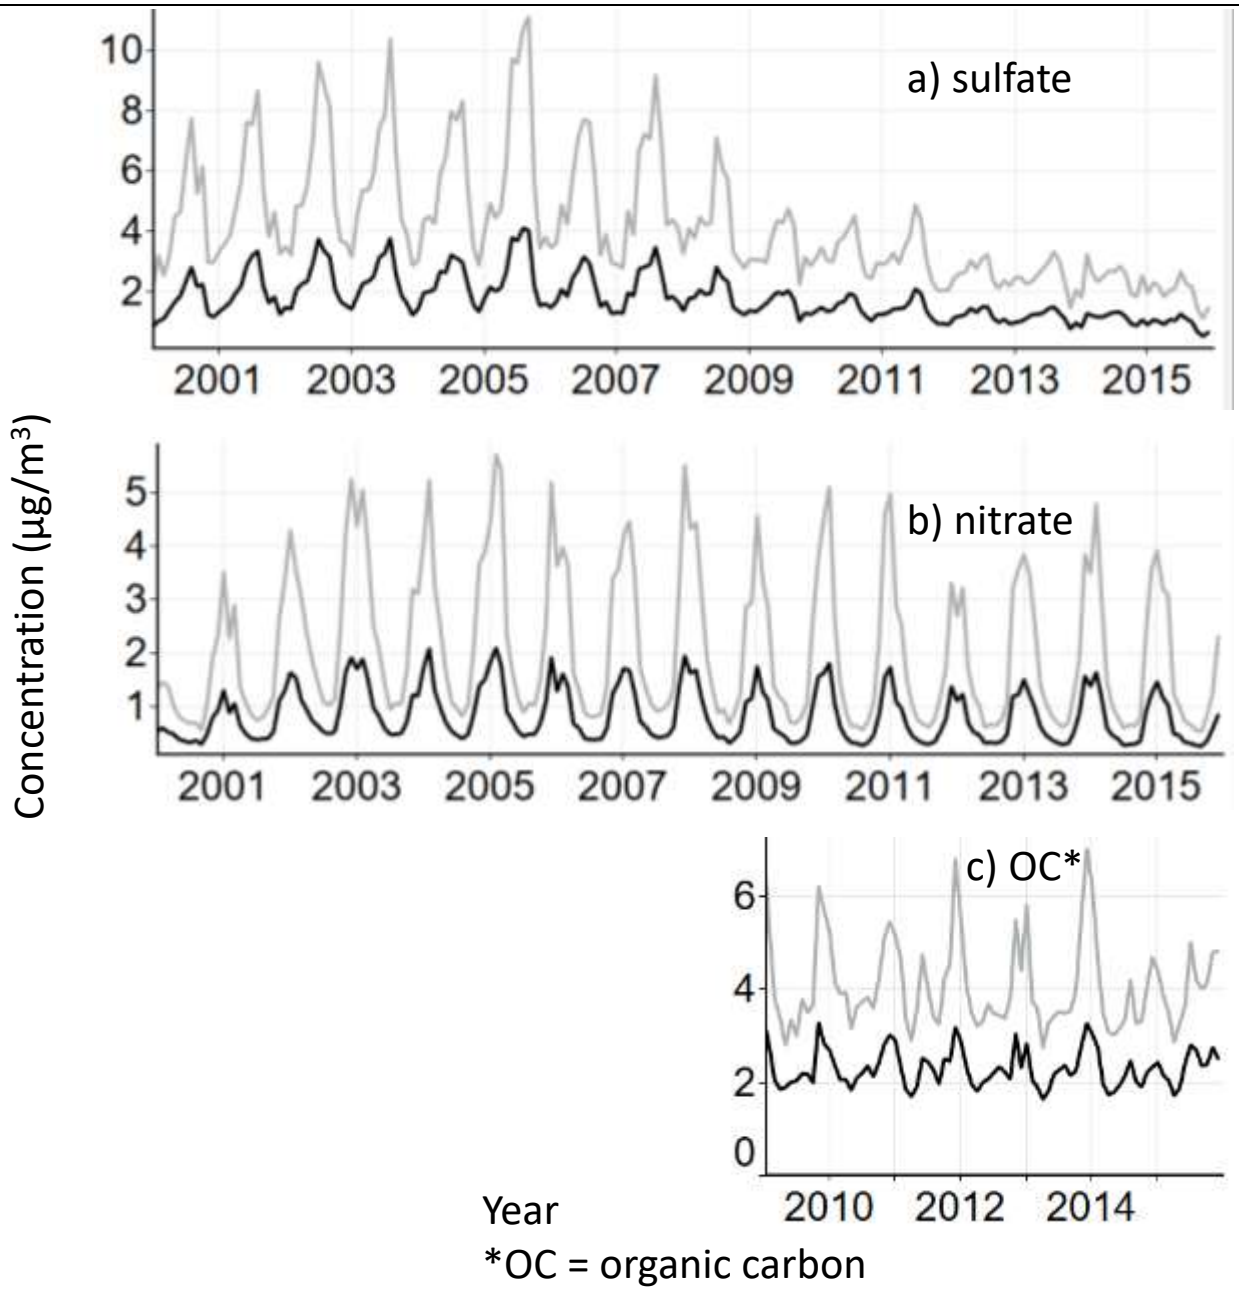
Figure 2-26 Contributions of sulfate, nitrate, organic carbon (OC), elemental carbon (EC), crustal material, and sea salt to $PM_{2.5}$ at selected sites 2013−2015.

Figure 2-27 shows $PM_{2.5}$ sulfate, nitrate and OC concentrations from 2000−2015 based on IMPROVE and CSN network data. A steep decline in sulfate concentration is observed, but less change is evident for nitrate and OC concentrations. Like the summer $PM_{2.5}$ maximum (Figure 2-22), the summer sulfate peak also declines to become almost imperceptible toward the end of the period. Based on these observations, it appears that decreases in SO_2 emissions (Section 2.3) have contributed to a substantial decrease in atmospheric sulfate concentrations. The declining sulfate concentrations are also consistent with CMAQ predictions of the sulfate response to decreasing SO_2 emissions. Because sulfate has accounted for such a large fraction of $PM_{2.5}$ mass, the decreasing trend in sulfate concentration is also manifested in lower $PM_{2.5}$ concentrations (Section 2.5.2.1.1) and smaller $PM_{2.5}/PM_{10}$ ratios (Section 2.5.1.1.4). However, sulfate is not the only $PM_{2.5}$ species that exhibited decreasing concentrations over this period, as described below.



Black = mean, gray = 90th percentile.

Figure 2-27 National monthly concentrations (µg/m^3) of (a) sulfate, (b) nitrate, and (c) organic carbon (OC) from 2000−2015.

Long-term trends in $PM_{2.5}$ component concentrations from the CSN and IMPROVE networks were also recently described in a series of papers (Hand et al., 2013; Hand et al., 2012a; Hand et al., 2012b). In general sulfate has decreased fairly consistently at rural sites at a rate of −2.7% per year from 1992 to 2010 (Hand et al., 2012b). An even steeper decrease in sulfate concentrations has been observed in the most recent years, of −4.6% per year at rural sites from 2001 to 2010 and −6.2% per year at urban sites from 2002−2010 (Hand et al., 2012b). This is similar to the rate of decrease of SO_2 emissions from power plants, and decreases were greater and more linear in the East, where power plant emissions had the greatest contributions to sulfate concentration (Hand et al., 2012b). However, in the winter in the northern and central Great Plains sulfate and nitrate concentrations have increased at a rate of over 5% per year over the period 2000−2010, in spite of decreased nationwide emissions (Hand et al., 2012a), and sulfate increases in spring in some parts of the West were also observed (Hand et al., 2012b). These increases could not be explained by known changes in local or regional emissions (Hand et al., 2012b). In the SEARCH network downward trends in mean annual sulfate concentrations from 1999 to 2010 ranged from -3.7 ± 1.1 to -6.2 ± 1.1% per year. The sulfate reduction was linearly related but not proportional to SO_2 decrease of -7.9 ± 1.1% per year from 1999 to 2010. Over the same period mean organic matter concentration decreased by -3.3 ± 0.8 to 6.5 ± 0.3% per year and elemental carbon by -3.2 ± 1.4 to -7.8 ± 0.7% per year (Blanchard et al., 2013). Total carbon (OC + EC) generally decreased in both urban and rural areas, with the strongest trends in the West (Hand et al., 2013).

For species that are more strongly influenced by local urban sources, trends are manifested more locally, and largely controlled by changes in local source emissions. Al, Fe, and Si decreased in Los Angeles, suggesting successful control of fugitive dust emissions, but Cu declined little, probably indicating similar contributions from brake wear (Cheung et al., 2012b).

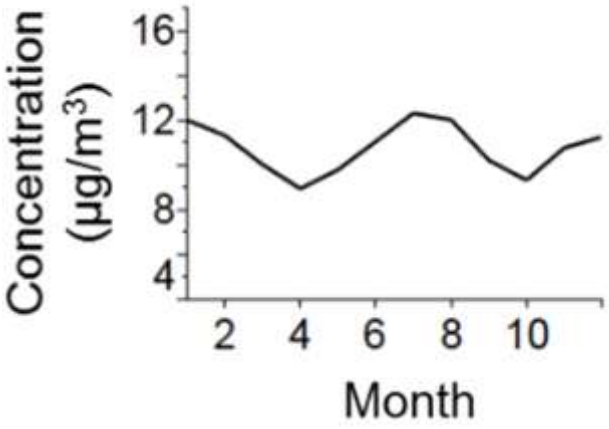
2.5.2.2 Seasonal Variations

2.5.2.2.1 $PM_{2.5}$

Observations described in Section 2.5.2.1.1 indicated that national average $PM_{2.5}$ concentrations and 98th percentile concentrations from 2013−2015 were both higher in winter than in summer (Table 2-4), and observations described in Section 2.5.2.1.1 indicated that monthly average $PM_{2.5}$ concentrations exhibited distinct summer and winter peaks superimposed on a steadily declining national average $PM_{2.5}$ (Figure 2-22). Averaged over all locations and years from 2001−2016, seasonal average $PM_{2.5}$ concentrations were approximately 12 µg/m^3 in summer and winter, but declined to approximately 9 µg/m^3 in the spring and fall (see Figure 2-28).

While monthly average $PM_{2.5}$ concentrations are higher in summer than in winter from 2002−2008, this pattern is reversed from 2009−2015, when monthly average $PM_{2.5}$ concentrations become higher in winter than in summer (see Section 2.5.2.1.1, Figure 2-22). This is a major departure

from previous concentration trends. Observations that the highest seasonal average concentrations occurred in summer in the Eastern U.S. and in winter in the Western U.S. with a few exceptions was already clearly established from 1999−2001 data from the newly operational $PM_{2.5}$ network (U.S. EPA, 2004). These early $PM_{2.5}$ network results were in turn consistent with previous studies carried out prior to its implementation, and were confirmed in the 2009 PM ISA (U.S. EPA, 2009). The observed reduction in summer $PM_{2.5}$ concentrations in the East to the extent that summer is no longer the season with the highest national average $PM_{2.5}$ concentrations is a major development, and is a predictable consequence of successful reduction of SO_2 emissions.



Source Permission pending: Chan et al. (2018).

Figure 2-28 National average $PM_{2.5}$ concentration by month 2000−2015.

2.5.2.2.2 $PM_{10-2.5}$

Relatively little had been published on the seasonal variability in $PM_{10-2.5}$ concentrations at the time of the 2009 PM ISA (U.S. EPA, 2009). Figure 2-29 shows three U.S. regions used for comparison of $PM_{10-2.5}$: the U.S. East of the Mississippi and the Northern and Southern portions of the U.S. West of the Mississippi. The regions were divided in this way because previous discussions based on limited data had suggested that PM_{10} was mostly $PM_{2.5}$ in the eastern U.S. and mostly $PM_{10-2.5}$ in the western U.S. (U.S. EPA, 2009, 2004), and these two regions were compared to investigate whether there were also seasonal differences between East and West. However, because results indicated that geographic differences within the western U.S. were greater than observed East-West differences, the western U.S. was further divided into northern and southern portions.

Figure 2-30 shows average concentrations on each day for 4 years from 2011−2014 by region based on data from the IMPROVE network, after dividing the U.S. into these three regions. All regions

display clear seasonal variations, with the lowest concentrations occurring around January and the highest occurring in the summer months. The highest $PM_{10-2.5}$ concentrations are observed in the Southwest/Central region. Concentrations in this region are much higher than concentrations in the East and a seasonal pattern of high summer and low winter concentrations is apparent. By contrast, average concentrations in the Northwest region stretching all the way from the Pacific to the Dakotas were more similar to those in the East, but with a more pronounced seasonal pattern than either the East or the Southwest. These observations indicate that geographic patterns of $PM_{10-2.5}$ concentrations are more complicated than a simple East-West split, but that there are large areas of the Western U.S. where average $PM_{10-2.5}$ concentrations are similar to the Eastern U.S.

Figure 2-30 Average daily $PM_{10-2.5}$ concentrations over the 4-year period 2011−2014 collected by the Interagency Monitoring of Protected Visual Environments (IMPROVE) network.

The seasonal differences described in Section 2.5.1.1.3 of highest $PM_{10-2.5}$ concentrations in Spring and Fall and lowest concentration in winter (see Table 2-6) are consistent with other recent observations. In Colorado the highest $PM_{10-2.5}$ concentrations were observed in the Spring and Fall (Clements et al., 2014b). The monsoon period in this region is characterized by high wind events that increase $PM_{10-2.5}$ concentrations due to local wind driven soil, especially at rural sites with agricultural activity (Clements et al., 2014b). In Los Angeles $PM_{10-2.5}$ concentrations were 2−4 times higher in summer than in winter (Pakbin et al., 2010). However, organic coarse PM in Southern California was higher in winter than summer, and mostly was due to soil or biota, especially in "semirural" areas like Riverside and Lancaster (Cheung et al., 2012b).

2.5.2.2.3 Ultrafine Particles

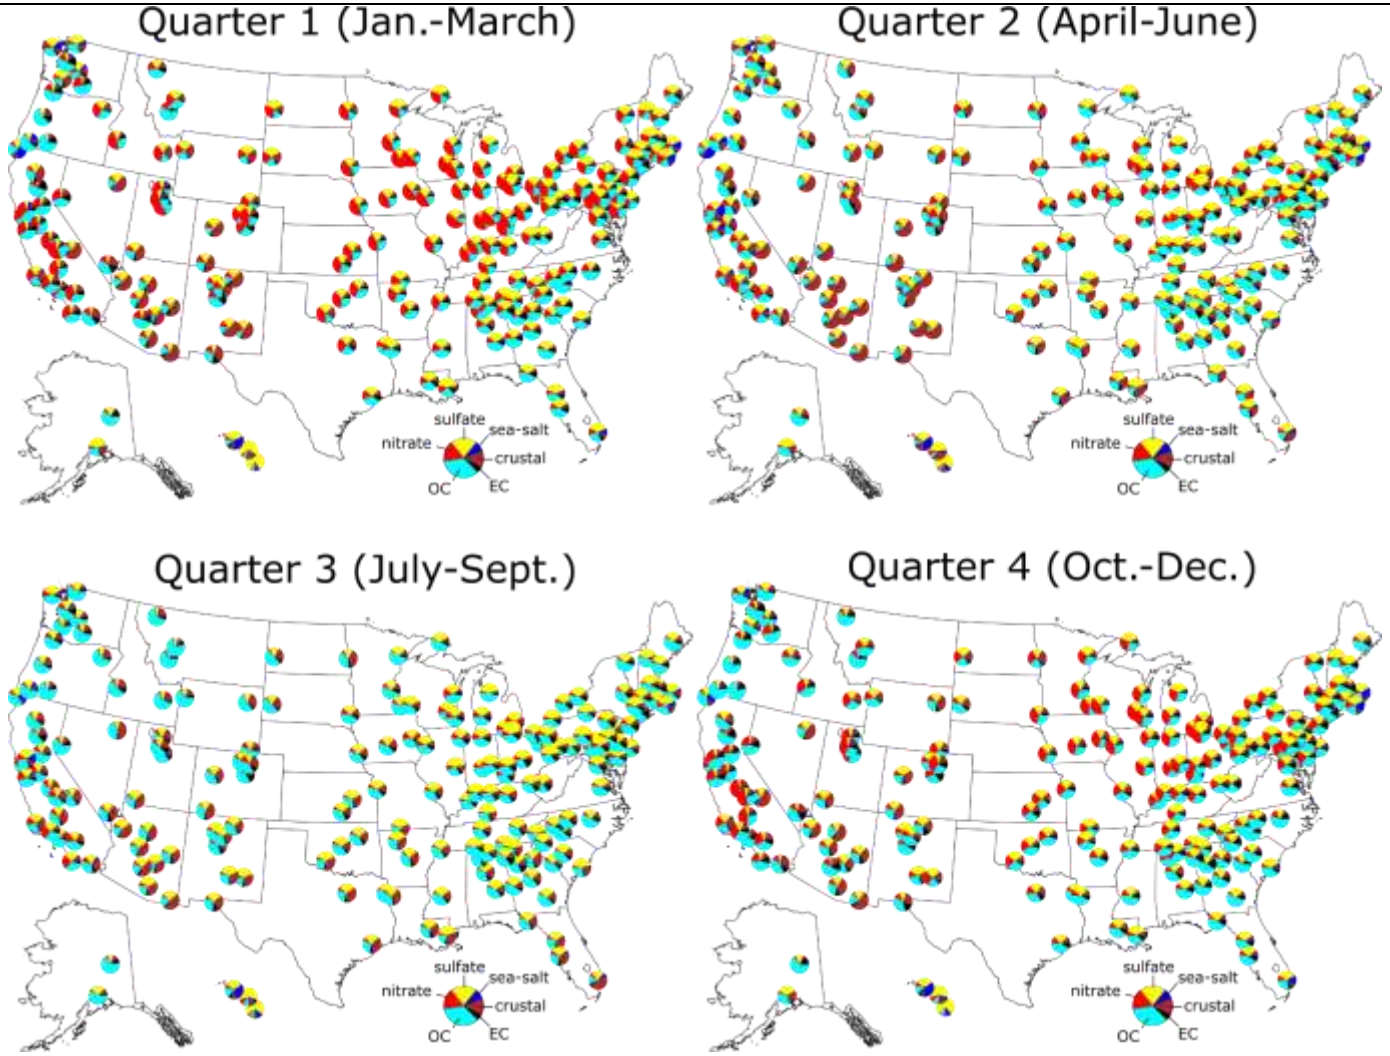
Relatively little has been published about seasonal or hourly differences in UFP concentrations except for localized studies in a few locations suggesting higher concentrations in winter than summer and an inverse relationship between UFP number and temperature (U.S. EPA, 2009). High afternoon concentrations during warmer months were attributed to NPF and high winter and evening UFP concentrations were attributed to lower mixing heights (U.S. EPA, 2009). More recent results indicate urban episodes of high UFP concentrations occur more often in winter than in summer (NYDEC, 2016).

2.5.2.2.4 PM Components

PM composition varies considerably with season. Figure 2-31 shows these changes. Seasonal concentration patterns are for the most part similar to those reported in the 2009 PM ISA (U.S. EPA, 2009) and conclusions from recent analyses of network data (Hand et al., 2013; Hand et al., 2012c) are consistent with patterns that can be observed in Figure 2-31. Sulfate and OC together accounted for the majority of $PM_{2.5}$ mass in many metropolitan areas in the summer, while higher nitrate concentrations were observed in the winter (U.S. EPA, 2009). Urban and rural seasonal variations of ammonium sulfate were similar, and both urban and rural concentrations were substantially higher in the East (Hand et al., 2012c). High winter nitrate concentrations were common in both urban and rural areas, but higher in urban areas (Hand et al., 2012c). Fine soil concentrations, highest in the Southwest, also had similar seasonal patterns for urban and rural sites (Hand et al., 2012c).

The higher OC contributions in fall and winter in the West compared to lower OC concentrations in winter in the Southeast reported in the 2009 PM ISA (U.S. EPA, 2009) are evident in Figure 2-31. EC mass concentration exhibited smaller seasonal variability than OC, particularly in the eastern half of the U.S. Carbonaceous aerosols varied more with season in the West than in the East for both urban and rural sites, although the seasonal patterns were different between Western urban and rural sites (Hand et al., 2013). PBAP often contributes more to PM mass in spring and summer than in fall and winter (U.S. EPA, 2009).

The metals Cu, Fe, Se, Pb, V, and Ni showed less seasonal variability than the sulfate, nitrate, and OC as reported in the 2009 PM ISA (U.S. EPA, 2009). More recently, in Los Angeles, trace element concentrations were higher in drier months of September and October, compared to December and January (Na and Cocker, 2009).



Source Permission pending: U.S. EPA 2016 analysis of Air Quality System network data 2013−2015.

Figure 2-31 Ambient $PM_{2.5}$ seasonal composition 2013−2015.

2.5.2.3 Hourly and Weekday-Weekend Variability

As described in the 2009 PM ISA (U.S. EPA, 2009), hourly $PM_{2.5}$ and PM_{10} measurements are conducted at several hundred network monitoring sites. A two-peaked diel pattern was observed in diverse urban locations and attributed to rush-hour traffic for the morning peak and a combination of rush hour traffic, decreasing atmospheric dilution, and nucleation for the afternoon/evening peak (U.S. EPA, 2009). In most cities, a morning $PM_{2.5}$ peak was present starting at approximately 6:00 a.m., corresponding with the start of the morning rush hour just before the break-up of the planetary boundary layer. Figure 2-32 shows diurnal patterns for multiple cities using more recent data showing rush hour peaks in the morning and evening in most cases, which is consistent with the daily variability in $PM_{2.5}$ concentrations observed in the 2009 PM ISA (U.S. EPA, 2009).

Diurnal variations in $PM_{10-2.5}$ concentrations have also been investigated. In Los Angeles in the summer the highest concentrations of $PM_{10-2.5}$ were observed in midday and afternoon when winds were the strongest. Traffic was responsible for significant resuspension especially during winter nights when mixing heights were lowest at near-freeway sites in urban areas of Southern California (Cheung et al., 2012b).

As described in Section 2.5.1.1.5 (Figure 2-18), for UFP a diel maximum was observed on average during evening hours in diverse geographic locations. An inverse relationship between UFP number and temperature has also been observed, and high afternoon concentrations during warmer months were attributed to photochemical formation and high winter and evening UFP concentrations were attributed to lower mixing heights (U.S. EPA, 2009). Relatively little had been published about hourly differences in UFP concentrations at the time of the 2009 PM ISA except for localized studies in a few locations indicating a diel maximum during evening hours (U.S. EPA, 2009).

Figure 2-32 Diurnal variation of $PM_{2.5}$ concentrations in urban areas

2.5.3 Common Patterns of Particulate Matter Characteristics in the U.S.

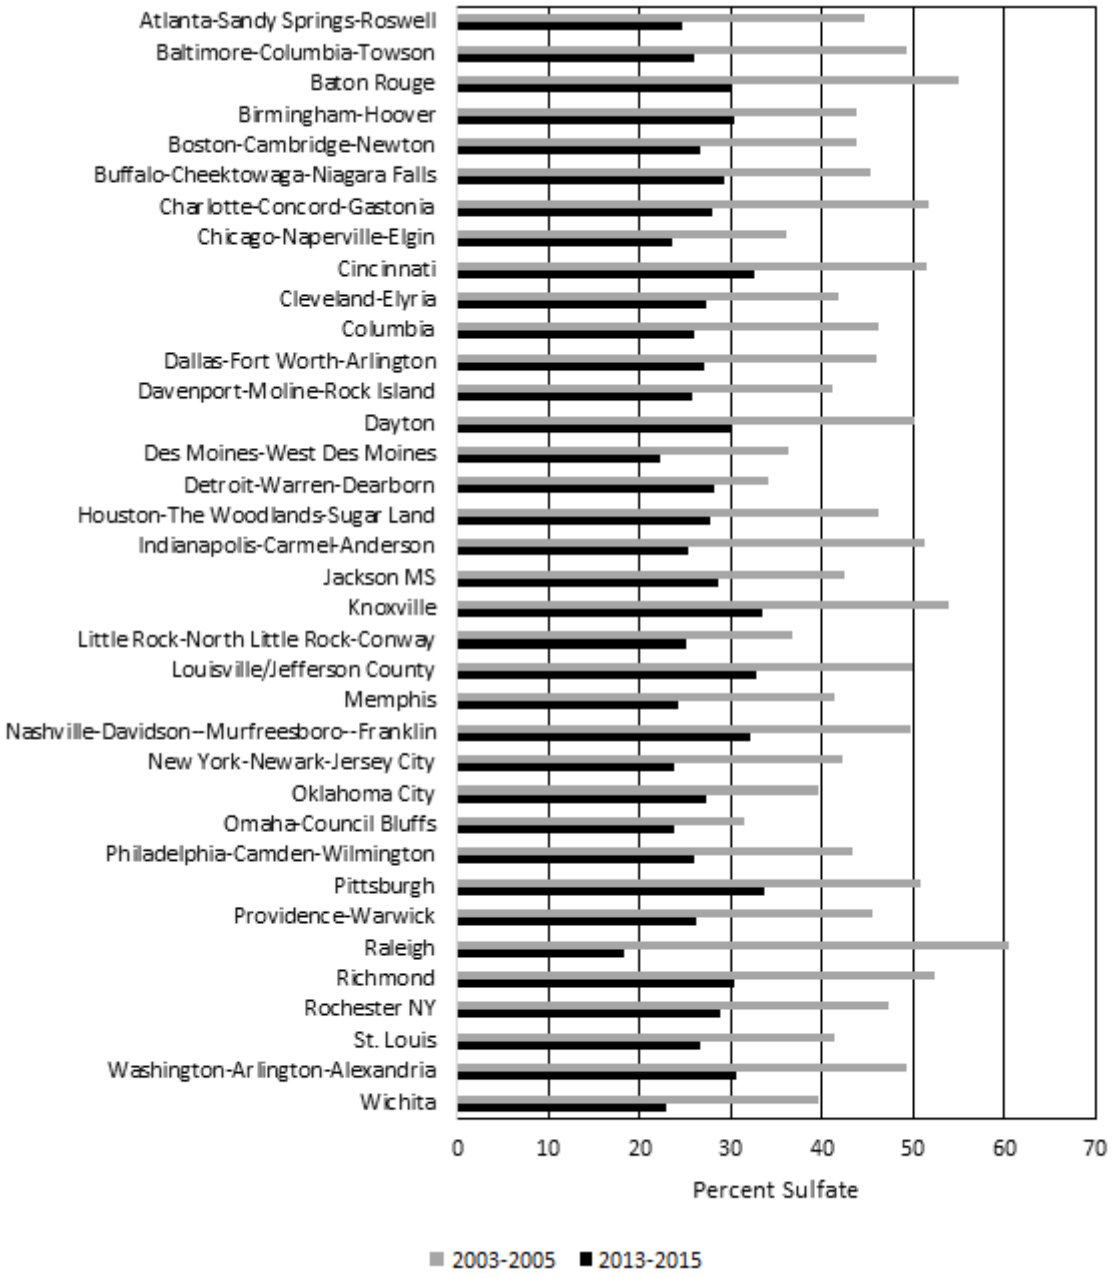
In this section the information on sources, particle size distribution and composition from recent research results and monitoring data are combined to describe common patterns of PM characteristics observed in the U.S. across different regional and seasonal conditions. Historically, $PM_{2.5}$ has been highest in the summer and has been largely accounted for by sulfate over a large area that encompasses most of the Eastern U.S., extending into the Great Plains. Figure 2-33 shows how sulfate concentrations have changed in major urban areas of the Eastern U.S. between 2003−2005 and 2013−2015 based on CSN monitors. At all of the locations shown in Figure 2-33 sulfate was the most abundant component measured for the period 2003−2005, accounting for close to half of the overall average $PM_{2.5}$ mass. In contrast, during the period 2013−2015 sulfate accounted for only about a quarter or a third of $PM_{2.5}$ mass.

For example, the sulfate fraction dropped from 49 to 31% in Washington DC, 51 to 34% in Pittsburgh, 42 to 24% in New York, 43 to 26% in Philadelphia, 44 to 27% in Boston, and 52 to 33% in Cincinnati. In all but five of these locations, mostly in Ohio or the Ohio Valley (Cleveland, Cincinnati, and Dayton, OH, Louisville, KY, Dallas, TX), OC has replaced sulfate as the most abundant component, although OC and sulfate concentrations are very similar in most locations, as shown in Figure 2-31.

In the Eastern half of the U.S., the steep decline in sulfate concentrations has led to major changes in PM composition, seasonal concentration patterns, and size characteristics since publication of the 2009 PM ISA (U.S. EPA, 2009). PM_{10} concentrations in the Eastern U.S. and Midwest previously peaked in summer and was mostly composed of $PM_{2.5}$, with sulfate as the largest single component. More recently, summer concentrations are similar to other seasons, the $PM_{10-2.5}$ and $PM_{2.5}$ fractions are often comparable, and OC is frequently the most abundant single component.

Some finer scale trends within the Eastern U.S. are evident. While OC is becoming the component with the highest concentration throughout the Eastern U.S., in the Southeast annual average OC concentrations are somewhat higher than in the Northeast or Midwest, reaching their highest monitoring concentrations in a large area encompassing most of Alabama, Georgia, and South Carolina (Hand et al., 2011). The origin of summer OC in the Southeast has been intensively studied and is largely SOA due to oxidation of biogenic precursors (Marais et al., 2017; Rattanavaraha et al., 2016; Lewandowski et al., 2013), and urban areas of the Southeast like Atlanta have considerably more biogenic VOC precursors than urban areas of the Northeastern U.S. like New York City (Weber et al., 2007). Integrated modeling and measurement results (Kim et al., 2015), modeling predictions (Marais et al., 2017; Ying et al., 2015), and product concentration measurements (Lewandowski et al., 2013) are also consistent with higher OC concentrations and biogenic SOA at Southeastern sites than in the Northeast or Midwest. OC concentrations in the Southeast are decreasing (Marais et al., 2017).

Another area in the Eastern half of the U.S. stretching from Minnesota and Iowa through Wisconsin, Michigan, Indiana, and Ohio comprises as a region susceptible to high winter nitrate episodes resulting from high emissions of ammonia from animal agriculture combining with atmospheric nitric acid, that lead to mean winter ammonium nitrate concentrations exceeding 4 $\mu g/m^3$ (Pitchford et al., 2009). This region can be distinguished in Figure 2-31 for 2012−2014 by winter nitrate contributions of more than 40% to seasonal average $PM_{2.5}$ mass in Chicago, IL, Minneapolis, MN, Milwaukee, WI, Detroit and Grand Rapids, MI, Indianapolis, IN, Cincinnati and Dayton, OH, Davenport and Des Moines, IA, Omaha, NE, Kansas City, MO and at several other sites in the upper Midwest.



Source Permission pending: U.S. EPA 2016 analysis of Air Quality System network data 2003−2005 and 2013−2015.

Figure 2-33 Sulfate as percentage of $PM_{2.5}$ in eastern urban areas 2003−2005 and 2013−2015.

While substantial differences in PM size distribution, composition, and other characteristics have been reported between the Eastern and Western U.S. (U.S. EPA, 2009), the diversity of PM characteristics across the West makes it more difficult to identify a set of fundamental PM characteristics that applies to the entire region. In interior urban areas, including Salt Lake City, UT, Reno, NV, Boise, ID, Missoula, MT, and Spokane, WA, $PM_{2.5}$ levels are higher under stable conditions on days with snow cover. In Salt Lake City, UT, Reno, NV, and Missoula, MT, most of the highest concentrations were observed on days with high nitrate concentrations enhanced by colder temperatures and higher relative humidity that occur with snow cover (Green et al., 2015). After multiday periods with stable conditions created by snow cover, $PM_{2.5}$ can build up rapidly in layers or in cold air pools. In one case in Salt Lake City $PM_{2.5}$ concentrations increased by 6 to 10 μg/m^3 per day over a period of several days (Whiteman et al., 2014; Silcox et al., 2011). This area is also subject to episodically high $PM_{10–2.5}$ concentrations from dust suspension.

Closer to the coast, high PM episodes cannot be explained by snow cover and extreme cold, yet some of the highest $PM_{2.5}$ concentrations in Figure 2-13 and Figure 2-14 are in California and concentrations are also highest in winter. In many California locations, a specific combination of conditions appears to be responsible for the highest PM concentrations. High winter $PM_{2.5}$ concentrations were studied intensively over 12 winters and the existence of several simultaneous conditions for at least 2 days duration were required for concentrations to exceed 35 μg/m^3, including a ridge of high pressure aloft, persistent easterly flow extending up vertically, orographically channeled winds resulting from stability, and enhanced nocturnal cooling under clear sky conditions (Beaver et al., 2010). Ammonium nitrate and organic PM from diverse combustion sources are the main contributors to $PM_{2.5}$ under winter conditions in California (Young et al., 2016; Zhang et al., 2016; Schiferl et al., 2014). Some of the highest 98th percentile concentrations were reported in California and other monitoring sites in the Western U.S. in Section 2.5.1.1.1 (Figure 2-14).

A common characteristic of PM in both California and the dryer areas of the Western U.S. that contrasts with the Eastern U.S. is the higher fraction of PM_{10} accounted for by $PM_{10–2.5}$, with $PM_{10–2.5}$ accounting for most PM_{10} mass in the West, but $PM_{2.5}$ accounting for most PM_{10} mass in the East (see Table 2-7). Populated areas of the Northwest (Western Oregon and Washington) make an exception to this trend. Table 2-7 shows that in both Seattle, WA and Portland, OR, $PM_{2.5}$ accounts for more than 50% of the PM_{10} mass and concentrations are higher in winter than in summer. Wood smoke is a major source of $PM_{2.5}$ in Portland, OR and Seattle, WA (Kotchenruther, 2016; U.S. EPA, 2009), as well as in smaller urban areas in this region.

$PM_{2.5}$ concentrations averaged over the 11-year period from 1998−2008 over the entire contiguous U.S. were reported to be 2.6 μg/m^3 higher on days under stagnant conditions than for non-stagnant days (Tai et al., 2010). When all U.S. data over a multiyear period are considered, temperature is positively correlated with $PM_{2.5}$ (Tai et al., 2012a; Tai et al., 2012b), especially in the Eastern U.S. (Tai et al., 2012a). Much of $PM_{2.5}$ variability could be explained by cold frontal passages in the East, maritime

inflow in the West, and cyclone frequency in the Midwest (Tai et al., 2012b). Other meteorological conditions that have been reported to enhance PM concentrations include sea breezes (Georgoulias et al., 2009) and drought (Wang et al., 2015).

2.5.4 Background Particulate Matter

The definition of background PM can vary depending upon context, but it generally refers to PM that is formed by sources or processes that cannot be influenced by actions within the jurisdiction of concern. Consistent with other recent NAAQS reviews (U.S. EPA, 2014); U.S. EPA, 2015, 4679035}, there are two specific definitions of background PM of interest: natural background and U.S. background. Natural background is the narrowest definition of background, and it is defined as the PM that would exist in the absence of any manmade emissions of PM or PM precursors. U.S. background PM is defined as any PM formed from sources or processes other than U.S. manmade emissions. Approaches to estimating background PM have evolved over the years. Different approaches for estimating background concentrations in the western and eastern U.S. were taken in the 2004 PM AQCD (U.S. EPA, 2004). Data from IMPROVE monitoring sites in the western U.S. thought to be among the least influenced by regional pollution sources exhibited annual mean concentrations of ~3 $\mu g/m^3$. However, even the most remote monitors within the U.S. can be periodically affected by U.S. anthropogenic emissions, and concentrations observed at the most remote sites in the Eastern U.S. were considerably higher than in the western U.S. In the 2009 ISA (U.S. EPA, 2009), estimates of background concentrations were calculated by CMAQ and classified by region and quarter. All quarterly and annual estimates were less than 2 $\mu g/m^3$, with many <1 $\mu g/m^3$. However, episodic contributions from dust storms or wildfires can be much higher. Further details are given by (U.S. EPA, 2009).

As illustrated by this example, background PM concentrations can be best characterized with chemical transport modeling simulations via source apportionment modeling or estimating what the residual PM concentrations would be were the U.S. anthropogenic emissions entirely removed (i.e., "zero-out" modeling). Unfortunately, there has not been a similar national scale effort to update background $PM_{2.5}$ concentration estimates since the 2009 PM ISA. However, there has been considerable research focused on better understanding the sources and processes that influence background contribution to $PM_{2.5}$ in the U.S.

Background contributions to PM can come from a variety of sources. Natural sources include wind erosion of natural surfaces, volcanic production of SO_4^{2-}; primary biological aerosol particles (PBAP); wildfires producing EC, OC, and inorganic and organic PM precursors; and SOA produced by oxidation of biogenic hydrocarbons such as isoprene and terpenes (U.S. EPA, 2009). However, human intervention can be involved in the formation of SOA. For example, the production of SOA from the oxidation products of isoprene and other biogenic VOC's can be enhanced by the presence of SO_2, NO_X, and other anthropogenic pollutants, accounting for as much 50% of SOA from biogenic VOC's

(Section 2.3.2.3). Other sources of background PM are anthropogenic, principally emissions from outside the U.S. which can be transported into the U.S. The importance of different contributors to background PM varies across the contiguous U.S. (CONUS) by region and season as a function of the complex mechanisms of transport, dispersion, deposition, and re-entrainment.

Background PM can also be viewed as coming from two conceptually separate components: a somewhat consistent "baseline" component and an episodic component. The baseline component consists of contributions that are generally well characterized by a reasonably consistent distribution of daily values each year, although there is variability by region and season. The episodic component consists of infrequent, sporadic contributions from high-concentration events occurring over shorter periods of time (e.g., hours to several days) both within North America (e.g., volcanic eruptions, large forest fires, dust storms) and outside North America (e.g., transport from dust storms occurring in deserts in North Africa and China). These episodic natural events, as well as events like the uncontrolled biomass burning in Central America, are essentially uncontrollable and do not necessarily occur in all years. Section 2.5.4.1 and Section 2.5.4.2 below discuss natural background and intercontinental transport contributions to background PM in the U.S.

2.5.4.1 Natural Background

On average, natural sources including soil dust and sea salt have been estimated to account for approximately 10% of U.S. urban $PM_{2.5}$ (Karagulian et al., 2015). Dust storms are common occurrences in arid regions of the U.S. and the rest of the world. An extreme example is the haboob. During one of these affecting Phoenix in July of 2011, peak hourly average PM_{10} concentrations were >5,000 $\mu g/m^3$ with area wide average hourly concentrations ranging from a few hundred to a few thousand $\mu g/m^3$ (Vukovic et al., 2014). Dust can also make up a substantial fraction of total $PM_{2.5}$ in the Southwestern U.S. This is illustrated in Figure 2-19 (Section 2.5.1.1.6), which shows that at many locations in the Southwestern U.S., crustal material from soil accounts for close to half of the annual average $PM_{2.5}$ mass. Although similar network data do not exist for $PM_{10-2.5}$, the soil contribution to $PM_{10-2.5}$ mass in these locations is likely to be even higher. Dust also accounts for much of the PM that originates from outside the U.S. (Section 2.5.4.2).

Wildfires are a variable contributor to particulate matter emissions. Satellite-based fire detections are combined with ground-based estimates of area burned, fuel availability, and emission factors to quantify PM and precursor emissions at high spatial and temporal resolution (Strand et al., 2012). The gas-phase species emitted from fires can affect oxidation and formation of semivolatile compounds that can condense into the particle phase (Baker et al., 2016). Invasive species, historical fire management practices, frequency of drought, and extreme heat have brought longer fire seasons (Jolly et al., 2015) and more large fires (Dennison et al., 2014). In addition to emissions from forest fires in the U.S., emissions from forest fires in other countries can be transported to the U.S., and transport from Canada, Mexico,

Central America, and Siberia have been documented (U.S. EPA, 2009). According to the U.S. EPA's National Emission Inventory, wildfire smoke contributes between 10 and 20% of primary PM emissions per year (Section 2.3.1), however these emissions are concentrated at the burn area and mostly during the wildfire season, rather than evenly distributed through the year (Sturtz et al., 2014).

Primary biological aerosol particles (PBAP) such as bacteria and pollen can also contribute substantially to $PM_{10-2.5}$ mass in some locations. These are discussed in more detail in Section 2.3.3.

2.5.4.2 Intercontinental Transport

Intercontinental transport contributes 0.05 to 0.15 μg/m^3 to annual average $PM_{2.5}$ concentrations in the U.S. (Kolb et al., 2010). Large continuous data sets are available to examine the intensity and frequency of intercontinental PM transport events. Ground-based lidar networks and mountain top measurements in Europe, North America, and Asia have been used to establish that intercontinental transport of PM from dust, forest fires, and anthropogenic sources impact local $PM_{2.5}$ and PM_{10} concentrations. Satellites also provide estimates of the amount of PM transported, as well as the altitude at which the transport occurs. Transport at midlatitudes is dominated by westerly winds, which transport East Asian emissions across the North Pacific Ocean to North America. Transport occurs at greater speeds and over longer distances in winter than in summer because the westerly winds are stronger, and greater precipitation in winter in the Western U.S. brings more of the transported PM to the surface. Numerous studies have now documented long-range transport of desert dust from East Asian deserts. Both the frequency of transport events and the overall contribution to PM in the U.S. are reported to be increasing (Kolb et al., 2010; TFHTAP, 2006). By one estimate, 18 Tg/year PM exits Asia between 30 to 60 degrees N latitude, with 4.4 Tg/yr arriving in North America (Yu et al., 2008).

Episodic concentrations as high as 20 μg/m^3 of PM associated with transport to the U.S. from Asia have been estimated (Jaffe et al., 2005), and $PM_{2.5}$ from Asia has been shown to account for a large fraction total $PM_{2.5}$ in polluted urban air (Jaffe et al., 2003). Over longer time periods, long range transport can make a substantial contribution to local PM concentrations in remote areas like the Arctic. However, in regions with local sources, observed trends in PM are usually more closely related to local emission trends than to long-range transport, and at monitoring sites throughout the U.S. intercontinental influences are small (Henze et al., 2009).

On average, Asian dust contributes typically <~1 μg/m^3 to $PM_{2.5}$ at remote sites in western states (Creamean et al., 2014). However, transport of Asian dust shows both strong seasonal and interannual variability. Dust emissions are at a maximum in spring, associated with strong winds following cold fronts as the Siberian High extends southward and before there is sufficient vegetation to stabilize the surface. Based on inverse modeling of Asian dust over the period 2005−2012, Yumimoto and Takemura (2015) suggested that dust emissions, transport and deposition are largest during the La Niña phase of the El Niño-Southern Oscillation cycle. They also found that dust emissions were closely related to a strong

meridional pressure gradient and a strong winter monsoon. Husar et al. (2001) report that the average PM_{10} concentration at 25 reporting stations throughout the northwestern U.S. reached 65 μg/m^3 during an episode of Asian dust transport during the last week of April 1998, compared to an average of 10−25 μg/m^3 during the rest of April and May. This was accompanied by visual reports of milky-white discoloration of the normally blue sky in nonurban areas along the West Coast. Satellite data have been especially useful for tracking the trans-Pacific transport of Asian dust. Uno et al. (2011) documented the occurrence of multiple large plumes of Asian dust in April of 2010 that had passed over most of the continental U.S. based on space-borne lidar (the Cloud-Aerosol Lidar with orthogonal Polarization) on board the CALIPSO satellite. Three-dimensional, global-scale CTMs have also been used to estimate intercontinental transport of PM pollution (TFHTAP, 2007) and trans-Pacific transport of mineral dust from Asian deserts (Fairlie et al., 2007).

Transport of dust from the Sahara Desert and the Sahel in North Africa (Prospero, 1999a, b), (Chiapello et al., 2005), (Mckendry et al., 2007) can affect the eastern U.S., while transport of dust from the Gobi and Taklimikan deserts in Asia (Vancuren and Cahill, 2002), (Yu et al., 2008) can exert effects in the western U.S. The ability of African dust to substantively affect PM levels in the U.S. was extensively reviewed in the 2004 PM AQCD (U.S. EPA, 2004) and in the 2009 PM ISA (U.S. EPA, 2009). A multidecade record of African dust reaching Miami indicates that the highest loadings are found in July (Prospero, 1999a, b) with concentrations ranging from ~10 to ~100 μg/m^3. Sample collection began in 1974, before network PM_{10} and $PM_{2.5}$ samplers were developed, and no size cut was specified (Prospero, 1999b). Yu et al. (2015) found that the transport of North African dust across the Atlantic Ocean is strongly negatively correlated with precipitation in the Sahel during preceding year. Dust from Africa has shown a decreasing trend of ~ 10% per decade from 1982 to 2008, based on measurements of aerosol optical depth and surface concentrations in Barbados by Ridley et al. (2014), who also suggest that this decrease is due to a corresponding decrease in surface winds over source regions.

In addition to desert dust, a portion of the PM reaching the U.S. through intercontinental transport is from combustion and industrial sources, and formation of sulfate from SO_2 during transport of air masses to the U.S. from Asia is also well documented. In the Spring in the Northwestern U.S., transport from Asia accounted for 0.16 ± 0.08 μg/m^3 $PM_{2.5}$ sulfate (Heald et al., 2006). Sulfate of Asian origin can account for a large fraction of sulfate in the upper troposphere in western North America, and an increasing fraction of sulfate measured off the northwest coast of the U.S. is of Asian origin. Measurements from an event over the Pacific Ocean were consistent with nearly pure sulfuric acid. Transboundary transport within North America can also be important. Model results suggest that SO_2 emissions in Mexico influence sulfate formation in the U.S. (Henze et al., 2009). Leibensperger et al. (2011) estimated that trans-Pacific transport of SO_2 and NO_X results in a combined increase in background PM[40] in the western U.S. of a few tenths of a μg/m^3.

2.6 Summary

New observations indicate that some fundamental characteristics of atmospheric PM in the U.S. are changing. These range from source emissions and atmospheric formation processes to size distributions, particle composition, and spatial and temporal concentration trends. The most noticeable change in PM or precursor source emissions is the large reduction in SO_2 emissions, mainly from decreased EGU coal combustion. In addition, advances in engine and emissions control technologies have led to continued decreases in automobile emissions. The major urban stationary sources of PM are still industrial processes, construction and road dust, residential wood burning and other fuel combustion, and cooking. The major primary mobile sources are still diesel and gasoline powered highway vehicles as well as off-road vehicles and engines like locomotives, ships, aircraft, and construction and agricultural equipment. $PM_{2.5}$ particles from combustion sources are usually emitted as UFP and grow into larger particles after emission. Secondary $PM_{2.5}$ still accounts for a substantial fraction of the $PM_{2.5}$ mass from both natural and anthropogenic sources (U.S. EPA, 2009). Major $PM_{10–2.5}$ sources are dust suspension, sea spray, and biological materials. Automobile traffic, other combustion sources, and new particle formation are major UFP sources.

Research on atmospheric chemistry has largely focused on better understanding OC sources and SOA formation pathways. Progress in understanding SOA precursors centered on model results of large fractions of SOA from aromatic and monoterpene precursors, observations of gas phase VOC oxidation products continuing to react to form PM, and the discovery of isoprene as a major SOA precursor. Progress related to understanding SOA formation processes was directed toward evidence of cloud processing as well as repeated cycles of volatilization and condensation of semivolatile reaction products as important processes for SOA evolution, investigation of misclassification of SOA as primary organic

[40] PM size was not specified, but secondary PM formed from NO_X and SO_2 is usually nearly all in the $PM_{2.5}$ size range.

aerosol under typical sampling conditions, and observations of greater SOA yields at high NO_X concentrations. Progress in understanding SOA products involved identification of higher molecular weight particle phase oligomers and organic peroxides as an abundant class of reactive oxygen species (ROS) with high oxidizing potential in SOA, as well as observations of abundant organosulfates and organonitrates in SOA.

Major developments in PM monitoring and monitoring capabilities have taken place, and these have had an important impact on our understanding of PM characteristics. For example, before the availability of network data, the 2009 PM ISA was based on literature results and concluded that $PM_{10-2.5}$ concentrations were higher in the Western U.S. than in the Eastern U.S. (U.S. EPA, 2009). The NCore network was implemented in 2011 and now produces multipollutant concentration and data at 78 stations throughout the U.S. Through NCore, more reliable data on $PM_{10-2.5}$ concentrations are available than were possible before. The first years of NCore data reveal a more complicated concentration pattern than a simple East-West split, with the highest $PM_{10-2.5}$ concentrations observed in the Southwest from California to Texas, and in the Central U.S. from Texas and Louisiana as far north as Nebraska and Iowa. In contrast, there are large areas in the Northwest where average $PM_{10-2.5}$ concentrations and $PM_{2.5}/PM_{10}$ are similar to the Eastern U.S. Rapid advances are taking place in UFP measurement technology, but measurements are more method dependent and network monitoring is in its beginning stages. Network monitoring of $PM_{2.5}$ has expanded to include numerous near road monitoring sites.

Annual mean ambient $PM_{2.5}$ concentrations in the U.S. on average are 4−5 $\mu g/m^3$ lower than they were in the last decade, continuing a downward trend described in the 2009 PM ISA (U.S. EPA, 2009). $PM_{2.5}$ concentrations are highest in the San Joaquin Valley, the Los Angeles-South Coast Air Basin of California, and parts of Utah. In the Eastern U.S. there is a region of higher $PM_{2.5}$ concentrations with annual average concentrations greater than 10 $\mu g/m^3$ stretching from Eastern Iowa and Northern Illinois across Indiana, Ohio, and into to Eastern Pennsylvania. While monthly national average $PM_{2.5}$ concentrations were higher in summer than in winter from 2002−2008, this pattern is reversed from 2012−2015, when monthly average $PM_{2.5}$ concentrations become higher in winter than in summer. Summer $PM_{10-2.5}$ concentrations are generally higher than other seasons, but extreme $PM_{10-2.5}$ events appear to be more likely in the spring. PM_{10} reflects characteristic concentration patterns of both $PM_{10-2.5}$ and $PM_{2.5}$, with the highest concentrations in summer. The decrease in $PM_{2.5}$ concentrations has resulted in smaller $PM_{2.5}/PM_{10}$ ratios, and PM_{10} in the East and Northwest is in the range of 50−60% $PM_{2.5}$, while PM_{10} in the Western U.S. is generally less than 50% $PM_{2.5}$. On urban and neighborhood scales, both spatial and temporal variations are strongly influenced by motor vehicle emissions, with the highest $PM_{2.5}$ and UFP concentrations at rush hour, and the highest concentrations of $PM_{10-2.5}$, UFP, and many $PM_{2.5}$ components near roads with heavy traffic.

Recent changes in $PM_{2.5}$ long-term and seasonal concentration trends are consistent with observed changes in $PM_{2.5}$ composition compared to the 2009 PM ISA (U.S. EPA, 2009), the greatest of which is the reduction in sulfate concentrations, resulting in a smaller sulfate contribution to $PM_{2.5}$ mass

in 2013−2015 than in the last decade, especially in the Eastern U.S. As a result, at many locations sulfate has been replaced as the greatest single contributor to $PM_{2.5}$ mass by organic matter. Sulfate and OC are the components with the highest contribution to total mass in most eastern locations and OC usually makes the greatest contribution to $PM_{2.5}$ mass in the west, although sulfate, nitrate, and crustal material can also be abundant. The highest nitrate concentrations are found in the west, particularly in California, but with some elevated concentrations in the upper Midwest. Ammonium concentrations follow both nitrate and sulfate spatial patterns because it is mostly present as ammonium sulfate and ammonium nitrate. Larger contributions of OC to $PM_{2.5}$ mass are observed in the Southeast and the West than in the Central and Northeastern U.S. A large fraction of organic PM can be water soluble. Crustal elements and biological material account for large fraction of $PM_{10-2.5}$ mass. There is still little information on the composition of UFP, but urban UFP is often rich in OC and EC.

Background PM originates from natural and international sources. Natural sources include windblown dust, wildfires, and sea salt. International contributions include intercontinental transport of dust, wildfire smoke, and pollution as well as transboundary transport of these contributors from Canada, Mexico. Background PM usually makes a relatively small contribution to urban annual average $PM_{2.5}$ concentrations. However, it is an important contributor to $PM_{2.5}$ concentrations in the southwestern U.S., and impacts $PM_{2.5}$ concentrations elsewhere on an episodic basis. Background contributions to $PM_{10-2.5}$ can be substantial, as it is generally dominated by dust and sea salt. Less is known about background contributions to UFP.

CHAPTER 3 EXPOSURE TO AMBIENT PARTICULATE MATTER

Overall Conclusions regarding Exposure to Ambient PM

- Recent and existing evidence indicate that exposure error typically produces *underestimation* of health effects in epidemiologic studies of short-term and long-term PM exposure. Bias away from the null can sometimes occur for long-term exposure studies if a monitor or model underestimates population exposure.
- New developments in PM exposure assessment methods, including hybrid spatiotemporal models that incorporate satellite observations of AOD, land use variables, surface monitoring data from FRMs, and/or CTMs, have reduced bias and uncertainty in health effect estimates by improving the spatial resolution and accuracy of exposure predictions.
- High correlations of $PM_{2.5}$ with some gaseous copollutants necessitate evaluation of the impact of confounding on health effect estimates.
- There is typically more uncertainty for health effect estimates for exposure to $PM_{10–2.5}$ and UFP, because their concentrations tend to be more spatially variable than $PM_{2.5}$ concentrations and concentration data for $PM_{10–2.5}$ and UFP are less frequently available and/or more uncertain.

3.1 Introduction

Assessment of exposure to ambient PM builds from the characterization of concentrations and atmospheric chemistry presented in CHAPTER 2. The primary conclusions from CHAPTER 2 were that $PM_{2.5}$ concentrations continue to decrease over time with few areas exceeding the level of the current NAAQS, sulfates comprise a smaller proportion of total $PM_{2.5}$ throughout the country including in the eastern half of the country, $PM_{10–2.5}$ contributes most substantially to PM_{10} in the southwestern U.S. but is highly variable across urban areas, and substantial uncertainty still exists regarding UFP sources, composition, and concentrations.

This chapter presents new developments in exposure assessment methodology and interpretation of epidemiological study results given strengths and limitations of the exposure assessment data. The chapter describes concepts and terminology relating to exposure (Section 3.2), methodological considerations for use of exposure data (Section 3.3), and exposure assessment and interpretation of epidemiologic study results (Section 3.4). This chapter focuses on the ambient component of personal exposure to PM, because the NAAQS pertains to ambient PM. However, studies using total personal PM measurements or indoor PM concentrations to represent exposure can also inform the understanding of the relationship between exposure and health effects and so are included as supporting evidence if ambient PM exposure can be deduced from the information provided in the studies. This chapter focuses on studies of exposure among the general population. Exposure of groups potentially at increased risk of PM-related health effects, based for example on socioeconomic status and race, is addressed in CHAPTER 12. Intake of PM based on ventilation rate, and in relation to physical activity, is described in CHAPTER 4. The information provided in this chapter will be used to help interpret the evidence for the

health effects of PM exposure presented in the health chapters that follow (CHAPTER 5, CHAPTER 6, CHAPTER 7, CHAPTER 8, CHAPTER 9, CHAPTER 10, and CHAPTER 11).

3.2 Conceptual Overview of Human Exposure

The 2009 PM ISA (U.S. EPA, 2009b) provided a conceptual model of exposure to form a distinction between ambient PM exposure and total personal exposure. This section illustrated that exposure is integrated over time and across the microenvironments in which a person spends time. This section also introduced the concept of an infiltration factor that depends on both penetration of PM indoors and the ventilation and deposition characteristics that influence indoor PM concentration. That discussion is currently updated and presented in Section 3.2.2.

This ISA contains two new sections to orient the reader to concepts relevant to exposure. Section 3.2.1 introduces terminology that is used throughout the chapter when describing exposure assessment studies. Section 3.2.3 highlights facets of exposure assessment that are particularly relevant to PM.

3.2.1 Exposure Terminology

A variety of metrics and terms are used to characterize air pollution exposure. They are described here at the beginning of the chapter to provide clarity for the subsequent discussion.

The *concentration* of PM is defined as the mass of the pollutant in a given volume of air (e.g., $\mu g/m^3$). Concentrations observed in outdoor locations accessible to the public are referred to as ambient concentrations. The term exposure refers to contact at the interface of the breathing zone with the ambient concentration of a specific pollutant over a certain period of time (Zartarian et al., 2005), in single or multiple locations. For example, contact with a concentration of 10 $\mu g/m^3$ $PM_{2.5}$ for 1-hour would be referred to as a 1-hour exposure to 10 $\mu g/m^3$ $PM_{2.5}$, and 10 $\mu g/m^3$ is referred to as the *exposure concentration*. As discussed in CHAPTER 4, dose incorporates the concept of intake into the body (via inhalation).

A location where exposure occurs is referred to as a *microenvironment*, and an individual's daily exposure consists of the time-integrated concentrations in each of the microenvironments visited during the day. Ambient air pollution may penetrate indoors (see Section 3.4.1.1 on infiltration), where it combines with air pollution from indoor sources (*nonambient air pollution*) to produce the total measured indoor concentration. Exposure to the ambient fraction of total indoor concentration, together with exposure to ambient concentrations in outdoor microenvironments such as parks, yards, sidewalks, and bicycles or motorcycles, is referred to as ambient exposure (Wilson et al., 2000). *Total personal exposure to ambient PM* is the concentration of PM emitted from ambient sources or formed in the atmosphere that

is encountered by an individual over a given time. This differs from overall total personal exposure, which may also include exposure to nonambient air pollution. Personal exposure to ambient PM is influenced by several factors, including:

- Time-activity in different microenvironments (e.g., vehicle, residence, workplace, outdoor);
- climate (e.g., weather, season);
- characteristics of indoor microenvironments (e.g., window openings, draftiness, air conditioning); and
- microenvironmental emission sources (e.g., roadways, construction equipment, indoor gas stoves) and concentrations.

Because personal exposures are not routinely measured, the term *exposure surrogate* is used in this chapter to describe a quantity meant to estimate or represent exposure, such as $PM_{2.5}$ concentration measured at an ambient monitor (Sarnat et al., 2000). A *fixed-site monitor* (i.e., a monitor with a fixed position) is a type of *ambient monitor* used to estimate population average exposure concentrations and their trends over neighborhood- and urban-scales for epidemiologic studies.

When surrogates are used for exposure estimation in epidemiologic studies, exposure error or exposure misclassification can result. *Exposure error* refers to the bias and uncertainty associated with using concentration metrics to represent the actual exposure of an individual or population (Lipfert and Wyzga, 1996). Exposure misclassification refers to exposure error that occurs when exposure conditions such as location, timing, or population grouping are incorrectly assigned. *Exposure misclassification* due to exposure assignment methods and spatial and temporal variability in pollutant concentrations may be either differential (i.e., systematic), or nondifferential (i.e., random). *Differential misclassification* refers to the situation where exposure errors differ between groups. An example of differential misclassification is the use of geocoding to estimate air pollution exposure by proximity to roadways, because concentrations decrease with distance from roadways and are different upwind and downwind of a major roadway (Lane et al., 2013; Singer et al., 2004). *Nondifferential misclassification* refers to the situation where exposure characterization has the same probability of being misclassified to a similar degree across all groups.

Exposure misclassification and exposure error can result in bias and reduced precision of the effect estimate in epidemiologic studies. *Bias* refers to the difference between the population-average measured and true exposure, while precision is a measure of the variation of measurement error in the population (Armstrong et al., 1992). Bias toward the null, or attenuation of the effect estimate, indicates an underestimate of the magnitude of the effect, and is characteristic of nondifferential measurement error. Bias away from the null can occur through differential exposure measurement error, such as may occur when an exposed person or group of people are located far from a source that is captured by a fixed-site monitor (Armstrong et al., 1992).

Exposure error has two components: (1) exposure measurement error derived from uncertainty in the metric being used to represent exposure and (2) use of a surrogate parameter of interest in the epidemiologic study in lieu of the true exposure, which may be unobservable. *Classical error* is defined as error scattered around the true personal exposure and independent of the measured exposure. Classical error results in bias of the epidemiologic health effect estimate. Because variation in the measurements tends to be greater than variation in the true exposures, classical error typically biases the health effect estimate towards the null (no effect of the exposure). This would cause the health effect estimate to be underestimated. Classical error can also cause inflation or reduction of the standard error of the health effect estimate. For example, classical error may occur when a fixed-site monitor measuring exposure concentration is imprecise. *Berkson error* is defined as error scattered around the measured exposure surrogate (in most cases, the ambient monitoring measurement) and independent of the true exposure (Goldman et al., 2011; Reeves et al., 1998). Pure Berkson error is not expected to bias the health effect estimate. Berkson error tends not to cause bias in the health effect estimate. For example, Berkson error may occur when personal monitors used in a panel study capture ambient and nonambient exposures, if the objective of the study is to evaluate the effect of ambient exposures on health and the ambient and nonambient exposures are independent of each other.

Definitions for *classical-like* and *Berkson-like errors* were developed for modeled exposures. These errors depend on how exposure metrics are averaged across space. Classical-like errors can add variability to predicted exposures and can bias health effect estimates in a manner similar to pure classical errors, but they differ from pure classical errors in that the variability in estimated exposures is also not independent across space. Szpiro et al. (2011a) defined Berkson-like and classical-like errors as errors sharing some characteristics with Berkson and classical errors, respectively, but with some differences. Specifically, Berkson-like errors occur when the modeled exposure does not capture all of the variability in the true exposure. Berkson-like errors increase the variability around the health effect estimate in a manner similar to pure Berkson error, but Berkson-like errors are spatially correlated and not independent of predicted exposures, unlike pure Berkson errors. Berkson-like error can lead to bias of the health effect estimate in either direction (Szpiro and Paciorek, 2013).

The influence of these types of exposure errors on health effect estimates for specific short-term and long-term exposure study designs is evaluated in Section 3.4.5. This review of the influence of error on exposure estimates used in epidemiology studies informs evaluation of confounding and other biases and uncertainties when considering the health effects evidence in CHAPTER 5, CHAPTER 6, CHAPTER 7, CHAPTER 8, CHAPTER 9, CHAPTER 10, and CHAPTER 11.

3.2.2 Conceptual Model of Total Personal Exposure

A conceptual model of personal exposure is presented to highlight measurable quantities and the uncertainties that exist in this framework. An individual's time-integrated total exposure to PM can be described based on a compartmentalization of the person's activities throughout a given time period:

$$E_T = \int_1^n C_j dt$$

Equation 3-1

where E_T = total exposure over a time-period of interest, C_j = airborne PM concentration at microenvironment *j*, *n* = total number of microenvironments, and *dt* = portion of the time-period spent in microenvironment *j*. Total exposure (E_T) can be decomposed into a model that accounts for exposure to PM of ambient (E_a) and nonambient (E_{na}) origin of the form:

$$E_T = E_a + E_{na}$$

Equation 3-2

Indoor combustion, such as cooking, smoking, or candle burning, as well as cleaning, and other activities are nonambient sources of PM (see Section 3.4.1.2, indoor-outdoor [I/O] relationships on indoor PM) that are specific to individuals and result in variable nonambient exposures across the population. Assuming steady-state outdoor conditions, E_a can be expressed in terms of the fraction of time spent in various outdoor and indoor microenvironments (U.S. EPA, 2006; Wilson et al., 2000):

$$E_a = \Sigma f_o C_o + \Sigma f_i F_{inf,i} C_{o,i}$$

Equation 3-3

where f_o = fraction of the relevant time period (equivalent to dt in Equation 3-1) in outdoor microenvironments; f_i = fraction of the relevant time period (equivalent to dt in Equation 3-1) in indoor microenvironments; C_o = PM concentration in outdoor microenvironments; $C_{o,I}$ = PM concentration in outdoor microenvironments adjacent to an indoor microenvironment *i*; and $F_{inf,i}$ = infiltration factor for indoor microenvironment *i*. Equation 3-3 is subject to the constraint $\Sigma_{fo} + \Sigma_{fi} = 1$ to reflect the total exposure over a specified time period, and each term on the right hand side of the equation has a summation because it reflects various microenvironmental exposures. Here, "indoors" refers to being inside any aspect of the built environment, [e.g., homes, schools, office buildings, enclosed vehicles (automobiles, trains, buses), and/or recreational facilities (movie theaters, restaurants, bars)], while "outdoors" refers to outdoor microenvironments (e.g., parks, yards, sidewalks, and bicycles or motorcycles). Assuming steady state ventilation conditions, the infiltration factor (F_{inf}) is a function of the penetration (*P*) of PM into the microenvironment, the air exchange rate (*a*) of the microenvironment, and the rate of PM loss (*k*) in the microenvironment:

$$F_{inf} = \frac{Pa}{(a+k)}$$

Equation 3-4

In epidemiologic studies, the ambient PM concentration, *Ca*, is often used in lieu of outdoor microenvironmental data to represent these exposures based on the availability of data. Thus, it is often assumed that $C_o = C_a$ and that the fraction of time spent outdoors can be expressed cumulatively as f_o; the indoor terms still retain a summation because infiltration differs for different microenvironments. If an epidemiologic study employs only C_a, then it is assumed that exposure to ambient PM, E_a given in Equation 3-3, is re-expressed solely as a function of C_a:

$$E_a = (f_o + \Sigma f_i F_{inf,i}) C_a$$

Equation 3-5

Equation 3-5 encapsulates several facets of the relationship between ambient concentration and E_a. First, C_a represents all ambient PM concentrations combined. Measurements and models to quantify C_a may assign one uniform PM concentration in the region of study (e.g., Section 3.3.1.1), or it might be modeled to represent how it varies outdoors across space (Section 3.4.2.2). Second, exposure is related to both concentration encountered and time spent in a given microenvironment. Outdoor exposure is directly influenced by ambient concentration and time spent outdoors. Indoor exposure occurs where infiltration of ambient PM into the envelope of an enclosed space (e.g., building, bus) likely reduces ambient PM exposure by filtering out a fraction of the ambient PM, but the influence of ambient concentration and time of exposure is still present. The components of indoor and outdoor exposure to ambient PM to comprise total ambient PM exposure, E_a. Further combining these factors with human activity level influences dose (Section 4.1.7).

Certain factors influence whether Equation 3-5 is a reasonable approximation for Equation 3-3, including the spatial variability of outdoor PM concentrations due to spatial distribution of sources; meteorology, topography, oxidation rates, and the design of the epidemiologic study. These equations also assume steady-state microenvironmental concentrations. Errors and uncertainties inherent in using Equation 3-5 in lieu of Equation 3-3 are described in Section 3.4. with respect to implications for interpreting epidemiologic studies. Epidemiologic studies often use concentration measured at an ambient monitor to represent ambient concentration; thus α, the ratio between personal exposure to ambient PM and the ambient concentration of PM, is defined as:

$$\alpha = \frac{E_a}{C_a}$$

Equation 3-6

Combining Equation 3-5 and Equation 3-6 yields:

$$\alpha = f_o + \Sigma f_i F_{inf,i}$$

Equation 3-7

where α varies between 0 and 1. If a person's exposure occurs in a single microenvironment, the ambient component of the microenvironmental PM concentration can be represented as the product of the ambient concentration and F_{inf}. Time-activity data and corresponding estimates of F_{inf} for each microenvironmental exposure are needed to compute an individual's α with accuracy (U.S. EPA, 2006). In epidemiologic studies, α is assumed to be constant in lieu of time-activity data and estimates of F_{inf}, which can vary spatially (between homes) and temporally (within a home) based on building and meteorology-related air exchange characteristics.

The conceptual model presented in Equation 3-1 through Equation 3-7 establish a framework for considering the influence of exposure measurement error on statistical models used in epidemiology studies. Exposure measurement error occurs when there is an absence of information for the variables in this framework, so assumptions must be made regarding ambient exposures. If important local outdoor sources and sinks exist but are not captured by ambient monitors, then the ambient component of the local outdoor concentration may be estimated using dispersion models, land use regression (LUR) models, chemical transport models (CTMs), satellite data, or some combination of these techniques, which are described in Section 3.3.2.

3.2.3 Exposure Considerations Specific to PM

The inhalation exposure route relevant for PM is influenced by sources, chemistry, particle size distribution, meteorology, and ambient concentrations, as described in detail in Chapter 2 and briefly summarized here.

The polydisperse size distribution (Section 2.2) and composition (Section 2.3) of PM interact to influence several aspects of exposure. UFP dominates the number concentration (NC) distribution of PM, while $PM_{2.5}$ typically dominates the mass distribution. Combustion via energy production, mobile sources, and industrial processes is the main primary anthropogenic source of UFP and $PM_{2.5}$. Brake, tire, and clutch wear can also contribute to primary UFP, $PM_{2.5}$, and $PM_{10-2.5}$. Secondary production of NO_3^-, NH_4^+, and SO_4^{2-} are also major contributors to $PM_{2.5}$, and the magnitude of those contributions varies by region, time of day, and season. UFP will also grow to the accumulation mode following emissions on time scales of hours to days. Road and construction dust are important anthropogenic sources of $PM_{10-2.5}$ in urban areas, while agricultural dust is an anthropogenic source of $PM_{10-2.5}$ in rural areas. Biogenic $PM_{10-2.5}$ from pollen can also be a substantial contributor to overall $PM_{10-2.5}$.

The size distribution influences transport and dispersion of PM, therefore affecting spatial and temporal variability of PM concentration and hence exposure (U.S. EPA, 2009b). UFP has a short lifetime because it either readily evaporates or undergoes rapid growth into the accumulation mode via

agglomeration of UFP into larger particles, condensation or adsorption of vapors onto UFP, or reaction of gases in or on the particles (Section 2.2). $PM_{2.5}$ will tend to follow the wind unless evaporating, participating in a surface reaction, and/or accumulating to a larger size. Particle growth may enhance deposition. $PM_{10–2.5}$ in dust can settle out of the air at a faster rate than $PM_{2.5}$. Resuspension by vehicle-generated turbulence, tire motion, or other activities may occur for particles of any size but are more likely for $PM_{10–2.5}$, which forms more readily via mechanical generation (Section 2.3.3). As a result, spatial and temporal variability of PM exposure concentration tends to be greater for UFP and $PM_{10–2.5}$ compared with $PM_{2.5}$ (Section 2.5).

Size distribution will also affect what fraction of the ambient air penetrates indoors (U.S. EPA, 2009b). Because $PM_{2.5}$ navigates changes in direction more easily, more $PM_{2.5}$ tends to infiltrate indoors compared with $PM_{10–2.5}$, which impacts onto building envelope surfaces more easily. UFP is more likely to diffuse onto building envelope surfaces compared with $PM_{2.5}$, so it would be expected that a lower proportion of UFP would infiltrate indoors compared with $PM_{2.5}$.

In summary, variability and uncertainties in accounting for PM emissions, chemistry, transport, and dispersion (noted here and described in detail in CHAPTER 2) leads to variability and uncertainties in estimates of exposure concentrations. For PM, uncertainties extend to characterization of the statistical distribution of particles by size and concentration (spatially and temporally). Because they have shorter lifetimes compared with $PM_{2.5}$, spatial and temporal variability is more pronounced for the lower (UFP) and upper ($PM_{10–2.5}$) segments of the particle size distribution compared with the accumulation mode ($PM_{2.5}$). Such uncertainties may complicate estimation of exposure concentrations using models such as CTMs (Section 3.3.2.4) or satellite-based methods where a relationship between $PM_{2.5}$ and surface measurements is derived (Section 3.3.3). Errors associated with these factors are described further in Section 3.4.2, and their influence on epidemiologic study results is considered in Section 3.4.5.

3.3 Methodological Considerations for Use of Exposure Data and Models

This section describes methods for estimating human exposure to PM, along with their strengths and limitations, which are important to understand when developing associations between PM exposure and health endpoints in epidemiologic analyses. The 2009 PM ISA (U.S. EPA, 2009b) and other literature [e.g., Madrigano et al. (2013); Hubbell (2012); Tagaris et al. (2009)] presented information about ambient and personal monitoring, as well as models for data averaging, spatial interpolation, LUR, CTM, and dispersion models. The current section extends that presentation by updating the assessment with discussion of new methodology and a more detailed consideration of features, strengths, and limitations of measurement and modeling techniques for PM exposure assessment.

For epidemiologic analyses, accurately assigning air pollutant exposure concentrations to individuals is difficult given the limited spatial and temporal resolution of the available observations.

Applications can vary in scale, from personal (Baxter et al., 2013; Brown et al., 2012; Dons et al., 2012; Kaur and Nieuwenhuijsen, 2009) to national (Fann et al., 2012; Bell et al., 2011b) to global (Lelieveld et al., 2015; Brauer et al., 2012; Lim et al., 2012). In some studies, personal monitoring has been used, but study limitations (e.g., expense, recruiting subjects to participate) typically constrain the size of the population studied in panel studies (Baxter et al., 2013; Ozkaynak et al., 2013; Jerrett et al., 2005a; Sarnat et al., 2000). Thus, methods are employed that use the limited observational data available from ambient air quality monitoring regulatory networks (Solomon et al., 2011) and special, often intensive studies that may be designed to provide data for exposure assessment and/or spatial characterization (Vedal et al., 2013; Hansen et al., 2006; Edgerton et al., 2005; Jerrett et al., 2005b; Butler et al., 2003; Hansen et al., 2003). In addition, health studies are taking advantage of satellite data [e.g., Madrigano et al. (2013); Liu et al. (2009)], mobile monitoring data [e.g., Levy et al. (2014); Bergen et al. (2013)], and models [e.g., Jerrett et al. (2016); Turner et al. (2016); Villeneuve et al. (2015); Pope et al. (2014)].

Modeling PM exposure concentrations can be challenging because PM may contain a mixture of components and is found in a continuum of sizes (Section 2.2). Approaches for modeling PM exposure concentration can generally be used for different sized particles ($PM_{10–2.5}$, $PM_{2.5}$, UFP) and components, though additional considerations may be involved. For example, there are very limited observational data on UFP for cross-validation (Section 2.5); $PM_{2.5}$ composition data from ambient monitoring networks are typically available every few days (e.g., every third or every sixth day) using 24-hour integrated measurements. Different observational techniques for $PM_{10–2.5}$, $PM_{2.5}$, and UFP have different biases and uncertainties, and composition may influence biases and uncertainties within a given size fraction. Some observed components (e.g., OC) are composed of multiple compounds that behave differently in the environment.

There are a range of approaches used to model PM exposure that are applied for specific purposes, and their uses depend upon available data. Ozkaynak et al. (2013) developed a hierarchy of methods based upon complexity, ranging from using ambient monitoring data as an exposure surrogate to human exposure models accounting for time-activity data and microenvironmental exposure concentrations (Figure 3-1). This list can be extended to include source apportionment models. The amount and complexity of model input data increases with increasing complexity of the models. Increasing the complexity of the exposure modeling methods may reduce exposure error in some cases (Sarnat et al., 2013b).

This section includes discussions of surface measurements (including fixed-site and personal monitoring [Section 3.3]), modeling approaches (increasing in complexity from data averaging techniques through microenvironmental models [Section 3.3.2]), and satellite-based methods (Section 3.3.3). Each of these approaches has strengths and limitations, and several new studies discussed in Section 3.3.2.4.3 and Section 3.3.3 blend observations and air quality model results to reduce exposure measurement error. An analysis of the relative strengths and limitations of these methods for application in epidemiologic studies is provided in Section 3.3.5.

Figure 3-1 Tiers of exposure models relevant to epidemiology studies and input data types for each exposure model tier.

3.3.1 Surface Measurement

The 2009 PM ISA (U.S. EPA, 2009b) discussed the use of ambient PM concentration data measured at FRMs and FEMs and used as surrogates for PM exposures, and main points are summarized in Section 2.4. The technology for measuring ambient PM at fixed-site monitors has largely stayed the same. More attention is given in Section 2.4.3 to measuring UFP concentrations. New insights to help interpret $PM_{2.5}$, $PM_{10–2.5}$, and UFP concentration data for use in exposure assessment studies are provided in Section 3.4.1.1.

The 2009 PM ISA (U.S. EPA, 2009b) described developments in using personal monitors for exposure assessment. Specifically, developments in light scattering continuous monitoring instrumentation, passive sampling, cascade impactor sampling for $PM_{10–2.5}$ and $PM_{2.5}$, and use of GPS for estimating time-activity were presented. Since then, new developments have been made in active sampling of $PM_{10–2.5}$, $PM_{2.5}$, and UFP. Important developments include reducing the size and increasing portability and battery life of samplers. These are described in Section 3.3.1.2.

3.3.1.1 Ambient Monitoring

Ambient PM data from FRM or FEM from individual sites continue to be used widely in health studies as a surrogate for PM exposure concentration. (Pope et al., 2009; Zanobetti and Schwartz, 2009) provide a number of reasons for the continued use of fixed-site monitor data as exposure surrogates:

(1) instrument error is typically small compared to spatiotemporal modeling error, (2) an ambient monitor may provide a comprehensive set of measurements, (3) the need to capture temporal variation is typically greater than the need to capture spatial variation in short-term exposure studies, and (4) ambient monitor data provide a useful reference for comparing population exposure concentration estimates in long-term exposure studies. The ambient monitor approach is the least data intensive approach among all exposure concentration estimation methods because it only requires data from a single monitor to represent exposures to a large area (on the order of 100 km^2).

Differences in sampler design for $PM_{2.5}$, $PM_{10–2.5}$, and UFP influence the quality of exposure concentration data available for epidemiologic studies of each respective size cut. For $PM_{2.5}$ samplers, quality assurance testing has demonstrated that $PM_{2.5}$ concentration measurements are replicable [(U.S. EPA, 2004), Section 2.4.1.1], lending confidence to their frequent application in exposure assessment studies. In contrast, $PM_{10–2.5}$ exposure concentration has been measured in three ways [dichotomous samplers, differencing using concentrations from collocated PM_{10} and $PM_{2.5}$ monitors, and subtracting area-wide (e.g., county-wide) $PM_{2.5}$ concentration from area-wide PM_{10} concentration] with large differences in quality assurance (Section 2.4.2). It is expected that dichotomous samplers would produce the most accurate measure of $PM_{10–2.5}$ concentration for use as an exposure surrogate, because dichotomous samplers are designed for isokinetic flow appropriate for each PM cut point. However, a systematic study comparing all three methods has not yet been performed. Differences in spatial variability of $PM_{2.5}$ and $PM_{10–2.5}$ (Section 2.5) coupled with low-moderate correlation (Section 3.4.3.1) suggest that area-wide differences would provide the least accurate measure of $PM_{10–2.5}$ concentration for use in exposure assessment studies. UFP is usually measured by condensation particle counters (CPC) (Section 2.4.3.1) and at times by inertial impaction (Section 2.4.3.3). Testing of CPCs has shown that CPCs may operate at 95% counting efficiency. However, concentrations measured by UFP samplers are also more susceptible to negative bias due to larger evaporative losses compared with $PM_{2.5}$ or $PM_{10–2.5}$ concentration measurements. Hence, there is generally higher confidence in $PM_{2.5}$ concentration measurements than in $PM_{10–2.5}$ and UFP concentration measurements used as exposure surrogates.

3.3.1.2 Personal Monitoring

Methods for personal PM monitoring were described in the 2009 PM ISA (U.S. EPA, 2009b). At that time, filter-based personal monitors were used most frequently. Developments at the time of the 2009 PM ISA included size selectivity of personal samples using a Personal Cascade Impactor Sampler that can sample down to a cut point of 250 nm (Singh et al., 2003), a mini-cyclone with the capability of sampling down to 210 nm (Hsiao et al., 2009), and a two-stage cascade impactor for $PM_{10–2.5}$ sampling (Case et al., 2008). A passive monitor had also been adapted for $PM_{10–2.5}$ sampling (Ott et al., 2008; Leith et al., 2007) based on a passive sampler developed earlier that can be used for user-defined size fractions including $PM_{2.5}$ (Wagner and Leith, 2001a, b). Light-scattering detection devices for continuous monitoring, such as the Personal DataRam (pDR, Thermo Scientific, Waltham, MA), the DustTrak (TSI,

Inc., Shoreview, MN), and the SidePak (TSI, Inc., Shoreview, MN) for PM_{10} or $PM_{2.5}$ mass concentration and the P-Trak (TSI, Inc., Shoreview, MN) or personal CPC Model 3007 (TSI, Inc., Shoreview, MN) for UFP count concentration were also described in the 2009 PM ISA. The P-Trak samples between 20 nm and 1 µm, and the CPC samples between 10 nm and 1 µm. However, it is anticipated that the majority of particles are smaller than 100 nm when measuring NC (see Preface). Additionally, the 2009 PM ISA detailed new methodologies used by investigators to enhance personal sampling by incorporating videotape (Sabin et al., 2005) or Global Positioning Systems (GPS) (Westerdahl et al., 2005) into their sampling protocols to estimate personal exposure by using simultaneous measures of exposure concentration and time-activity data. Techniques discussed in the 2009 PM ISA are widely in use, and development of new samplers have largely built upon these techniques. Table 3-1 lists these new techniques with sampling size fraction, speciation, mechanism, and error characteristics.

Table 3-1 New or innovative methods for personal sampling of PM exposure concentrations published since the 2009 PM ISA.

Reference	Active or Passive Sampling	Sampler	Size Fraction	Species	Mechanism	Error Characteristics
Thornburg et al. (2009)	Active	Coarse Particulate Exposure Monitor (CPEM)	$PM_{10-2.5}$, $PM_{2.5}$	NA	Three-stage impactor	$PM_{10-2.5}$: −23% (R^2 = 0.81) $PM_{2.5}$: −3% (R^2 = 0.91) compared with a dichotomous $PM_{10-2.5}$ sampler
Volckens et al. (2016)	Active	Ultrasonic Personal Aerosol Sampler (UPAS)	$PM_{2.5}$	NA	Miniature piezoelectric pump with a cyclone for 2.5 µm size cut plus additional sensors for air flow, sunlight, temperature, pressure, relative humidity, and acceleration	−1.4% compared with a $PM_{2.5}$ FRM
Ryan et al. (2015b)	Active	Personal UFP Sampler (PUFP)	UFP	NA	Water-based CPC plus GPS for location	+16% (R^2 = 0.99)

Table 3-1 (Continued): New or innovative methods for personal sampling of PM exposure concentrations published since the 2009 PM ISA.

Reference	Active or Passive Sampling	Sampler	Size Fraction	Species	Mechanism	Error Characteristics
Nash and Leith (2010)	Passive	Algorithm to modify output from the Wagner-Leith passive sampler to UFP	UFP	Yes	Model of deposition flux developed the passive sampler's size range	6% compared with SMPS
Cai et al. (2014); Cai et al. (2013)	Active	Modification to the Microaethalometer (AethLabs, Berkeley, CA)	$PM_{2.5}$	BC	Reduced humidity and temperature fluctuations through addition of a diffusion dryer	53 ± 238% difference in 1-min readings between the original and diffusion dryer inlet on 97−100% RH day and 5 ± 33% difference between original and diffusion dryer inlet on 65% RH day. The differences reduce to approximately 1% when data are averaged over an hour.
Hagler et al. (2011);Cheng and Lin (2013)	Active	Algorithm to modify output from the Microaethalometer (AethLabs, Berkeley, CA)	$PM_{2.5}$	BC	Introduced a data cleaning algorithm to reduce erroneous fluctuations in the signal (i.e., noise)	Comparison between 1-min data with optimized noise reduction algorithm was comparable to 5-min data averaged with noise
Sameenoi et al. (2012)	Active	Microfluidic electrochemical sensor to detect oxidative potential of PM	Any	ROS	Incorporated DTT assay into Particle into Liquid Sampler (PILS)	Comparison with traditional DTT assay: R^2 = 0.98
Sameenoi et al. (2013)	Active	Microfluidic paper-based analytical device (µPAD) to detect oxidative potential of PM	Any	ROS	Collected $PM_{2.5}$ and PM_{10} on filters, desorbed, then pipetted onto µPAD	Comparison with traditional DTT assay: bias = 10.5%, R^2 = 0.98

Table 3-1 (Continued): New or innovative methods for personal sampling of PM exposure concentrations published since the 2009 PM ISA.

Reference	Active or Passive Sampling	Sampler	Size Fraction	Species	Mechanism	Error Characteristics
Landreman et al. (2008)	Active	Expose rat macrophages to collected aerosol sample to detect oxidative potential of PM	Any	ROS	Collected $PM_{2.5}$ onto filters, desorbed, then pipetted onto a 96-well plate seeded with rat macrophages	Response corresponded to spikes for samples exposed to different numbers of macrophages (not quantitative)

BC = black carbon; DTT = dithiothreitol; ROS = reactive oxygen species.

Prevalent field usage of continuous personal PM monitors using optical techniques necessitates validation of these instruments, since calibration is not possible given that ambient PM does not have replicable optical properties. Wallace et al. (2011) tested the 6 pDR and 14−16 DustTrak (number varied with tests) for $PM_{2.5}$ (with a size-selective inlet), and 14 P-Trak personal samplers for particle number to measure UFP exposure concentrations to establish operational parameters (MDL, bias, precision, drift) for each sampler compared with the median. MDL for the DustTrak and pDR were estimated to be 5 $\mu g/m^3$ and 5.5 $\mu g/m^3$, respectively (not detected for the P-Trak), and relative precision was within 10% for all four monitors. The pDR measurements were 60% higher than collocated personal gravimetric samples from the field tests ($R^2 = 0.7$), and the DustTrak measurements were 164% higher than personal gravimetric measurements ($R^2 = 0.9$). The authors pointed out that the higher readings from the light-scattering instruments relative to the gravimetric measurements are due in part to the lower density of ambient PM relative to the density of the aerosol standard used for laboratory calibration. Another factor Wallace et al. (2011) noted to influence the performance of light-scattering personal PM monitors is relative humidity (RH). High RH results in sorption of water to particles and an increase in volume and mass detected by the instrument. Quintana et al. (2000) found that pDRs produced much higher readings than a gravimetric TEOM instrument when RH was above 85%, but that pDR readings tracked the TEOM readings relatively well at RH values below 60%. Since indoor RH is generally maintained below 60%, the influence of RH is likely to mainly affect outdoor light-scattering measurements, particularly in morning, evening, and overnight hours when RH is highest. Optical personal samplers are subject to errors given the inability to calibrate the monitors for ambient characteristics. The characterization work described above has been done for optical sampling of $PM_{2.5}$, so uncertainties are greater for the $PM_{10-2.5}$ and UFP size fractions. Instrument error and replicability and the factors that affect them must be evaluated for each use in panel studies.

3.3.2 Modeling

At the time of the 2009 PM ISA (U.S. EPA, 2009b), fine-scale exposure prediction models were still relatively nascent in their development. Methods reviewed include time-weighted microenvironmental models and stochastic exposure models for estimation of PM exposure and dispersion models, LUR, and GIS-based modeling approaches for estimation of PM exposure concentration, and attention was given to the models' limitations in adequately capturing spatial variability of PM concentration, particularly for more variable UFP and $PM_{10-2.5}$. Since the 2009 PM ISA, more approaches to spatial averaging of concentrations used for estimating exposure concentrations (Section 3.3.2.1), and new developments in spatiotemporal interpolation of exposure concentration surfaces (Section 3.3.2.2), LUR (Section 3.3.2.3), and dispersion models (Section 3.3.2.4.2) have appeared in the peer-reviewed literature. Additionally, there has been growing use of chemical transport models (CTMs) in exposure assessment studies (Section 3.3.2.4.1) in recent years. Table 3-2 provides an overview of the modeling approaches discussed in this section.

The models discussed in the following sections are typically validated by the study authors using surface monitoring data, but model validation is not performed consistently across the literature. Table 3-3 lists performance measures that have been utilized in the recent PM exposure modeling literature. Model performance is typically evaluated for bias or error using both absolute and relative (or normalized) metrics.

Table 3-2 Comparison of models used for estimating exposure concentration or exposure.

	Type of Model						
Factors[a]	**Data averaging**	**IDW/ Kriging**	**LUR/ ST**	**CTM and Hybrid**	**Dispersion**	**Satellite and Hybrid**	**Microenvironmental**
Type of model	C	C	C	C	C	C	E
Distance from source	X	X	X	X	X	X	X
Emission rate			X	X	X	X	X
Terrain or land use			X	X	X	X	X
Dispersion				X	X	X	X
Chemistry				X	X	X	X

Factors[a]	Type of Model						
	Data averaging	IDW/ Kriging	LUR/ ST	CTM and Hybrid	Dispersion	Satellite and Hybrid	Microenvironmental
Human activity							X
Infiltration							X
Inhalation							X

C = concentration model, CTM = chemical transport model, E = exposure model, IDW = inverse distance weighting, LUR = land use regression, ST = spatiotemporal models.

[a]Factors that may be available in each model are checked.

Table 3-3 Statistical measures used for air quality model performance evaluation.

Performance Measures	Definition[a]
Mean bias (MB)	$\frac{1}{N}\sum_{i=1}^{N}(P_i - O_i)$
Mean error (ME)	$\frac{1}{N}\sum_{i=1}^{N}\lvert P_i - O_i\rvert$
Root mean square error (RMSE)	$\sqrt{\frac{1}{N}\sum_{i=1}^{N}(P_i - O_i)^2}$
Coefficient of determination (R^2)	$\frac{\left\{\sum_{i=1}^{N}\left(O_i - \overline{O}\right)\left(P_i - \overline{P}\right)\right\}^2}{\sum_{i=1}^{N}\left(O_i - \overline{O}\right)^2 \sum_{i=1}^{N}\left(P_i - \overline{P}\right)^2}$

[a]P_i and O_i are prediction and observation at the ith monitoring site, respectively; N is the number of monitoring sites.

3.3.2.1 Data Averaging

Averaging measurements from all monitors in a study area is frequently used to mitigate some of the errors associated with using data from a single ambient monitor to estimate exposure concentrations for a population. There are many averaging approaches in use to provide more representative exposure concentration estimates than those derived from a fixed-site ambient monitor. For example, Strickland et al. (2011) compared nearest fixed-site monitor concentrations of $PM_{2.5}$ and $PM_{2.5}$ components (SO_4^{2-}, OC, EC) averaged over 24 hours with concentrations averaged over three monitors (unweighted). They found that $PM_{2.5}$ and $PM_{2.5}$–SO_4^{2-} mass concentrations were within 8% of each other, with strong correlations between the concentration obtained by a fixed-site monitor and with that obtained by a population-weighted average Spearman $R = 0.969$. Reported $PM_{2.5-OC}$ concentrations had a Spearman correlation of $R = 0.847$, but more spatially varying $PM_{2.5-EC}$ had a Spearman correlation of $R = 0.831$. Goldman et al. (2012) had similar findings when comparing nearest monitor with unweighted averaging. Strickland et al. (2013) compared unweighted averages across monitors with concentrations measured at fixed-site monitors and concentrations estimated to be the "true" exposure concentrations at grid cells within the study domain. The fixed-site monitor produced $PM_{2.5}$ concentrations with the largest biases of −31.3%, in comparison with the unweighted average (−9.0%). Biases for $PM_{2.5}$ components (SO_4^{2-}, NO_3^-, NH_4^+, EC, OC) were similar for both the fixed-site monitor and unweighted average. In the unweighted averaging technique studied by Strickland et al. (2013), temporal variability may be dampened, leading to Berkson errors. As described below, more spatial heterogeneity inherent to the exposure concentration field implies greater Berkson errors.

Spatial averaging techniques include area-weighting and population-weighting (Vaidyanathan et al., 2013). Such schemes require some type of spatial modeling of data before averaging. For example, area and population-weighting might involve use of a regression model of PM or PM component concentration and population density, land use, or emission estimates to develop exposure concentration estimates at grid locations. Concentrations for census tracts, zip codes, or counties can then be averaged and weighted by the associated areas or populations. In such schemes, the objective of the spatial modeling is to develop more representative area or population estimates.

Population-weighted averaging is designed to reduce bias in the health effect estimate by giving greater weight to the locations where more people live. As part of the study referenced above, Strickland et al. (2013) compared population-weighted averages across monitors with concentrations measured at fixed-site monitors and concentrations estimated to be the "true" exposure concentrations at grid cells within the study domain. The population-weighted average produced $PM_{2.5}$ concentrations with biases of −8.1% in comparison with the true $PM_{2.5}$ exposure concentrations. Biases for $PM_{2.5}$ components (SO_4^{2-}, NO_3^-, NH_4^+, EC, OC) were similar for both the fixed-site monitor and unweighted average. Strickland et al. (2011) compared nearest fixed-site monitor concentrations of $PM_{2.5}$ and $PM_{2.5}$ components (SO_4^{2-}, OC, EC) averaged over 24 hours with concentrations averaged using population-weighted averages. They found that $PM_{2.5}$ and $PM_{2.5}$–SO_4^{2-} mass concentrations were within 8% of each other, with correlations

among the three spatial representations ranging from Spearman R = 0.963−0.995. Reported $PM_{2.5-OC}$ concentrations had Spearman correlations of R = 0.891, but more spatially varying $PM_{2.5-EC}$ had Spearman R = 0.804. Goldman et al. (2012) had similar findings when comparing nearest monitor, unweighted, and population-weighted averaging. These results suggest that population-weighted averaging may provide a small improvement over unweighted averaging for estimation of exposure concentration.

Spatial averaging approaches may influence exposure measurement error (Goldman et al., 2010) and associations between short-term $PM_{2.5}$ exposure and health outcomes (Goldman et al., 2012). In the latter study, the authors noted improved population-weighted R^2 values (relative to the fixed-site ambient monitoring method) between exposure concentration metrics estimated using data averaging methods and the simulated "true" ambient concentration field. For example, the R^2 values increased from 0.25 for a fixed-site ambient monitoring method to approximately 0.38 for data averaging methods.

Various methods can be chosen for temporal averaging, such as straight arithmetic averaging or methods that account for site-specific variability and that also account for the lack of some observations during the period. Temporal averaging is used to estimate exposure concentrations over different time intervals. Hourly and daily measures are averaged to provide metrics of interest (e.g., daily, weekly, monthly, seasonal, and annual). Darrow et al. (2011) tested different averaging intervals and found that 1-hour daily max $PM_{2.5}$ concentrations had high correlation with 24-hour average (Spearman R = 0.82) and moderate correlations (Spearman R = 0.75 and 0.68) with commuting time (7:00–10:00 and 16:00−19:00) and daytime (8:00−19:00) average $PM_{2.5}$ concentrations, respectively. As with the development of spatial averages, the objective of temporal averaging is to minimize error that might be introduced due to missing data from a time-series, so that diurnal, weekly, seasonal, or annual trends can be well characterized.

Spatial and temporal averaging methods provide a mechanism for interpolating where data are missing over space or in a time-series, respectively. The literature shows that averaging techniques produce some bias when compared with true exposure concentrations, but averaging techniques do present an improvement over using data from a single fixed-site monitor.

3.3.2.2 Spatial Interpolation Methods

The single fixed-site ambient monitor and methods that average concentration data across monitoring sites in an area both lead to exposure concentration estimates with no spatial variation. When spatially resolved estimates of PM exposure concentration are desired, a variety of approaches are available for two-dimensional interpolation of observations ranging from smoothing techniques (described here) to statistical modeling techniques involving additional data (Section 3.3.2.4). Various spatial interpolation methods exist that use multiple monitors to provide spatially varying fields. Such

methods include: inverse distance weighting (IDW), inverse distance squared weighting (ID2W) (Hoek et al., 2002), and kriging (Mercer et al., 2011; Whitworth et al., 2011).

IDW, in which ambient PM concentration at a receptor point is calculated as the weighted average of ambient PM concentration measured at monitoring locations, is a commonly used simple interpolation method [e.g., Tai et al. (2010)]. Several variations of IDW have been used to estimate exposure based on ambient PM concentration surfaces. The weighting factor is an inverse function of distance between the receptor and the monitor. For example, Brauer et al. (2008) and MacIntyre et al. (2011) estimated exposure to ambient $PM_{2.5}$ and other industrial pollutants within 10 km of point sources using an IDW sum of ambient $PM_{2.5}$ concentration and the three closest monitors within 50 km. Often, the weighting factor is the inverse distance raised to some power, and a higher power is applied to increase the weight on monitors that are closer to the receptor. Rivera-González et al. (2015) applied an ID2W model and compared the results with a citywide average, use of the nearest monitor, or kriging for development of an ambient $PM_{2.5}$ concentration surface. The results from IDW were correlated with the other city-wide averaging, nearest monitor, and ordinary kriging (Pearson R = 0.83−0.99), and the mean ambient $PM_{2.5}$ concentration estimated with IDW was within 5% of the mean computed with the other methods. Neupane et al. (2010) compared estimates of the ambient $PM_{2.5}$ concentration surface calculated using IDW with a $PM_{2.5}$ concentration surface calculated using both bicubic spline interpolation. Bicubic spline interpolation produced a lower mean ambient $PM_{2.5}$ concentration and larger IQR compared with IDW. Because there is no reference value in these studies, it is difficult to conclude that IDW presents any substantial improvement in prediction accuracy compared with other methods. These findings indicate that the results of IDW are comparable to methods that average concentrations across monitors and to methods that smooth concentration surfaces when estimating $PM_{2.5}$ concentration.

Kriging is a set of well-established methods that use observed covariance for geostatistical interpolation [e.g., Beelen et al. (2009)]. Recent developments have been made to improve kriging techniques. Pang et al. (2010) developed a space-time Bayesian Maximum Entropy (BME) model and compared it with ordinary kriging (OK). OK assumes linearity between data points, and it also assumes that the data are normally distributed. BME is not restricted to linearity or normality and so can draw on different sources of information, such as space-time relationships between variables and probability distributions describing the concentration dataset, to address missing data. Pang et al. (2010) found that estimation errors were 2−4 times larger for OK compared with BME. The ability to apply nonlinear models to address missing data thus provide BME-kriging approaches greater accuracy in modeling $PM_{2.5}$ concentration surfaces.

Berkson-like error in the estimated exposure concentration may arise from smoothing inherent to spatial interpolation models, such as IDW and kriging (see Section 3.2.1 for definition of Berkson-like error). The potential for Berkson-like error may be evaluated by cross-validation across receptor locations distributed over space, and the statistical performance of spatial interpolation methods may vary from study to study. When an interpolation model is fit using a relatively sparsely distributed monitoring

network, Berkson-like errors in estimated exposure concentration can be substantial (Alexeeff et al., 2015; Whitworth et al., 2011). All of the spatial interpolation approaches will produce spatially smoothed pollutant exposure concentration fields from monitoring data. However, spatial and temporal variabilities not captured by monitors are also not captured by these approaches.

If the quantity of data is small in each given site, or if the quality of the data obtained at the monitors is low, then classical-like error may arise (Szpiro et al., 2011a). If there are few observations, all of the interpolation methods suffer. This includes kriging, which depends on developing a variogram. With few observations at the monitoring locations, there is limited information to determine the functional coefficients used for kriging (e.g., the nugget, sill, and range). Weighting schemes for the interpolation models may amplify these errors (Wong et al., 2004).

3.3.2.3 Land Use Regression and Spatiotemporal Modeling

Direct spatial interpolation of PM exposure concentration and methods that employ static parameters to capture spatial variance can lead to excessive spatial autocorrelation when spatial variability of PM is high (Krewski et al., 2009). $PM_{2.5}$ tends to have less spatial heterogeneity than $PM_{10-2.5}$ or UFP (Section 3.4.2) given secondary production (U.S. EPA, 2009b), but high concentrations can still occur near primary sources. Statistical approaches that utilize data that vary over space and time can address this limitation. Geographic information system (GIS) models are being used to incorporate land use, emissions data, and geographic covariates into PM exposure concentration estimates. Two types of models are covered in this section, LUR and spatiotemporal models. LUR models regress observed PM concentrations on land use (and sometimes additional geographic) covariates and then use the model to predict exposure concentrations where PM is not measured (Hoek et al., 2008a; Ryan and Lemasters, 2007). Spatiotemporal models tend to incorporate kriging or autocorrelation into the response variable, which is then fit to the land use and geographic covariates [e.g., Sampson et al. (2013)].

3.3.2.3.1 Land Use Regression

LUR is an empirical approach to estimate exposure concentrations, often at very high resolution in more densely populated locations, by relating observed concentrations to the detailed information on land use. The basic approach is to develop an equation, via regression, relating observed pollutant concentrations (Hoek et al., 2008a; Ryan and Lemasters, 2007) to land use characteristics and other inputs:

$$Y(s_i, t_j) = \beta_0(s_i, t_j) + \sum_k \beta_{1,k}(s_i, t_j) X_k(s_i, t_j) + \epsilon(s_i, t_j)$$

Equation 3-8

Here, $Y(s_i,t_j)$ is the observed concentration at location (monitor) s_i (where i is a monitor location) and time t_j, β_0 and $\beta_{1,k}$ are the regression coefficients (intercept and slopes that are potentially spatially and temporally varying, but may also be constant in time and space), X are the independent variables (e.g., land use or meteorological parameters that may vary in time and/or space), k is the index indicating type of land use, and ϵ is the residual error term. β_0 is also called the additive bias and $\beta_{1,k}$ the multiplicative bias. Other forms of LUR models are also used. While the regression equation often is linear in the independent variables (as shown above), it can include nonlinear and mixed terms, particularly if there is specific knowledge of the relationship between a concentration and a variable that would suggest a specific functional form. The resulting regression equation can then be used to predict exposure concentrations at other times (t) and locations (s) where observations are not available.

Recent studies demonstrate typical LUR model performance, performance evaluation, and variability between cities. Eeftens et al. (2012) evaluated the application of LUR models in 20 cities in Europe for $PM_{2.5}$, PM_{10}, $PM_{2.5}$ absorbance, and $PM_{10-2.5}$. First, the models for the various cities had substantially different independent variables used in the final models, as well as coefficients associated with similar independent variables, demonstrating the location-specific nature of the models. Second, the in-sample R^2 of the various city models varied between 35 and 89% for $PM_{2.5}$ and between 32 and 81% for $PM_{10-2.5}$. Evaluation using a leave one out cross-validation (LOOCV) produced R^2 levels of 21 to 79% for $PM_{2.5}$ and 3 to 73% for $PM_{10-2.5}$. R^2 was not consistent between each city. Wang et al. (2014) expanded on the same model for $PM_{2.5}$ in thirty-six European cities. They found a LOOCV R^2 of 81% (RMSE = 2.38 μg/m^3) for cities where the model was fit. However, Wang et al. (2014) tested transferability of the model to areas where the model was not fit, and R^2 dropped to 42% (RMSE = 1.14 μg/m^3). Estimation of $PM_{10-2.5}$ in the LUR can be accomplished using the difference between the PM_{10} and $PM_{2.5}$ LUR models, since each model was trained using PM_{10} and $PM_{2.5}$ concentration data. However, low LOOCV R^2 for $PM_{10-2.5}$ in select cities may have been related to how measured $PM_{10-2.5}$ concentration was calculated for the validation dataset. If reference $PM_{10-2.5}$ concentration was calculated by the difference of two collocated monitors rather than by a dichotomous sampler, flow rate differences could cause some error in the reported $PM_{10-2.5}$ concentrations. If $PM_{10-2.5}$ was calculated by the difference between concentrations measured by PM_{10} and $PM_{2.5}$ monitors that were not collocated, then errors would likely be larger.

Several features of LUR have the potential to limit the accuracy of modeled exposure concentrations. Beckerman et al. (2013a) noted that two major limitations with LUR are variable selection and how to best deal with unbalanced repeated measures, potentially involving arbitrary decisions in the model building process. They used a generalized linear model with a deletion/substitution/addition machine learning algorithm to model $PM_{2.5}$, resulting in an out-of-sample R^2 of 0.65 based on fivefold cross-validation (n-fold cross-validation means that 1/n of the data are reserved for validation with the rest used for model training, and the process is repeated n times). The ability of an LUR method to relate air pollutant concentrations to specific land uses, and thus estimate high resolution exposure concentration fields, is directly dependent on having sufficient numbers of observations in time and/or space to develop

the regression equation with reasonable uncertainties in each of the coefficients (Wang et al., 2014). The sparseness of the routine monitoring networks may incur Berkson-like error in the exposure estimates. More intensive studies may be conducted where additional monitoring data are available (sometimes called saturation monitoring if the additional monitors lead to extensive spatial coverage). Saturation sampling can also lead to introduction of classical-like error in the exposure predictions if different measurement methods are used and differences in the methods are not fully understood (Vedal et al., 2013; Levy et al., 2010).

A related weakness of LUR is its limited generalizability when the monitor and study participant locations are different. The developed regression equations are usually restricted to the study region (typically city-scale) alone and may not be directly applied to another region, due largely to the empirical nature of LUR (Wu et al., 2011; Jerrett et al., 2005a). Local PM data are required to calibrate LUR models, and measurements must be available that estimate the spatial patterns of exposure concentrations. For example, Patton et al. (2015) found during estimation of UFP exposure concentrations in Boston urban neighborhoods that models fit to one neighborhood did not necessarily provide robust estimates of particle NC for another neighborhood, and acceptable model performance required calibration with local data. Hoek et al. (2008a) also reviewed the performance of the LUR model regarding their application for $PM_{2.5}$ given differences between where the model was fit and where it was used for predictions. R^2 values for the developed LUR models for $PM_{2.5}$ ranges from 0.17 to 0.69, with substantially lower out-of-sample R^2 in evaluation (0.09−0.47, with fewer studies performed evaluation/cross-validation). This suggests that comparing performance statistics between cities, even when using one method (in this case, LUR) can yield very different performance and that using cross-validation reduces performance, but to a degree that is not predicable from the full model R^2. This work was extended by Wang et al. (2015) to show the association between the LOOCV R^2 and a health outcome (forced vital capacity: FVC). For models of $PM_{2.5}$, Wang et al. (2015) note that cross-holdout validation, where the model is rebuilt after removing data from a site and retraining the model using the same variables, may be more appropriate than traditional LOOCV for assessing LUR performance, particularly when there are a small number of training sites, because it makes use of all data in the model evaluation process instead of leaving out a portion of the data. In summary, LUR models can have relatively good validation ($0.4 < R^2 < 0.7$), even for spatially variable $PM_{10–2.5}$, but good validation will only occur when the model is used to predict concentrations in the same geographic area where it was fit.

Although LUR models have been used to estimate long-term (e.g., annual) average PM exposure concentrations within large metropolitan areas by using variables such as road type, traffic count, land cover, and topography (Gulliver et al., 2011; Hoek et al., 2008a) and can be applied to current or historical conditions (Hystad et al., 2013), LUR has been used less frequently for time-series exposure studies. Land use variables (e.g., elevation, road-type, distance to road, land cover) usually do not vary in time. Temporal variation in the model is gained by including both the available observations and other temporally-varying inputs, such as meteorological parameters. As part of the New York City Community Air Survey (NYCCAS) in which $PM_{2.5}$ samples were collected from 150 sites across the five boroughs of

New York City, Ross et al. (2013) built a LUR for application in a birth defects exposure study and developed a temporal adjustment procedure to increase the temporal resolution of $PM_{2.5}$ exposure concentration estimates to 2 weeks. This was accomplished by multiplying an LUR derived for one year by the ratio of 2-week averages to annual averages. Validation of the method using data from a second year of measurements produced out-of-sample R^2 of 0.83 (R^2 = 0.88 if two outliers were removed from the dataset). Dons et al. (2013) aimed to fit a LUR model of black carbon (BC) concentration to hourly data for a time-activity exposure study. However, they observed that many variables became insignificant when inputting hourly data into an annual model. Dons et al. (2013) instead built a LUR for hourly data using static and dynamic variables in different models. They found that LOOCV R^2 varied from 0.13 to 0.78. Higher R^2 but also higher RMSE were observed during the late morning to evening hours for the model with dynamic variables. These studies demonstrate that LUR can be extended to study temporal variability of $PM_{2.5}$ and BC, but caution must be used for application in time-series studies since model accuracy is sometimes low.

Recently, LUR has been applied to predict spatial distribution of $PM_{2.5}$ components. As part of the NYCCAS study, Ito et al. (2016) speciated the collected $PM_{2.5}$ samples and built a LUR model to predict $PM_{2.5}$ components concentrations across New York City. The temporal adjustment described above from Ross et al. (2013) was applied in the Ito et al. (2016) study, as well. LOOCV was used to test the models, and models for $PM_{2.5}$ mass and several components (Ca, Ni, V, and Zn) produced $R^2 > 0.8$. Several other components produced R^2 in the range of 0.6–0.7 (Cu, Fe, K, S, and Si), and others produced $R^2 \leq 0.5$ (Al, Br, Mn, Pb, and Ti). Spatial coefficient of variation (CV) was calculated for each component model, and high spatial variability did not always correspond to low LOOCV. For example, Ni had a spatial CV of 0.70 and LOOCV R^2 of 0.85, while Mn had a spatial CV of 0.68 and LOOCV R^2 of 0.36. The LUR models were then applied to a source attribution analysis in which 50–1,000 m buffers were placed around sources, and then annual average concentrations for each component modeled by the LUR were compared to the sources within those buffers.

In summary, new developments for LUR include adaptation of LUR models for short time resolutions and for spatially variable size fractions (UFP, $PM_{10-2.5}$) of PM and $PM_{2.5}$ components (e.g., Ca, Cu, Fe, K, Ni, S, Si, V, Zn). At the same time, several studies have improved characterization of errors and uncertainties in LUR modeling and how best to quality assure those models. Several studies drew attention to poor validations produced when LUR models were fit to one geographic area and then applied to another. Similarly, lack of spatial correlation between predicted concentrations at the model receptors and actual exposure concentrations of study participants can lead to Berkson-like error, and incompatibility of methods to model and measure PM can lead to classical-like errors (see error type definitions in Section 3.2.1).

3.3.2.3.2 Spatiotemporal Modeling

A GIS-based spatiotemporal model provides a useful tool for large-scale spatiotemporal analysis. GIS-based mapping such as kriging utilizes the covariogram for statistical smoothing but may lead to invalid spatial features due to insufficient data for characterizing spatial variation. Generalized additive models that describe regional and small-scale spatial and temporal (monthly) gradients (and corresponding uncertainties) were developed for $PM_{10-2.5}$ and $PM_{2.5}$ over the U.S. for 1998−2007 for use in health studies (Yanosky et al., 2014). Model validation was higher for $PM_{2.5}$ (out-of-sample $R^2 = 0.77$, normalized mean bias factor, NMBF = −1.6%) compared with $PM_{10-2.5}$ (out-of-sample $R^2 = 0.52$, NMBF = −3.2%). Bias increased and precision decreased for $PM_{10-2.5}$ compared with $PM_{2.5}$. Spatial covariates, including elevation, urbanized land use within 1 km, county-level population density, distance to roadways of moderate to heavy traffic, and point-source emissions density were all determined by the authors to be important predictors of $PM_{2.5}$, although the authors did not present data for the relative contribution of each variable to the model. Yanosky et al. (2009) developed spatially and temporally resolved concentration fields of $PM_{2.5}$ and $PM_{10-2.5}$ to be used as exposure concentration estimates in long-term exposure studies for the northeastern and Midwestern U.S. Out-of-sample R^2 for the $PM_{2.5}$ model was 0.77 with precision of 2.2 $\mu g/m^3$ for 1999 to 2002, compared with out-of-sample R^2 for the $PM_{10-2.5}$ model of 0.39 with precision of 5.5 $\mu g/m^3$. The IDW method was applied as an alternative to compare with a semiempirical model. For a $PM_{2.5}$ concentration field developed for 1999 to 2002, cross-validation results for IDW show reasonable performance with out-of-sample $R^2 = 0.60$ (and cross-validation results for IDW were not available for $PM_{10-2.5}$).

Recent studies have attempted to estimate spatially resolved $PM_{2.5}$ exposure across larger regions of the U.S. for application in epidemiologic studies. For example, Sampson et al. (2013) developed a model combining universal kriging that builds from regional partial least squares regression LUR models with categorical variables describing land use, population, emissions, vegetative index, roadway type, impervious surfaces, and proximity to features. Results of cross-validation with 10-fold cross-validation produced out-of-sample $R^2 = 0.52-0.63$ at the national scale and $R^2 = 0.84-0.88$ at the regional scale. Keller et al. (2015) applied this model to $PM_{2.5}$ and BC prediction in the six MESA Air cities (Baltimore, MD, Chicago, IL, Los Angeles, CA, New York City, NY, St. Paul, MN, and Winston-Salem, NC) and obtained out-of-sample R^2 of 0.82−0.91 for $PM_{2.5}$ and 0.79−0.99 for BC (using both AQS and MESA Air monitors for cross-validation). Bergen et al. (2013) applied a similar method for four $PM_{2.5}$ components: EC, OC, silicon, and sulfur, and the out-of-sample R^2 ranges from 0.62 to 0.95. Kim et al. (2015) examined $PM_{2.5}$ component networks for suitability of the data inputs for applying spatiotemporal models for PM component exposure concentrations, and they found that the Chemical Speciation Network (CSN) and Interagency Monitoring of Protected Visual Environments (IMPROVE) networks were too sparse to fit the model. They found that the greater density of the National Particle Component Toxicity (NPACT) study network, set up outside study participants' homes, would be needed to fit the model. Additionally, differences among the three networks with respect to averaging times, quality assurance, and pump flow rates, complicates the ability to combine networks into one database for fitting the model.

Recent developments in spatiotemporal modeling have enabled modeling of larger geographic regions and to overcome some of the limitations of kriging. In some cases, these models have been fit with good accuracy and precision. However, differences in model calibration in different regions introduce model errors, and sparse networks have been found insufficient for model fitting.

3.3.2.4 Mechanistic Models

Improvements in computational resources have led to mechanistic models (see Section 2.4.7 for a description) that are more amenable to exposure assessment studies, because they provide finer spatial resolution over larger domains and can include more components, more sources, and longer time periods compared with previous versions of CTMs (Garcia-Menendez et al., 2015; Ivey et al., 2015; Li et al., 2015; Turner et al., 2015; Hu et al., 2014d; Burr and Zhang, 2011; Civerolo et al., 2010; Wagstrom et al., 2008). Such models computationally solve the atmospheric-diffusion-reaction equations that describe the transport and physical and chemical transformations of pollutants (Seinfeld and Pandis, 2006). Turbulent diffusion is typically treated by using atmospheric dispersion coefficients or diffusivities. Mechanistic models may be used to characterize exposure concentrations where monitoring data are limited or not available.

3.3.2.4.1 Chemical Transport Model Applications for Exposure Concentration Estimation

CTMs commonly utilized for exposure concentration modeling in the U.S. include the Community Multiscale Air Quality (CMAQ) model, Particulate Matter-Comprehensive Air Quality Model with Extensions (PM-CAMx), and the University of California at Davis/California Institute of Technology (UCD/CIT) CTM (Gaydos et al., 2007; Byun and Schere, 2006; Kleeman and Cass, 2001; Russell et al., 1988) at the urban-to-regional scales and global models such as the Goddard Earth Observing System CTM (GEOS-Chem) and Comprehensive Air Quality Chemistry Model (CAM-Chem) (Garcia-Menendez et al., 2015; Bey et al., 2001). The European Air Pollution Dispersion and Chemistry Transport Model (EURAD-CTM) has been used in Europe for PM and related exposure concentration modeling (Weinmayr et al., 2015; Nonnemacher et al., 2014), and GEM-MACH is being used in Canada (Peng et al., 2017). More specialized models may also be used to model specific sources, such as forest fires (Rappold et al., 2014).

CTMs are typically applied over grid sizes of 1 km or more, depending upon the application (while grid resolutions of less than 10 km are used over urban areas, continental scale applications typically are done at about 10−40 km, and global scale applications with larger grids yet). Nested grids are used to achieve a range of resolutions in many applications (Isakov et al., 2007; Byun and Schere, 2006; Zhang et al., 2004). In some applications, CTMs are coupled directly (i.e., on-line) to a meteorological model to provide meteorological fields, commonly WRF and CMAQ (Mathur et al.,

2010). Inputs include meteorological parameters (e.g., wind speed and direction, temperature, relative humidity, etc.) throughout the vertical layers of the atmosphere up to and including portions of the stratosphere and source emissions. The model outputs are the pollutant concentrations, and how they vary in space and/or time (Figure 3-1). The resulting fields are then used for epidemiologic studies and other studies of air quality. The ambient concentration fields are also used as inputs to microenvironmental models for estimating exposure (Baxter et al., 2013; Jones et al., 2013; Georgopoulos et al., 2005; Burke et al., 2002).

CTM models have been used for estimation of exposure concentrations, including for use in epidemiologic studies, both in North America and abroad (Ostro et al., 2015; Weinmayr et al., 2015; Anenberg et al., 2014; Marshall et al., 2014; Nonnemacher et al., 2014; Silva et al., 2013; West et al., 2013; Lim et al., 2012; Tagaris et al., 2010). For studies covering a large geographic area, CTM models can provide location-specific estimates without gaps in coverage. Issues with using CTM models relevant for exposure assessment studies are discussed below. Hu et al. (2015) used the UCD/CIT model to develop a 9-year set of simulated pollutant concentration fields, which were then used by Ostro et al. (2015) to assess the associations of $PM_{2.5}$ and UFP with health in a cohort epidemiologic study. When evaluating the model against monitoring data, they observed low error for $PM_{2.5}$ mass compared with error for individual components, such as SO_4^{2-}. In general, errors were higher when matching observations and simulated values on a daily basis compared with monthly and annual averaging periods, suggesting that model results are more accurate over longer averaging times. They did not report RMSEs or R^2. They noted one advantage of using model results over ambient monitoring was the availability of PM component concentrations every day, versus one out of three. Hou et al. (2015) extended the application of CMAQ to the study of human health effects by using the emissions input data to calculate the sensitivity of $PM_{2.5}$ concentrations to EGU and non-EGU emissions from four regions of the U.S. The sensitivities were then used to estimate changes in mortality as a function of $PM_{2.5}$ exposure concentrations and sensitivity of mortality to regional EGU and non-EGU emissions. Bravo et al. (2012) simulated $PM_{2.5}$ over the eastern U.S. using a 12 km× 12 km grid with a normalized mean bias of 2.1% over the course of a year. However, $PM_{2.5}$ concentrations were underestimated by up to 27% in summer and by up to 32% in late fall. In a related study, Mannshardt et al. (2013) compared results using observations and CMAQ-estimated exposure concentration fields in a study of $PM_{2.5}$ and O_3 associations on emergency hospital emissions in three counties of New York City for 2002−2006. CMAQ was run for the eastern U.S. using 12 km grids and used as input to a human exposure model, SHEDS-PM.

Results from CTMs can be biased and subject to various errors due to inputs and model parameterizations, but factors leading to simulation errors continue to be identified and reduced [e.g., Yu et al. (2014); Barsanti et al. (2013); Baek et al. (2011); Foley et al. (2010)]. For example, PM chemistry modules in CMAQ have been added and revised to address limitations in modeling secondary organic PM formation and nitrate chemistry. Nonetheless, biases and errors persist that may have weekly and seasonal trends due to limitations in emission inventory specifications and chemical and meteorological inputs, respectively. Nolte et al. (2015) compared MOUDI measurements of PM size distribution with

predictions of size distribution (ranging from 0.05 to 20 μm) for several PM components (SO_4^{2-}, NO_3^-, NH_4^+, Na^+, Cl^-, Mg_2^+, Ca_2^+, K^+) at different sites. Nolte et al. (2015) observed discrepancies between the modeled and monitored size distributions where the emissions data were not accurate. Typically, where data were omitted from the NEI, modeled size fractions were negatively biased so that exposure concentrations would be underestimated for those size fractions. Differential bias may also be observed across regions in space. Many such biases can be corrected for using adjustment factors based on comparisons of simulation results with observational data.

The dearth of ambient UFP observations, given that necessary instrumentation is not standard to routine monitoring networks (Section 2.4.5), has limited development and validation of CTMs at this size fraction. UFPs are derived from both direct emissions as well as atmospheric nucleation, and they coagulate on shorter time scales than larger particles (Section 2.3.4). Their concentrations can vary rapidly, and there is an observed steep spatial gradient in NC near sources, e.g., within a few hundred meters of highways (Karner et al., 2010; Zhou and Levy, 2007), suggesting finer resolution modeling should be used when using models to estimate exposure fields for UFPs. The lack of emissions information on UFPs also complicates CTM development. Hu et al. (2014a) and Hu et al. (2014b) developed source-based CTMs to predict $PM_{0.1}$ mass concentration surfaces for estimation of exposure concentrations that were used in an epidemiologic study by Ostro et al. (2015). The model included emissions, advection, diffusion, wet deposition, and dry deposition, but it omitted gas-to-particle phase chemistry, gas-to-particle phase conversion, nucleation, and coagulation. Hu et al. (2014b) used a 4 km × 4 km grid, which creates uncertainties because it is larger than the spatial scale over which UFPs evolve. They noted the need for either fine grid resolution or a subgrid scale model such as large eddy simulation to capture finer-scale dynamics. Hu et al. (2014b) reported Pearson $R = 0.92$ for comparison of $PM_{0.1}$ mass concentration predictions with measurements and Pearson $R = 0.94$ for comparison of $PM_{0.1}$ EC mass concentration predictions with measurements. Bias was not reported, but the authors noted that model performance degrades for $PM_{0.1}$ mass concentration >4 μg/m^3 or <1 μg/m^3 and for $PM_{0.1}$ EC mass concentration >1 μg/m^3 or <0.2 μg/m^3. Using SEARCH data to evaluate CMAQ performance for application in epidemiologic studies, Park et al. (2006) found that CMAQ did not capture UFP dynamics well, finding biases of an order of magnitude and more in NC. Elleman and Covert (2010, 2009a), and Elleman and Covert (2009b) also found that CMAQ did not accurately predict UFP numbers. They linked the biases to the treatment of particle nucleation, emissions estimates, and how the size distribution is captured. Stanier et al. (2014) developed a nonlinear, Lagrangian trajectory model designed to capture the size distribution of UFPs, and applied it to simulate UFPs in the Los Angeles area for a period when more detailed observations existed. They were able to reproduce NC within a factor of two 94% of the time at the four sites being used in the evaluation. In a comparison of 12 different nucleation parameterizations, Zhang et al. (2010a) found that the predicted NC of Aitken mode particles can vary by three orders of magnitude. These recent efforts illustrate that the large uncertainties in UFPs are still a great limitation in applying CTMs to model UFP exposure concentration.

Several new developments in CTM have made the technology more amenable for application in exposure assessment, such as improvements to the model through bias correction methods. However, several limitations still exist, including large grid sizes, uncertainties regarding emissions inputs, and uncertainties in modeling UFP. Specific modeling decisions must therefore be evaluated when CTMs are employed in epidemiologic studies.

3.3.2.4.2 Dispersion Modeling Applications for Exposure Concentration Estimation

Dispersion modeling has been performed to develop relatively fine resolution PM exposure concentration fields (Jerrett et al., 2005a). Dispersion models describe the relationship between emissions, meteorology and the resulting pollutant concentrations using algebraic relationships (e.g., the Gaussian Plume Equation), but they typically have limited ability to model chemistry (if any) (Holmes and Morawska, 2006). Examples of dispersion models include AERMOD, Research LINE-Source Model (or R-LINE), Community LINE-source Model (C-LINE), and California LINE Source Dispersion Model (CALINE) (Barzyk et al., 2015; Snyder et al., 2013; Cimorelli et al., 2005; Perry et al., 2005; Benson, 1992).

Model intercomparison has more recently focused on near-road dispersion modeling. Heist et al. (2013) conducted an intermodel comparison of AERMOD, CALINE, ADMS, and R-LINE for tracer (SF6) dispersion and found that the more recently developed ADMS and R-LINE exhibited lower error and better validation compared with CALINE and AERMOD. The models were each compared with results from a tracer study in Idaho Falls, ID (for open field and constructed barrier conditions) under different convective mixing conditions and near Highway 99 in Sacramento, CA and showed that ADMS, R-LINE, and both versions of AERMOD performed better than the CALINE models for both sites (Table 3-4). ADMS and R-LINE were further compared for near-neutral, weakly stable, convective, and moderately-to-strongly stable convective mixing conditions. At low concentrations (<1 pbb), both models exhibited a tendency for positive bias except for the moderately-to-strongly stable conditions, where both models exhibited some negative bias with more scatter. Chen et al. (2009) tested the performance of three dispersion models, CALINE4, CAL3QHC and AERMOD, at Sacramento, CA and London, U.K. regarding their application in modeling near road $PM_{2.5}$ concentrations. All three models produced R^2 values ranges from 0.85 to 0.90 comparing with measurement data (without adding background concentrations) in Sacramento, CA. However, the models perform less well at London, U.K. with R^2 value at around 0.03 without background concentrations due to the influence of street canyons on receptor performance.

Dispersion models are typically applied over smaller domains (near-source to urban) than CTMs (urban to global). For example, AERMOD is designed for simulating "near source" dispersion from point and area sources, and is most useful for assessing source impacts within 20 km of the source (Silverman et al., 2007), although it has been evaluated for distances up to 50 km for certain applications (Perry et al.,

2005). R-LINE is used for line source modeling, and was originally evaluated by Snyder et al. (2013) for distances of 200 m, though applications have applied it to urban scale (Batterman et al., 2014). While AERMOD is designed to simulate point and area/volume sources, it has been used to estimate the impacts of road networks by approximating road segments as area or volume sources (Isakov et al., 2014; Chen et al., 2009). Rowangould (2015) proposed a new dispersion modeling method for urban environments by breaking the city into coarse and fine grid cells (depending on the roadway density) and modeling dispersion from roadway sources in each roster in parallel. No validation was presented in the Rowangould (2015) paper.

Table 3-4 Comparison of dispersion models with data from a tracer study in Idaho Falls, ID and a near road study in Sacramento, CA and an UFP study in Somerville, MA and Chinatown in Boston, MA.

	Idaho Falls, ID		Sacramento, CA		Somerville, MA		Boston, MA	
Model	NMSE	*R*	NMSE	*R*	NMSE	R^2	NMSE	R^2
CALINE3	NR	NR	2.26	0.29	NR	NR	NR	NR
CALINE4	1.94	0.76	0.86	0.47	0.06	0.54	0.02	0.78
AERMOD-V	1.26	0.84	0.28	0.77	0.11	0.57	0.02	0.81
AERMOD-A	1.25	0.82	0.31	0.72	NR	NR	NR	NR
ADMS	1.14	0.88	0.20	0.78	NR	NR	NR	NR
R-LINE	0.96	0.85	0.34	0.75	0.13	0.58	0.02	0.81

NMSE = normalized mean squared error; NR = not reported, *R* = correlation (not specified if Pearson or Spearman); R^2 = coefficient of determination.

Assessing the suitability of multiple dispersion and land use regression models for urban traffic-related ultrafine particles. Environ Sci Technol. 2017;51:384-392. Copyright (2017) American Chemical Society. (Patton et al., 2017).

Several studies have used dispersion models at urban or neighborhood scales to estimate exposure concentrations. For example, Isakov et al. (2014) applied both AERMOD and R-LINE in Detroit, MI to estimate exposure concentrations to $PM_{2.5}$, EC, OC and pollutant gases at homes and schools of children with asthma participating in the Near Road Exposure of Urban Air Pollutants Study (NEXUS). CMAQ and kriging of observations were used to define regional air pollutant levels. Comparison between model results and measurement show reasonable performance with Pearson *R* range from 0.78 to 0.94 (daily average $PM_{2.5}$ concentrations) at different monitor sites. Simulated concentrations of PM are often used in conjunction with other estimates of regional PM because dispersion models are the more limited in spatial extent and so not designed for PM transport over large distances. For example, in an Atlanta application

(Dionisio et al., 2013; Sarnat et al., 2013b), a variety of approaches were used to estimate exposure concentrations. One approach used AERMOD to model impacts of traffic emissions and added the resulting concentrations to background concentrations (developed from observations) to construct a high-resolution PM field for use in an epidemiologic study. Sarnat et al. (2013b) used the fine-scale resolution to help identify potential health disparities linked to socioeconomic status that were not apparent when using a single fixed-site monitor. Maroko (2012) used AERMOD to simulate $PM_{2.5}$ impacts from point sources in the New York City area to assess environmental justice issues. Dispersion models can also be used to simulate components of PM, assuming that they do not undergo a chemical reaction in the atmosphere. For example, Colledge et al. (2015) used AERMOD to estimate particulate manganese exposure in two Ohio towns.

A recent development in dispersion modeling is the inclusion of UFP when modeling PM dispersion in the vicinity of a road. Patton et al. (2017) evaluated CALINE4, R-LINE, and AERMOD for UFP transport near roads in the greater Boston, MA area (Somerville, MA and Chinatown, within Boston). They found similar performance among all three models (Table 3-4). Stanier et al. (2014) recognized that it is challenging to model UFP emitted from mobile sources, because the UFP size distribution rapidly evolves upon emission from vehicle tailpipes. They fit emissions factors based on existing data for cruising and acceleration of heavy-duty and light-duty vehicles, estimating across a size distribution down to 7 nm and correcting for coagulation and deposition. The emissions factors were incorporated into a dispersion term in the model. Modeled particle NC was compared with measured concentration at two sites within the Los Angeles, CA metropolitan area and showed underestimation of the model (below a factor of 1:2) at one location and modeled data within a factor of two at the other site. Stanier et al. (2014) propose that the model is suitable for estimating spatially resolved UFP exposure concentrations on a daily basis.

Dispersion modeling continues to be used in exposure assessment studies, often in conjunction with CTMs to provide fine-scale spatial resolution. Recent improvements have been made in modeling dispersion of traffic-related air pollution and applying dispersion models at urban scales. However, dispersion models are still limited when applied in dense urban environments since dispersion models are not designed to deal with complex built topography (Kakosimos et al., 2010), and they are limited in their ability to represent UFP transport because they are not designed to capture size-specific UFP dynamics (Stanier et al., 2014).

3.3.2.4.3 Hybrid Approaches

Although spatiotemporal and LUR models have been applied to estimate long-term (e.g., monthly and annual) spatially-resolved ambient PM exposure concentrations, these techniques are typically not as successful for short-term (e.g., hourly and daily) applications as they do not include the impacts of changing source emissions and meteorology. PM data from ambient monitors provide accurate information on temporal trends at monitoring sites but little information on spatial patterns.

Emissions-based models provide spatial information consistent with emissions, chemistry, and meteorology but subject to limitations in the accuracy of these inputs as well as in the ability of models to simulate air pollution physical and chemical processes. "Hybrid" approaches that combine observational data with emissions-based model results are being developed and used to provide better estimates of single component and mixtures along with estimates of the associated uncertainties. These approaches range from rescaling model results to correction for known biases to combining observational and simulation data and optimizing spatiotemporal exposure concentration estimates.

Fusion of Model Outputs for Exposure Concentration Estimation

As noted above, CTMs by themselves typically have spatial resolution of 4 km or greater due to computational limitations, but they provide regional variations in PM (and PM component levels) and capture the formation of secondary PM, while dispersion models provide near-source impacts with a finer resolution. Given these complementary characteristics, it is natural to couple them (though care must be taken to not double count emissions) (Isakov et al., 2009).

Several recent studies have merged CMAQ with dispersion models. For example, Beevers et al. (2013) combined CMAQ results with the ADMS (a dispersion model) in London, England. They found that the combination could capture the spatial and temporal variations in air quality, with a mean bias of 0.6 $\mu g/m^3$ when comparing the model to monitors at five sites. Similarly, Zhai et al. (2016) combined R-LINE results with CMAQ-data fusion fields to estimate $PM_{2.5}$ exposure concentration fields for Atlanta, GA for a birth cohort study, with Pearson $R^2 = 0.72$ between the model and monitoring data with LOOCV normalized RMSE = 0.50 and normalized mean bias of 12%. A combined AERMOD-CMAQ application to New Haven, CT, was conducted (Lobdell et al., 2011; Isakov et al., 2009) to develop local scale (census block level) PM exposure concentrations in a base year (2001) and future years (2010, 2020 and 2030 to assess pollutant control programs). They noted the uncertainties due to model inputs, with coefficients of variation (standard deviation of concentration/mean concentration) ranging from 10−70% within different census tracts, but no estimates of model uncertainty with respect to $PM_{2.5}$ were provided. They linked their results to the HAPEM (Ozkaynak et al., 2008) and SHEDS (Isakov et al., 2009) exposure models, as described further in Section 3.3.4.

Another method of addressing the low spatial resolution of a CTM is to combine the model results with dispersion model results and LUR modeling output for exposure concentration. Wang et al. (2016) combined CTM with LUR using a hierarchical spatiotemporal modeling technique in which the 2-week average LUR-derived $PM_{2.5}$ concentration is modeled as a function of spatiotemporal trends and spatiotemporal residual terms, where the trend terms can be decomposed into an average and a spatially-varying trend (Keller et al., 2015). Wang et al. (2016) incorporated the CTM predictions into the spatially-varying trend term. The advantage of combining these two models is that the CTM is a mechanistic model employing principles of transport, dispersion, and atmospheric chemistry with finer temporal resolution (daily for this study), while the LUR offers fine-scale spatial resolution. The LUR

was fit to fixed-site $PM_{2.5}$ monitoring data in AQS and from the MESA Air study and incorporated a variable for long-term average concentration derived from the CAL3QHCR near-road line source dispersion model. Wang et al. (2016) found that addition of the CTM to the spatiotemporal model of Keller et al. (2015) only produced a marginal improvement in the prediction ability of the model for capturing $PM_{2.5}$ exposure concentrations. Di et al. (2016b) combined GEOS-Chem simulations, based on a 28 km × 25 km grid, with land use and meteorological variables to improve resolution to 1 km × 1 km across the northeastern U.S. Di et al. (2016b) compared the model results with monitoring data when the GEOS-Chem model was used alone and when it was combined with land use and meteorological variables. Out-of-sample R^2 for $PM_{2.5}$ improved from 0.47 for GEOS-Chem alone to 0.85 for the hybrid model. Out-of-sample R^2 ranged from 0.13−0.33 for $PM_{2.5}$ components (EC, OC, NO_3^-, SO_4^{2-}, NH_4^+, dust, sea salt) for GEOS-Chem alone, and R^2 improved to 0.41−0.83 across the $PM_{2.5}$ components for the hybrid model.

Fusion of Chemical Transport Model Predictions with Surface Observation Data

To take greater advantage of the strengths of observational data and model simulations, various data fusion approaches have been developed and applied. Such model-data fusion approaches used in estimating exposure concentration fields for health studies have frequently used CMAQ.

Downscaling approaches have been used frequently in recent years to correct biases in CTM output. Berrocal et al. (2009) proposed a downscaling approach combining monitoring and CMAQ modeling data to improve the accuracy of spatially resolved O_3 model data. Specifically, a Bayesian model was developed to regress CMAQ model estimates of O_3 concentration on monitoring data, and then the regression model was used to predict concentrations using the CMAQ model results as an input field. Although the downscaling method was originally developed for to model O_3 concentration, this technique has since been applied for modeling $PM_{2.5}$ concentration surfaces and found to have low NMB (0.95%) with mean correlation between model output and monitoring data of 0.97 (Bravo et al., 2017). Berrocal et al. (2010) extended the approach to include two pollutants (ozone and $PM_{2.5}$) in a single modeling framework. Predictive mean absolute error (PMAE) for $PM_{2.5}$ concentration in the bivariate model was 2.3 $\mu g/m^3$, compared with observations at 65 monitoring sites. PMAE for $PM_{2.5}$ was 2.4 $\mu g/m^3$ for the comparison of the single-pollutant model with the monitoring sites. Berrocal et al. (2012) also added smoothing processes that incorporate spatial autocorrelation and correction for spatial misalignment between monitoring and modeled data. Bentayeb et al. (2014) applied a similar data assimilation method in which local measurements and elevation data were combined with CTM output in a geostatistical forecasting model. This algorithm was applied for $PM_{2.5}$, PM_{10}, NO_2, SO_2, C_6H_6, and O_3. For the years 1989−2008, correlation between assimilated $PM_{2.5}$ concentration and local observations at 2 km resolution ranged from Pearson R = 0.12 to 0.85, with correlations decreasing with year. Bentayeb et al. (2014) explained the low correlations by a small number of $PM_{2.5}$ monitoring stations producing anomalous data and low correlations between emissions and concentration data.

Bias correction methods are variations on downscaling that have been developed to address spatiotemporal bias in the CMAQ model. For example, Crooks and Oezkaynak (2014) developed a statistical method of spatiotemporal bias correction of $PM_{2.5}$ mass and its major components for CMAQ fields. The correction uses speciated data from ambient monitors. Mass conservation for $PM_{2.5}$ observations constrains the sum of the $PM_{2.5}$ components' concentrations in locations without speciation monitors. The Crooks and Oezkaynak (2014) method is similar to downscaling methods in that it is a calibration method, but it corrects to the grid-scale rather than receptor points. The method was developed for use in an epidemiologic study investigating the association between $PM_{2.5}$ component ambient concentrations and birth outcomes throughout the state of New Jersey based on 1-month averages, so the focus was on addressing seasonal bias trends rather than daily biases. The bias-corrected CMAQ results were more accurate than the original CMAQ output (calculated as mean bias and RMSE using monitored concentrations as a reference), and a cross-validation study found that predictions improved when enforcing mass conservation. Comparison between the bias-corrected CMAQ and other downscaling or bias correction methods was not provided. Hogrefe et al. (2009) used a combined model-observation approach to estimate historic gridded fields of $PM_{2.5}$ mass and component concentrations, with corrections varying by component, season, and location. $PM_{2.5}$ mass concentration had a median bias of -0.3 $\mu g/m^3$ and median RMSE of 7.5 $\mu g/m^3$ compared with monitor values. Hogrefe et al. (2009) reported high relative biases and larger uncertainties for nitrate and organic carbon, compared with sulfate and ammonium. This was especially pronounced at remote IMPROVE sites, compared with urban CSN sites that have more monitors. Although more development is needed, these methods present additional options for applying CTMs for modeling $PM_{2.5}$ species.

A hierarchical Bayesian model (HBM) to predict daily $PM_{2.5}$ exposure concentrations for use in the Environmental Public Health Tracking Network has been developed through a CDC-EPA collaboration. This model integrates U.S. EPA monitor data with CMAQ simulation results to generate daily $PM_{2.5}$ concentration and error fields for a 36 km grid across the conterminous U.S. and for a 12 km grid across an eastern portion of the U.S. (Vaidyanathan et al., 2013; McMillan et al., 2010). In the application of HBM over a section of the eastern U.S., McMillan et al. (2010) found that the mean squared error using the HBM field was similar to a field developed using kriging, though the HBM outperformed kriging by 10−15% for bias. They found that 59% of the validation data was captured in the kriging prediction intervals as compared to 80−90% when using HBM. For the U.S.-wide application at 36 km resolution, the HBM method had Pearson *R*'s ranging from 0.91 to 0.94, depending upon the method used to impute the CMAQ data (Vaidyanathan et al., 2013), while the 12 km application over the eastern portion had Pearson *R*'s of 0.84 to 0.86.

Data fusion methods sometimes include fusing CTM modeling results with observations for exposure predictions. Chen et al. (2014) evaluated an observation-CMAQ fusion for population air pollution exposure assessment using an inverse distance weighting method on observation-CMAQ differences, concluding that data fusion improved the estimation of population-weighted average exposure concentrations. On average, $PM_{2.5}$ mass was estimated to be negatively biased by about 30%,

and individual components had a range of positive and negative biases from −150 to 100%. Nitrate and OC tended to see the largest biases and errors. After data fusion, the bias for $PM_{2.5}$ was near zero. Performance for individual components was similarly improved. Friberg et al. (2016) also fused CMAQ results to observations in a study focused on $PM_{2.5}$ exposures in Georgia. In this study, daily spatial exposure concentration fields for $PM_{2.5}$ mass, $PM_{2.5}$ components, and various gases were constructed from two blended fields. For one field, the temporal variance is driven by observations, while the spatial structure is driven by the annual mean CMAQ fields. The second field is constructed by scaling daily CMAQ simulated fields using mean observations to reduce bias. The final step blends the two fields based on using the temporal variance. The method intentionally does not force the fields to the observations at each monitor as they can be impacted by local emissions. The original CMAQ application for $PM_{2.5}$ was biased low about 12% with an RMSE of about 50% and an R^2 of 0.3. Typically, performance for individual $PM_{2.5}$ components was not as good. After applying the data fusion, the bias was almost totally removed, the RMSEs were about 20% for $PM_{2.5}$ and most PM components (though NO_3^- and EC were substantially higher), and the R^2 was about 0.92 (similar to individual components, though R^2 for EC was about 0.8). The method was tested using a 10−fold cross validation. In this case, the $PM_{2.5}$ R^2 was 0.75 and the RMSE was 30%.

Data fusion techniques have been tested in several other locations. Friberg et al. (2017) compared the fused CMAQ with original CMAQ model runs for five cities (Atlanta, GA, Birmingham, AL, Dallas, TX, Pittsburgh, PA, and St. Louis, MO) and found that the RMSE for $PM_{2.5}$ ranged from 2.21 to 3.76 μg/m^3 for the fused CMAQ, compared with 6.93 to 7.86 μg/m^3 for the original CMAQ.Huang et al. (2018) applied this method to North Carolina. In addition to doing the traditional 10-fold cross-validation, they also used spatial grouping of the 10% of monitors being removed to account for monitor clustering. In this case, the simulated $PM_{2.5}$ from the base CMAQ application had an RMSE of 6.3 μg/m^3 and an R^2 of 0.3, while after data fusion the RMSE decreased to 1.8 μg/m^3 and R^2 improved to 0.95. They also conducted 10-fold cross validation, both with and without (i.e., randomly withheld) spatial grouping. Finally, they compared the CMAQ-based data fusion fields with fields developed using a Bayesian-based method incorporating aerosol optical depth (AOD) from satellite data and found that the CMAQ-based approach performed slightly better (e.g., R^2 of 0.97 vs. 0.90 for AOD) using all of the data. The application of the same method in multiple locations shows that performance varies by domain.

Hybrid approaches can involve merging CTMs with dispersion and/or LUR models, merging CTMs with observational data, or some combination therein. Hybrid approaches improved CTM validation for $PM_{2.5}$ mass concentration when CTM was merged with either models or observational data. However, validation was not as good for $PM_{2.5}$ mass components, possibly due to the sparseness of validation data and limited data for $PM_{2.5}$ component emissions.

3.3.3 Satellite-based Methods for Exposure Concentration Estimation

At present, spatiotemporal methods for predicting exposure concentration based on satellite observations have been applied primarily to $PM_{2.5}$ using AOD information supplied by various satellite-based instruments [see Section 2.4.4 and (Lin et al., 2015; Hu et al., 2014c; van Donkelaar et al., 2014; Lee et al., 2012a; Mao et al., 2012; Liu et al., 2009)]. Satellite data (Section 2.4.5), obtained twice per day over the U.S., has been used in recent exposure assessment studies to estimate exposure concentrations in rural regions where monitoring is not conducted, to improve estimates of spatial variability in exposure concentrations, and to cover larger geographic regions. For example, Hystad et al. (2012) used a composite satellite image of AOD over the years 2001 to 2006 to estimate $PM_{2.5}$ exposure concentration across Canada, which includes urban and rural areas. The authors adjusted the satellite data by annual average $PM_{2.5}$ (or estimated $PM_{2.5}$ based on TSP measurements prior to $PM_{2.5}$ measurements, which began in 1984) and then used the study cohorts' residential locations to estimate their exposures based on their residential histories and exposure concentrations corresponding to those locations. Hystad et al. (2012) noted that incorrect assignment of exposure based on failure to account for movement between residences over time and space through this method resulted in 50% of individuals being classified in the wrong $PM_{2.5}$ exposure quintile. Prud'homme et al. (2013) computed the correlation of $PM_{2.5}$ exposure concentration predicted at a residential location with the nearest fixed-site monitor and found that the correlation decreased from $R = 0.74$ (not stated if Pearson or Spearman) when the home was within 1 km of the monitor and decreased to 0.60 for distances of 30−40 km between the home and the monitor. This result implies that the $PM_{2.5}$ exposure concentration predicted using AOD is a better predictor of exposure concentration within a given grid cell compared with exposure concentrations further away.

Errors in the relationship between $PM_{2.5}$ and AOD are related to variation in retrieval due to resolution of the satellite image and variation in meteorology, topography, and reflectance (Section 2.4.4). Hu (2009) calculated the correlation between surface $PM_{2.5}$ and AOD at 877 monitoring sites across the U.S. and found that average correlation east of the 100°W longitude line was Pearson $R = 0.67$, compared with Pearson $R = 0.22$ west of the 100°W longitude line. Negative correlations between $PM_{2.5}$ and AOD were calculated at several sites west of the 100°W longitude line but at only three locations east of the 100°W longitude line. van Donkelaar et al. (2010) also noted this discrepancy between satellite data quality in the eastern and western U.S. They used population-weighting to determine national and global estimates of exposure concentration. Population density happens to be lower in mountainous parts of the western U.S., where the highest biases in AOD were noted.

Improving the relationship between AOD and surface PM observations to estimate exposure concentrations has led to the use of more advanced statistical methods for fusion of satellite data with CTM output and surface data in recent years. Satellite-based exposure concentration models now use AOD and other information (e.g., direct pollutant observations, meteorology, and land-use). For example, van Donkelaar et al. (2012) applied a smoothed bias correction to satellite-derived $PM_{2.5}$ exposure

concentrations by first applying a 90-day moving average to the AOD prior to fitting $PM_{2.5}$ concentration estimates, and then smoothing the $PM_{2.5}$ exposure concentration field using IDW. The bias correction alone reduced the positive bias in the estimate to +29% with an estimated uncertainty of 54%. This is compared to the uncorrected $PM_{2.5}$ exposure concentration estimate, which had a bias of 97% with an estimated uncertainty of 67%. Incorporation of smoothing reduced the bias further to +14% with an uncertainty of 42%. An LUR approach to derive spatiotemporal pollutant fields accounts for the complexities in the AOD-PM relationships, including spatially and temporally varying conditions (Lee et al., 2016; Hu et al., 2014e; Ma et al., 2014; Chudnovsky et al., 2012; Hystad et al., 2011). Similar to LUR models, the approach is to develop a regression relationship between the observed $PM_{2.5}$ and AOD that includes the AOD field available from satellite observations and, potentially, other variables (e.g., those used in traditional LUR modeling). The regression coefficients can vary in time and space.

Not accounting for spatial and temporal variability in the relationship between $PM_{2.5}$ and AOD may lead to poor model performance (Hu et al., 2014d). Liu et al. (2009) recommended use of a two-stage general additive model including land use variables, with a stage one temporal model and stage two spatial model, so that the temporal and spatial variability are both addressed by the model, with an out-of-sample R^2 of 0.78, which was close to the model fit R^2 of 0.79 (stage one model-fit $R^2 = 0.77$, stage two model-fit $R^2 = 0.73$). Given the large spatial and temporal coverage of satellites, a large number of observations are typically available to develop the model. Additional spatial variation, particularly at scales finer than the resolution of the satellite observations, is provided by using fine scale land use variables. Lee et al. (2011) also recognized that the relationship between $PM_{2.5}$ and AOD is governed by time varying parameters affecting the vertical profile, the temporal variability of surface $PM_{2.5}$ over the course of a day. They developed a day-specific mixed effects model with random intercepts and slopes to quantify the relationship between surface $PM_{2.5}$ measured by surface monitors and AOD over New England in 2003. They assumed that temporal variability in properties that most strongly affect this relationship are much larger than their spatial variability over the domain of interest. In their model, the AOD fixed effect represents the average effect of AOD on $PM_{2.5}$ for all study days and the AOD random effects explain the daily variability in the $PM_{2.5}$-AOD relationship. Since some ground-based $PM_{2.5}$ monitors are located near strong sources, but Moderate Resolution Imaging Spectroradiometer (MODIS) samples represent an average over a 10 km × 10 km grid, an additional site specific random effects term is added to correct possible bias. Site specific out-of-sample R^2 varied from 0.87 to 1.0 with precision ranging from 8.8 to 38.6% for measured mean $PM_{2.5}$ at 26 urban sites (range: 9 to 19.5 $\mu g/m^3$).

Satellite observations of AOD have also been incorporated into hybrid modeling approaches. For example, Beckerman et al. (2013b) combined LUR, based on AOD observations, GEOS-Chem model output, land use data, and surface measurements of $PM_{2.5}$ concentration, with BME to predict $PM_{2.5}$ concentrations. BME was added to the model to improve spatiotemporal variability at scales smaller than the satellite's spatial resolution. Beckerman et al. (2013b) did not observe a substantial added benefit to including satellite data in an LUR model that also drew from land use data, surface measurements of $PM_{2.5}$ concentrations, and GEOS-Chem simulations. In this study, $PM_{2.5}$ concentrations were predicted

throughout the contiguous U.S. using an LUR-BME with and without satellite data. The LUR with inclusion of satellite data produced an out-of-sample R^2 of 0.27 compared with R^2 of 0.05 without inclusion of satellite data. When BME was incorporated in the LUR to interpolate between spatiotemporal residuals from the training model, out-of-sample R^2 improved to 0.79. R^2 was the same for the simulations both including and excluding satellite data. Using a similar hybrid satellite-modeling approach, Lee et al. (2012a) found that during the period 2000−2008 in the New England region of the U.S., a densely populated study domain with high traffic areas, $PM_{2.5}$ exposure concentrations were predicted with an out-of-sample R^2 value of 0.83 and a mean relative error of 3.5%. Chang et al. (2014) describe a statistical downscaling approach that incorporates LUR models utilizing AOD and statistical techniques for combining air quality data sets that have different spatial resolutions. In cross-validation experiments for a 3-year time period over the southeastern U.S., the model performed well (out-of-sample $R^2 = 0.78$ and RMSE = 3.61 μg/m^3 between observed and predicted daily $PM_{2.5}$ concentrations), with a 10% decrease in RMSE attributed to the use of AOD as a predictor. Validation of hybrid models has been inconsistent across studies.

Recent studies have tested the effect of satellite image resolution on $PM_{2.5}$ mass concentration predictions. Hu et al. (2014c), using a two-stage model, compared the more traditional MODIS AOD at 10 km resolution with a Multiangle Implementation of Atmospheric Correction (MAIAC) algorithm at 1 km in the Southeastern U.S. and found that, when using 10-fold cross-validation, the out-of-sample R^2 was slightly lower for the 1 km MAIAC observations (0.67 vs. 0.69), though the R^2 for model fitting was the same (0.83). This can be contrasted against Chudnovsky et al. (2013), discussed in Section 2.4.4 Alexeeff et al. (2015) also used the 1 km MAIAC fields to estimate exposure concentration fields, comparing their results to fields developed using kriging. They found that using the MAIAC-based fields had a higher cross-validation than kriging, and that the low out-of-sample R^2 yielded biases in areas with lower covariance in the concentration field. Lv et al. (2016) used MODIS AOD and a statistical method similar to Chang et al. (2014) in an application in China. It is discussed here in terms of how the evaluation was performed. Using all data (no withholding), the R^2 was 0.78 and the normalized mean error was 0.27. When they used a random leave 10% out procedure, the method led to an R^2, normalized mean error (NME) and RMSE of 0.68, 0.26 and 21.40 μg/m^3, respectively (like $PM_{2.5}$ concentrations, RMSE is much higher in China than in the U.S.). Using a process where monitors were removed after being grouped by city led to somewhat worse performance: 0.61, 0.28 and 23.53 μg/m^3, respectively. This suggests that method and application evaluations should use cross-validation methods that consider spatial groupings of monitors as a more stringent evaluation approach.

Recent efforts have fused satellite data with LUR model results and surface observations to maximize available data for estimation of exposure concentrations. Kloog et al. (2011) built a three-stage regression model using surface measurements as the response variable and including MODIS-derived AOD, land use variables, and a daily calibration $PM_{2.5}$ concentration from surface measurements to estimate $PM_{2.5}$ exposure concentration on a 1 km × 1 km grid across New England, and Kloog et al. (2012a) extended the model across the Mid-Atlantic states. When AOD was available, the

cross-validation out-of-sample R^2 was 0.83 for New England and 0.87 for the Mid-Atlantic states; when AOD was unavailable, cross-validation out-of-sample R^2 was still 0.81 for New England and 0.85 for the Mid-Atlantic states. When running the model for the two regions combined, Kloog et al. (2012b) found cross-validation out-of-sample R^2 was 0.81 for the total model of $PM_{2.5}$ and 0.81 for the LUR stage of the model. Kloog et al. (2014) built upon this method by first calibrating the AOD on daily measurements of $PM_{2.5}$ and adjusting for land use and meteorological variables for the Northeastern U.S. (New Jersey to Maine) for 2003−2011. Where AOD data were available, this model was used to predict $PM_{2.5}$ exposure concentration. The second model used the AOD−$PM_{2.5}$ calibration to predict AOD, which was then input into the regression model for a 1 km × 1 km grid. Finally, a 200 m × 200 m resolution prediction was developed by taking the residuals at each monitoring site and regressing them against the fine-scale resolution predictors to estimate fine-scale $PM_{2.5}$ exposure concentration. The models were built separately for temporal and spatial variables, and each had an average cross-validation out-of-sample $R^2 = 0.87$.

Similar to BME, machine learning approaches can be used to merge satellite observations with land use and other data for prediction of $PM_{2.5}$ mass concentration. For example, Reid et al. (2015) used a machine learning approach to estimate spatiotemporal $PM_{2.5}$ exposure concentration fields over the central region of California during a period of wildfires in the region by building spatiotemporal models using 11 model types from a set of 29 independent variables and selecting the optimal one for each model type. Input data included $PM_{2.5}$ and meteorological predictions from a CTM (WRF-Chem), land use data, and satellite AOD observations [three sets: the Geostationary Operational Environmental Satellite West Aerosol/Smoke Product (GASP) with a resolution of 4 km, the MODIS AOD product with a resolution of 10 km, and a local AOD product developed from MODIS data at a 500 m resolution, $PM_{2.5}$ and meteorological predictions from WRF-Chem, land use data, and distance to the nearest fire cluster]. The data were put in to each of the methods to develop a best model. Ten-fold cross-validation out-of-sample R^2 ranged from 0.387 to 0.803, and RMSE ranged from 1.49 μg/m^3 to 2.03 μg/m^3. It was found that similar model performance (within 1.5% of the RMSE) was achieved using only 13 variables, compared with a model of all 29 variables, with highest out-of-sample R^2 and lowest RMSE. They found that the variable most correlated with the $PM_{2.5}$ observations was the GASP followed by the distance to nearest active fire cluster, then the local AOD product and WRF-Chem $PM_{2.5}$ contributed equally. Di et al. (2016a) used a similar approach for a model of $PM_{2.5}$ exposure concentration across the contiguous U.S. GEOS-Chem simulation results were merged with satellite data for AOD, surface reflectance, and aerosol absorbance index, as well as with surface data from monitors reporting to AQS and data for meteorology and land use. For 2000−2012, out-of-sample $R^2 = 0.84$ with RMSE of 2.94 μg/m^3. The relationship between predicted and measured $PM_{2.5}$ concentrations was approximately linear until measured $PM_{2.5}$ concentrations were above approximately 60 μg/m^3. At that point, the predictions were insensitive to measured $PM_{2.5}$, but limited $PM_{2.5}$ concentration data were available above concentrations of 60 μg/m^3. These studies illustrate that the most important variables change, depending on the scenario modeled and the specific variables included.

Several other studies have devised novel methods to fuse observational data and results from models for estimation of exposure concentrations. Pirani et al. (2014) performed Bayesian spatiotemporal modeling for the assessment of short-term exposure to PM_{10} in London, U.K. using mass concentration measurements and output from the high spatial resolution air dispersion modeling system. They found exposure concentration estimates in urban areas are improved by including city-scale particle component and long-range transport component with covariates to account for residual spatiotemporal variation. Crooks and Isakov (2013) developed a novel method using wavelets to blend CMAQ, AERMOD, and observation fields to capture intra-urban transport of pollutants across a spectrum of spatial scales. They used it to estimate block group and zip code centroid exposure concentrations in Atlanta, GA and found that it captured the concentrations down to scales on the order of 100 m.

Several studies using AOD observations to predict $PM_{2.5}$ have been published in recent years. Progress in this approach includes incorporation of AOD with LUR, BME, and geostatistical modeling approaches that also may include surface measurements. Most applications of these hybrid models were designed to make comparisons across space for long-term exposure studies, where the temporal averages were more stable than for short-term exposure studies. Still, validation results across these studies were inconsistent, so attention must be given to the strengths and limitations of individual exposure models and their appropriateness for a given scenario (e.g., urban vs. rural, where monitoring for use in model training and validation may be sparse in the latter case) rather than assuming that the predicted $PM_{2.5}$ exposure concentration is accurate if it includes satellite data.

3.3.4 Microenvironmental Exposure Modeling

Indoor air exposures to total PM may be measured directly or estimated based on infiltration rates that typically use some level of mass balance model, potentially with chemistry, deposition, and other processes that can affect individual exposure. Inputs to indoor air mass balance models include ambient PM concentrations (observed or estimated), air exchange rates, indoor source emissions, and other factors that can affect the dynamics of pollutants. Such indoor air models are included in integrated exposure models (such as U.S. EPA's Stochastic Human Exposure and Dose Simulation [SHEDS] and Air Pollutants Exposure [APEX] models) or individual models (such as the Exposure Model for Individuals [EMI]), that also incorporate factors such as human activity patterns (Baxter et al., 2013). In Baxter et al. (2013), mean $PM_{2.5}$ exposure estimates obtained from models that considered time spent indoors and indoor-outdoor air exchange rates with no indoor sources were approximately half of the concentrations from ambient monitor measurements.

Personal exposure occurs in multiple microenvironments that people encounter through their daily activities (e.g., indoors, outdoors, in vehicles). Methods have been developed to simulate potential total exposures through such environments by tracking "representatives" of population groups as they move between indoor and outdoor microenvironments, using estimated pollutant concentrations in each

location to develop a time-weighted exposure profile for that population group. How individuals "move" though the different microenvironments is taken from studies of personal activity data [e.g., the Consolidated Human Activity Database, or CHAD (Isaacs, 2014)]. This database has information on sequential patterns of individual activities. This allows simulating not only "average" individual exposures, but also the distribution of exposures for different individuals or population groups over time.

Residential air exchange rate (AER) is a critical parameter for exposure models, such as APEX, SHEDS, and EMI (Breen et al., 2015; U.S. EPA, 2011, 2009a; Burke et al., 2001), with people spending the majority of their time indoors (Section 3.4.2.1). Since the appropriate AER measurements may not be available for exposure models, mechanistic, and empirical (i.e., regression-based) AER models can be used for exposure assessments. Empirical AER models do not consider the driving forces from the wind and indoor-outdoor temperature differences. Instead, a scaling constant can be used based on factors such as building age and floor area (Chan et al., 2005). Single-zone mechanistic models, such as the Lawrence Berkeley Laboratory (LBL) model, represent a building as a single well-mixed volume(Breen et al., 2010; Sherman and McWilliams, 2007; Sherman and Grimsrud, 1980). Recently, the LBL air infiltration model was linked with a leakage area model using population-level census and residential survey data (Sherman and McWilliams, 2007) and individual-level questionnaire data (Breen et al., 2010). Variations on the LBL model were compared with daily AER measurements in North Carolina (Breen et al., 2010) to find mean absolute differences of 40−43%.

The Hazardous Air Pollutant Exposure Model (HAPEM, now Version 6) is a screening level approach for modeling long-term inhalation exposures to ambient air pollutants, including PM. It can take modeled ambient pollutant concentrations as inputs or can use a parameterization of National Air Toxics Assessment (NATA)-generated PM estimates based on the near-road and far-from-road census tract populations (Rosenbaum and Huang, 2007). To develop exposure concentration estimates in microenvironments (e.g., commuting), microenvironmental factors are used to modify outdoor concentrations (e.g., provided by developing ambient exposure concentration fields). HAPEM has been used for nationwide assessments of exposure to sources of specific PM components and other pollutants (Ozkaynak et al., 2008) and, as noted above, coupled with a CMAQ/AERMOD combination (Isakov et al., 2009).

The SHEDS model and APEX model (which is now part of the Total Risk Integrated Methodology, or TRIM-Expo) both simulate individual movements though multiple microenvironments. APEX uses either a mass balance approach or a ratio to estimate in-vehicle or indoor concentrations (Che et al., 2015). Differences in subpopulation sampling methods between APEX and SHEDS produce small differences in predictions for population exposure concentrations (12.2 vs. 12.9 $\mu g/m^3$, respectively). SHEDS includes an activity-dependent ventilation rate to estimate dose. SHEDS-PM (the PM version of SHEDS) has a linear relationship between ambient concentrations and in-vehicle concentrations as well as in offices, restaurants/bars, schools, and stores. When analyzing contributions to exposure based on application of SHEDS-PM with daily $PM_{2.5}$ from CMAQ, Jiao et al. (2012) found that spatial variability

of ambient concentrations within urban areas was not substantial, but inter-individual variability in estimated exposures was substantial. Daily estimates of the ratio of ambient exposure to ambient concentration differed by a factor of 4−5 across the simulated individuals. SHEDS uses time-activity data from the CHAD database. Jiao et al. (2012) noted that there were not sufficient data in the CHAD database to quantify how time-activity patterns varied as a function of sex, region, or season when limited to the three areas studied, although statistically significant differences in time spent indoors or time spent outdoors by sex, region, and season were seen for CHAD data aggregated across large geographic regions. Liu and Frey (2011) proposed a method to estimate in-vehicle $PM_{2.5}$ exposure concentrations that combines using ambient concentrations and a local incremental concentration that accounts for near road enhancements in lieu of assuming a linear relationship between $PM_{2.5}$ concentration measured at fixed-site monitors and exposure concentrations estimated on the road using the CALINE4 dispersion model. Liu and Frey (2011) found that in-vehicle exposures contribute 10−20% of average daily $PM_{2.5}$ exposures. Georgopoulos et al. (2009) linked SHEDS with an environmental risk model (MENTOR) to estimate exposures (and the related risks) for $PM_{2.5}$ in Philadelphia, using a CTM to provide the $PM_{2.5}$ field. For those individuals with the highest 5% of $PM_{2.5}$ exposures, the major microenvironment was indoors, and environmental tobacco smoke was the dominant source. Ozkaynak et al. (2009) evaluated the uncertainty inherent in the coupled model formulation and compared it with a "crude" estimation of uncertainty when the models are run separately and with CMAQ outputs being used for SHEDS inputs. Uncertainty for the crude method was 1.2−4.4 times higher than for the coupled formulation.

The EMI model simulates individual exposure to $PM_{2.5}$ as the aggregate of exposures in multiple microenvironments (Breen et al., 2015). The EMI uses a five-tier system to model individual exposures. AER is predicted in Tier 1 based on surveys and variations on the LBL model for each microenvironment. Infiltration factors are predicted in Tier 2, and those values are used to predict outdoor concentrations infiltrated indoors measured immediately outside each microenvironment and measured at fixed-site monitors in Tier 3. A weighted average of the infiltration factor over time spent in different microenvironments is produced for each individual in Tier 4, and then personal exposures to pollution from directly outside the microenvironment and from the fixed-site concentration measurement are computed in Tier 5 for each individual. Personal monitoring and time-activity surveys are necessary inputs for the EMI. The Tier 2−5 metrics were observed to have approximately 15−25% error (Breen et al., 2018; Breen et al., 2015).

The trade-off between computational accuracy and efficiency in exposure and risk models has received limited discussion in the exposure model literature. Chang et al. (2012) described a simulation process incorporating SHEDS exposure simulation into two risk models: an "exposure simulator" in which an exposure time series was simulated stochastically and then incorporated into an ensemble average risk, and a two-stage "Bayesian" approach in which the computed time series was used as a prior in an exposure model. Risk of mortality (CHAPTER 11) associated with short-term $PM_{2.5}$ exposure was estimated using the exposure simulator model, the Bayesian model, and fixed-site $PM_{2.5}$ concentration as

an exposure surrogate. Little difference was observed between the exposure simulator and Bayesian models, but the exposure simulator was less computationally intensive.

3.3.5 Exposure Assignment Methods in Epidemiologic Studies

Epidemiologic studies use a variety of methods to assign exposures or exposure concentrations to study participants. Study design, data availability, and research objectives are all important factors for epidemiologists when selecting an exposure or exposure concentration estimation method. Common methods for estimating exposure concentrations from monitoring data include using fixed-site ambient monitoring, averaging concentrations from multiple monitors, and selecting the closest monitor to represent population exposure concentration. Investigators may also use statistical adjustment methods, such as trimming extreme values, to prepare the exposure concentration data set. Alternatively, modeling approaches described in Section 3.2.2 (modeling) can be used to estimate more spatially or temporally resolved exposure concentrations when data and resources are available.

Comparison studies have illustrated differences among the methods for producing estimates of exposure concentrations. For example, Dionisio et al. (2013) simulated $PM_{2.5}$ mass concentration, $PM_{2.5-EC}$, and $PM_{2.5}$–SO_4^{2-} exposures or exposure concentrations using different methods including a fixed-site monitor, an AERMOD model, a hybrid model combining regional background estimates with local contributions by AERMOD, and the SHEDS exposure model. The methods differed more with respect to modeling spatial variability (as measured by coefficient of variation) compared with temporal variability, with spatial variability being greater for the AERMOD and hybrid approaches for all three pollutants. Temporal variability was similar across methods for $PM_{2.5}$ and SO_4^{2-} with some difference across methods for EC. Mannshardt et al. (2013) compared use of fixed-site monitor concentration data, exposure concentrations estimated by CMAQ output, and exposures calculated using SHEDS to study respiratory emergency department visits associated with $PM_{2.5}$ exposure in New York County, NY, Queens, NY, and Bronx, NY. They found that the use of the SHEDS model led to a very similar relative risk as using CMAQ but provided additional information that helped reduce uncertainty. The effect estimates associated with exposure modeled by SHEDS and exposure concentration modeled by CMAQ were both higher and more precise than the effect estimate obtained from using fixed-site data as an estimate for exposure concentration. However, Mcguinn et al. (2017) estimated $PM_{2.5}$ exposure concentration and risks of coronary artery disease and myocardial infarction using a fixed-site monitor, CMAQ run with a census tract-level downscaler and with data fusion at 12 km resolution, and a satellite at 1 km and 10 km resolution. They did not find a relationship of model resolution with exposure concentration or with the magnitude of the effect estimates or with precision of the effect estimate for either health outcome studied.

Additional studies have also explored the effect of using different spatial averaging techniques to handle exposure concentration estimates from fixed-site monitoring data. Goldman et al. (2012) and

Strickland et al. (2013) compared exposure concentration estimates for $PM_{2.5}$, PM_{10}, SO_4^{2-}, NO_3^-, NH_4^+, EC, and OC among different methods, including fixed-site monitors, population-weighted averages of the (1) fixed-site monitors, (2) unweighted averages, (3) population-weighted averages, (4) area averages, and (5) a spatiotemporal model that used the pollutants' spatial and temporal autocorrelation structures to estimate exposure concentrations. Taking the spatiotemporal model as a reference, Goldman et al. (2012) found the fixed-site monitor had greater bias in the exposure metric compared with the averaging methods, and that bias increased for more-spatially-variable EC and OC compared with $PM_{2.5}$. These comparisons highlight differences among the methods in their ability to capture variability of exposures or exposure concentrations among study participants. The importance of capturing such variability also depends on the variability of the PM size cut or components.

Comparison of exposure concentration surfaces involving satellite observations have focused on spatial resolutions appropriate for different exposure concentration estimation techniques. Lee et al. (2012b) compared the appropriate averaging distance ranges for $PM_{2.5}$ exposure concentration surfaces estimated using satellite detection and kriging with $PM_{2.5}$ concentration measurements from fixed-site monitors using 6 years of data. Lee et al. (2012b) compared the kriged or remotely sensed data with the surface measurements over distances ranging from 7.6 km to 106.0 km using mean squared error (MSE), mean error, mean absolute error (MAE), Pearson correlation, and Spearman correlation. Lee et al. (2012b) estimated that kriging provided superior exposure concentration estimates when distances from the kriged estimate to the fixed-site monitor were smaller than 98 km while satellite detection provided superior exposure concentration estimates when distances from the remotely-sensed concentration centroid to the fixed-site monitor exceeded 98 km. Jerrett et al. (2016) compared remotely sensed $PM_{2.5}$ exposure concentration surfaces estimated from input by three satellite systems, downscaled CMAQ exposure concentration estimates, a spatiotemporal exposure concentration surface, a LUR model, and a combined LUR-kriging model. The mean and median $PM_{2.5}$ exposure concentrations were similar across methods (range of means: 11.4 to 12.2 $\mu g/m^3$), but the LUR models and one spatiotemporal model (geographically-weighted regression) produced higher variability than the other methods (IQRs range from 3.6 to 5.7 $\mu g/m^3$).

Epidemiologic study design influences the relevance and utility of exposure concentration estimation methods. Methods with high temporal resolution are preferable for short-term exposure studies even if spatial resolution is low, assuming the temporal variability at the site of data collection does not vary substantially across the study area. Fixed-site monitors, with temporal variability matching that of the health dataset, may be appropriate for this case, especially for $PM_{2.5}$ concentration, which tends to be less spatially variable than concentrations of $PM_{10-2.5}$ or UFP. Methods with high spatial resolution are preferable for long-term exposure studies where spatial contrasts are important. Methods that merge data from several sources, such as hybrid methods drawing from a combination of land use variables, satellite observations, CTM model output, and surface measurements, are designed to produce more spatial variability in the PM concentration surface. However, satellite data and CTM model output are not as readily available for $PM_{10-2.5}$ and UFP as they are for $PM_{2.5}$. Table 3-5 summarizes various exposure

concentration estimation methods used in PM epidemiologic studies, appropriate applications, and associated errors and uncertainties. In general, the methods listed in Table 3-5 that model spatial variability more accurately are often used in studies of health effects from long-term PM exposure, because uncertainties in spatial variability will have more of an influence on effect estimates from long-term exposure studies. Similarly, the methods that capture temporal variability are typically used in short-term PM exposure studies, because uncertainties in temporal variability will have more of an influence on effect estimates from short-term exposure studies.

Table 3-5 Summary of exposure or exposure concentration estimation methods, their typical use in PM epidemiologic studies, and related errors and uncertainties.

Exposure Concentration Assignment Method	Description	Epidemiologic Application	Strengths	Limitations	Exposure Errors
Measurement Methods					
Fixed-site monitor [Section 3.3.1.1; Section 2.4.1; U.S. EPA (2009b)]	Typically, the nearest monitor to a receptor location; monitor type varies with particle size: $PM_{2.5}$: A FRM or FEM monitor located at a fixed location to measure ambient PM concentration; $PM_{10-2.5}$: A dichotomous FRM or FEM monitor located at a fixed location to measure ambient PM concentration, collocated PM_{10} and $PM_{2.5}$ monitors used to calculate concentrations by differencing for a given location, or non-collocated PM_{10} and $PM_{2.5}$ monitors used to calculate concentrations by differencing across a city or county; UFP: typically, a CPC to measure particle number concentration.	Short-term exposure studies: surrogate for ambient PM exposure concentration of a population within a city. Long-term exposure studies: surrogate for ambient PM exposure concentration to compare populations within a city or among multiple cities.	Ambient PM concentration measurements undergo rigorous quality assurance	Non-FRM and non-FEM optical instruments cannot be calibrated to ambient conditions, based on differences in size distributions and composition of calibration particles (e.g., Arizona road dust) and ambient PM; measurements of ambient PM concentration made at a fixed location may differ from an exposed individual's true exposure concentration, and no spatial variation is assumed; smaller particles (e.g., UFP) are more susceptible to evaporative losses.	Correlation between outdoor PM concentrations proximal to the receptors and ambient PM concentration measurements typically decreases with increasing distance from the monitor, especially for $PM_{10-2.5}$ and UFP, potentially leading simultaneously to decreased precision and to bias towards the null, as increased noise drives the slope towards zero; errors in $PM_{10-2.5}$ concentrations related to different flow rates used in PM_{10} and $PM_{2.5}$ monitors for the differencing methods; errors in $PM_{10-2.5}$ concentrations due to differences in locations of PM_{10} and $PM_{2.5}$ monitors when the instruments are not collocated. Potential for bias if ambient PM concentration at a receptor location is higher or lower than the ambient PM concentration measured at the monitor, especially for $PM_{10-2.5}$ and UFP; potential for imprecision from assumption of constant PM concentration within some radius of the monitor, especially for $PM_{10-2.5}$ and UFP; errors in $PM_{10-2.5}$ concentrations related to different flow rates used in PM_{10} and $PM_{2.5}$ monitors for the differencing methods; errors in $PM_{10-2.5}$ concentrations due to differences in locations of PM_{10} and $PM_{2.5}$ monitors when the instruments are not collocated.

Table 3-5 (Continued): Summary of exposure or exposure concentration estimation methods, their typical use in PM epidemiologic studies, and related errors and uncertainties.

Exposure Concentration Assignment Method	Description	Epidemiologic Application	Strengths	Limitations	Exposure Errors
Microenvironmental monitor (Section 3.3.1.2)	Typically located in an outdoor or indoor microenvironment to measure ambient PM concentration; $PM_{2.5}$: A FRM or FEM monitor located at a fixed location to measure ambient PM concentration; $PM_{10-2.5}$: A dichotomous FRM or FEM monitor located at a fixed location to measure ambient PM concentration, or collocated PM_{10} and $PM_{2.5}$ monitors used to calculate concentrations by differencing for a given location; UFP: typically, a CPC to measure particle number concentration	Panel studies: PM exposure (e.g., personal or residential samples) within a geographic area	Ambient PM concentration measurements undergo rigorous quality assurance	Non-FRM and non-FEM optical instruments cannot be calibrated to ambient conditions, based on differences in size distributions and composition of calibration particles (e.g., Arizona road dust) and ambient PM; instrument expense may make it difficult to perform sampling simultaneously in multiple environments.	Nonambient PM exposure sampling may lead to bias if appropriate statistical methods are not used for handling biased data.

Table 3-5 (Continued): Summary of exposure or exposure concentration estimation methods, their typical use in PM epidemiologic studies, and related errors and uncertainties.

Exposure Concentration Assignment Method	Description	Epidemiologic Application	Strengths	Limitations	Exposure Errors
Active personal exposure monitor (Section 3.3.1.2)	Air is pulled through a pump and sampled for ambient PM concentration; $PM_{2.5}$ or $PM_{10-2.5}$: air is typically directed through a collection filter on an impaction plate or past an optical detector; upstream hardware (e.g., cyclone) may be used for separating PM by specific size fractions; UFP: typically, a CPC to measure particle number concentration; for BC, PM is typically measured with an aethalometer.	Panel studies: PM exposure (e.g., personal or residential samples) within a geographic area	PM and/or BC concentrations are obtained at the site of the exposed person	Non-FRM and non-FEM optical instruments cannot be calibrated to ambient conditions, based on differences in size distributions and composition of calibration particles (e.g., Arizona road dust) and ambient PM; some monitors can detect a minimum particle size of 0.1 µm and a few others can detect 0.25 µm, but the majority detect over the entire fine PM range; many monitors are noisy.	Nonambient PM exposure sampling may lead to bias if appropriate statistical methods are not used for handling biased data.
Passive personal exposure monitor (Section 3.3.1.2)	PM is captured on a treated substrate via passive exposure for a time period to measure a personal or area sample, and the substrate is analyzed by SEM; concentration is calculated based on a model of passive diffusion flux for $PM_{2.5}$, $PM_{10-2.5}$, or UFP.	Panel studies: ambient PM exposure within a city or among multiple cities	PM concentrations are obtained at the site of the exposed person	Long duration integrated sampling time (e.g., 7 days) does not allow for time-series analysis; diffusion-related losses to the passive sampler hardware have the potential to bias the concentration estimation based both on reduced particle counts and overestimation of flux to the sampling substrate.	Nonambient PM exposure sampling may lead to bias.

Table 3-5 (Continued): Summary of exposure or exposure concentration estimation methods, their typical use in PM epidemiologic studies, and related errors and uncertainties.

Exposure Concentration Assignment Method	Description	Epidemiologic Application	Strengths	Limitations	Exposure Errors
Modeling Methods					
Data averaging (Section 3.3.2.1)	Averaging across multiple monitors during the same time window and within a geographical area such as a city or county, typically using fixed-site monitoring data	Short-term exposure studies: surrogate for ambient PM exposure concentration of a population within a city	Ambient PM concentration measurements undergo rigorous quality assurance; averaging scheme designed for population or trend of interest	Non-FRM and non-FEM optical instruments cannot be calibrated to ambient conditions, based on differences in size distributions and composition of calibration particles (e.g., Arizona road dust) and ambient PM; measurements of ambient PM concentration made at a fixed location may differ from an exposed individual's true exposure concentration, and spatial variation is assumed to be well-represented by the averaging scheme.	Correlation between outdoor PM concentrations proximal to the receptors and ambient PM concentration measurements typically decreases with increasing distance from the monitor, especially for $PM_{10-2.5}$ and UFP, potentially leading simultaneously to decreased precision and to bias towards the null, as increased noise drives the slope towards zero.
	Spatial averaging (area averaging, population-weighted averaging), typically using fixed-site monitoring data	Long-term exposure studies: surrogate for ambient PM exposure concentration, usually within a city or geographic region			Potential for bias if ambient PM concentration at a receptor location is higher or lower than the spatial average, especially for $PM_{10-2.5}$ and UFP; potential for imprecision from assumption of constant PM concentration within some geographic area, especially for $PM_{10-2.5}$ and UFP.

Table 3-5 (Continued): Summary of exposure or exposure concentration estimation methods, their typical use in PM epidemiologic studies, and related errors and uncertainties.

Exposure Concentration Assignment Method	Description	Epidemiologic Application	Strengths	Limitations	Exposure Errors
Inverse distance weighting (Section 3.3.2.2)	Measured ambient PM concentrations are interpolated to estimate ambient PM concentration surfaces across regions; IDW uses an inverse function of distance to monitors	Long-term exposure studies: surrogate for ambient PM exposure concentration, usually within a city or geographic region	High spatial resolution	Over-smoothing based on assumption that ambient PM concentration is constant for a given distance from the source or based on smoothing function between monitors (which is more of an issue for $PM_{10-2.5}$ and UFP).	Potential for negative bias if ambient PM sources are not captured or PM concentration is overly smoothed; potential for positive bias if PM deposition or other loss processes; potential for imprecision from overly smoothed PM concentration.
Kriging (Section 3.3.2.2)	Measured ambient PM concentrations are interpolated to estimate ambient PM concentration surfaces across regions	Long-term exposure studies: surrogate for ambient PM exposure concentration, usually within a city or geographic region	High spatial resolution	Over-smoothing is possible based on smoothing function between monitors (which is more of an issue for $PM_{10-2.5}$ and UFP).	Potential for negative bias if ambient PM sources are not captured or PM concentration is overly smoothed; potential for positive bias if PM deposition or other loss processes; potential for imprecision from overly smoothed PM concentration.
Land use regression (Section 3.3.2.3)	Measured ambient PM concentrations are regressed on local variables (e.g., land use factors); the resulting model is used to estimate ambient PM concentrations at specific locations	Long-term exposure studies: surrogate for ambient PM exposure concentration, usually across a city but sometimes among multiple cities	High spatial resolution	Does not account for emission rates, dispersion, or atmospheric chemistry and may account for meteorology only in terms of wind speed and wind direction, depending on model formulation; has limited generalizability to other locations; uncertainties are highest where training monitors are sparse.	Potential for bias if grid is not finely resolved, if the model is misspecified, or if the model is applied to a location different from where the model was fit.

Table 3-5 (Continued): Summary of exposure or exposure concentration estimation methods, their typical use in PM epidemiologic studies, and related errors and uncertainties.

Exposure Concentration Assignment Method	Description	Epidemiologic Application	Strengths	Limitations	Exposure Errors
Spatiotemporal model (Section 3.3.2.3)	Measured ambient PM concentrations are modeled by a spatial average, spatially-varying covariates, and a spatiotemporal residual; the resulting model is used to estimate ambient PM concentrations at specific locations	Short-term and long-term exposure studies: surrogate for ambient PM exposure concentration, usually across a city but sometimes among multiple cities	High spatial resolution	Does not account for emission rates, dispersion, or atmospheric chemistry and may account for meteorology only in terms of wind speed and wind direction, depending on model formulation; has limited generalizability to other locations; uncertainties are highest where training monitors are sparse.	Potential for bias if grid is not finely resolved, if the model is misspecified, or if the model is applied to a location different from where the model was fit.
Chemical transport model (Section 3.3.2.4.1)	Grid-based ambient PM concentrations are estimated from emissions, meteorology, and atmospheric chemistry and physics	Short-term and long-term exposure studies: surrogate for ambient PM exposure concentration, sometimes within a city but more typically across a larger region	Strengths include accounting for emission rates, mixing height, atmospheric stability, meteorology, atmospheric chemistry, and complex terrain	Limited grid cell resolution (i.e., grid cell length scale is typically 4−36 km); spatial smoothing of local PM emissions sources; UFP not typically modeled; temporal emission allocations (e.g., by hour of weekday, by month, etc.) are generally the same over time.	Potential for bias when grid cells are too large to capture spatial variability of ambient PM exposures, especially for $PM_{10-2.5}$; bias in PM mass concentration and PM components related to underestimation of BC and OC.
Dispersion model (Section 3.3.2.4.2)	Ambient PM concentrations at specific locations are estimated from emissions, meteorology, and atmospheric physics	Short-term and long-term exposure studies: surrogate for ambient PM exposure concentration within a city or geographic region	High spatial and temporal resolution, accounts for atmospheric physics from local emission sources	Very limited representation of atmospheric chemistry or background PM concentrations; input emissions data are sometimes not available (e.g., roads where vehicle counts are not measured).	Potential for bias where the dispersion model does not capture boundary conditions and resulting fluid dynamics well (e.g., in large cities with urban topography affecting dispersion).

Table 3-5 (Continued): Summary of exposure or exposure concentration estimation methods, their typical use in PM epidemiologic studies, and related errors and uncertainties.

Exposure Concentration Assignment Method	Description	Epidemiologic Application	Strengths	Limitations	Exposure Errors
Hybrid approaches (Section 3.3.2.4.3)	Grid-based ambient PM concentrations are estimated from emissions, meteorology, and atmospheric chemistry and physics and bias corrected based on monitoring data	Short-term and long-term exposure studies: surrogate for ambient PM exposure concentration, sometimes within a city but more typically across a larger region	Strengths include accounting for emission rates, mixing height, atmospheric stability, meteorology, atmospheric chemistry, and complex terrain; bias correction improves model results, particularly where biases are large	Limited grid cell resolution (i.e., grid cell length scale is typically 4−36 km); resource-intensive; spatial smoothing of local PM emissions sources; UFP not typically modeled.	Although there is the potential for bias when grid cells are too large to capture spatial variability of ambient PM exposures (especially for $PM_{10-2.5}$; bias in PM mass concentration and PM components related to underestimation of BC and OC), fusing model results with monitoring data helps to minimize exposure errors.
Microenvironmental modeling [e.g., APEX, SHEDS (Section 3.3.4)]	Estimates distributions of micro-environmental PM concentrations, exposures, and doses for populations (e.g., census tracts) based on air quality data, demographic variables, and activity patterns	Short-term and long-term exposure studies; panel studies	Accounts for variability of PM exposures across large populations, accounts for different concentrations in different microenvironments, accounts for location-activity information	Models simulate individuals and their exposures; they do not model actual individuals but simulated representative individuals based on the population being modeled.	Potential for bias when the modeled distributions of ambient PM concentration, indoor:outdoor pollutant ratios, and time-activity patterns differ from the true distributions.

Table 3-5 (Continued): Summary of exposure or exposure concentration estimation methods, their typical use in PM epidemiologic studies, and related errors and uncertainties.

Exposure Concentration Assignment Method	Description	Epidemiologic Application	Strengths	Limitations	Exposure Errors
Satellite-based methods (Section 3.3.3)	Grid-based ambient PM concentrations are estimated from emissions, meteorology, and atmospheric chemistry and physics and bias corrected based on satellite data	Long-term exposure studies: surrogate for ambient PM exposure concentration, sometimes within a city but more typically across a larger region	Strengths include bias correction improves model results, particularly where biases are large	Limited temporal resolution (i.e., based on a daily observation); assume AOD is representative of ground-level $PM_{2.5}$ concentrations; algorithms converting AOD observations to $PM_{2.5}$ concentrations vary regionally; limited grid cell resolution (i.e., grid cell length scale is typically 1−36 km); spatial smoothing of local PM emissions sources; $PM_{10-2.5}$ and UFP not typically modeled.	Although there is the potential for bias when grid cells are too large to capture spatial variability of ambient PM exposures (especially for $PM_{10-2.5}$; bias in PM mass concentration and PM components related to underestimation of BC and OC), fusing model results with satellite data helps to minimize exposure errors.

APEX = air pollutants exposure model; BC = black carbon; CPC = condensation particle counter; FEM = federal equivalent method; FRM = federal reference method; IDW = inverse distance weighting; SHEDS = stochastic human exposure and dose simulation; PM = particulate matter $PM_{2.5}$ = PM with a 50% cut point at 2.5 µm; $PM_{10-2.5}$ = PM fraction captured between 50% cut points of 10 µm and 2.5 µm; SEM = scanning electron microscopy; UFP = ultrafine PM.

3.4 Exposure Assessment and Interpretation of Epidemiologic Study Results

The exposure assignment methods discussed in Section 3.3 inform different PM-health relationships, depending on the method chosen. These relationships include those between ambient concentration and health effects, between exposure concentration and health effects, and between ambient exposure and health effects. The ambient exposure-health relationship is the main relationship of interest for the causal determinations in the ISA, and it can be evaluated using personal monitors, microenvironmental models, or ambient concentration as a surrogate for exposure (Table 3-5). Methods that estimate local exposure concentration, including spatial averaging, LUR, and emissions/transport models inform the exposure concentration-health relationship. Ambient concentration measured at an ambient monitor can be used directly to inform the ambient concentration-health relationship.

The following sections review the available literature to explore how the selection of an exposure metric may influence these relationships. The following discussion focuses on the relationships influencing exposure, such as those between ambient PM concentration and exposure to ambient PM (Section 3.4.1), factors contributing to error in estimating exposure to ambient PM (Section 3.4.2), and the influence of exposure errors on epidemiologic study results (Section 3.4.4). Additionally, this section explores copollutant relationships that may influence interpretation of the health effect estimates for ambient PM exposures (Section 3.4.3).

3.4.1 Relationships Influencing Exposure

This section builds upon discussions from the 2009 PM ISA (U.S. EPA, 2009b) about relationships between ambient PM measured outdoors, ambient PM infiltrating indoors, and resulting relationships between indoor and outdoor ambient PM concentrations and between personal exposure to ambient PM and ambient PM concentration. Summaries of relevant discussions from the 2009 PM ISA are included in Section 3.4.1.1, Section 3.4.1.2, and Section 3.4.1.3.

3.4.1.1 Air Exchange Rate and Infiltration

When concentrations measured at an ambient monitor are used as a surrogate for $PM_{2.5}$, $PM_{10-2.5}$, or UFP exposure, the metric does not account for reduction in exposure concentration related to the process of infiltration indoors. The 2009 PM ISA (U.S. EPA, 2009b) describes how air exchange rate (AER) can influence the infiltration of PM into the building envelope. AER is the airflow into and out of a building and is represented by a in the conceptual model presented in Section 3.2.2. Several factors affect the AER, including weather conditions, building characteristics, and occupant behavior, resulting in

substantial spatial and temporal variations in AER. Deposition is dependent on PM size, where UFP loss can be expected to occur through Brownian diffusion, while $PM_{10-2.5}$ losses may occur through gravitational deposition or impaction. These phenomena were described in Sarnat et al. (2006a) and summarized in the 2009 PM ISA. New developments include characterizing infiltration of UFP, clarification on the factors influencing infiltration, and examination of air conditioning usage or AER as an effect modifier of $PM_{2.5}$ exposure for epidemiologic studies.

Field studies indicate that residential AER values vary by region and season, with substantial variability among different residences. Cao and Frey (2011) observed higher geometric mean AER in New York City (0.64 $hour^{-1}$), where housing stock tends to be older, compared with Harris County, TX (0.37 $hour^{-1}$) and a six-county region of central North Carolina (0.54 $hour^{-1}$). The RIOPA (Relationship Among Indoor, Outdoor, and Personal Air) study measured summer and winter AER in homes in three U.S. cities (Los Angeles, CA, Elizabeth, NJ, and Houston, TX). Median AER values were similar in Los Angeles and Elizabeth (0.87 $hour^{-1}$ and 0.88 $hour^{-1}$, respectively), but lower in Houston (0.47 $hour^{-1}$) (Yamamoto et al., 2010). Isaacs et al. (2013) analyzed seasonal RIOPA and DEARS data and found similar AER for the RIOPA cities and median AER of 0.92 $hour^{-1}$ in winter and 1.46 $hour^{-1}$ in summer. Summer AER was lower than winter AER in Elizabeth (0.88 $hour^{-1}$ vs. 1.07 $hour^{-1}$) and Houston (0.37 $hour^{-1}$ vs. 0.63 $hour^{-1}$). A similar seasonal difference was observed in Windsor, Ontario (0.14 $hour^{-1}$ vs. 0.3 $hour^{-1}$) (Wheeler et al., 2011). In contrast, Los Angeles AER values were higher in summer than winter (1.14 $hour^{-1}$ vs. 0.61 $hour^{-1}$). More prevalent use of open windows in Los Angeles and Detroit, where summertime tends to be less humid than in Elizabeth or Houston, may promote greater air exchange. These differences may grow smaller with the increased prevalence of air conditioning, because air conditioning usage is an important factor in infiltration (Allen et al., 2012). The higher winter AER values in the northern cities of Elizabeth and Windsor may be due to an increased "stack effect" resulting from indoor-outdoor temperature differential (Breen et al., 2014).

Between-city variability in residential building characteristics may explain heterogeneity in associations of $PM_{2.5}$ with risk estimates (Section 11.1.6.3.2). Baxter and Sacks (2014) explored this idea by performing *k*-means cluster analysis of factors related to AER, including percentage of homes with central air conditioning, mean year the home was built, and mean home size, from the American Housing Survey across 94 CBSAs across the U.S. Their analysis produced five clusters, labeled Clusters 1-5 by the study authors. Clusters 2 and 3 had high proportions of air conditioning (72% each), and those clusters primarily spanned the southern U.S. including the southeast and southwest. Homes in these clusters were built, on average, in 1989 and 1970. Cluster 1, which crossed the Northeast, Rust Belt, Pacific coast, and Denver, had slightly more than 1 quarter (27%) of homes with air conditioning, and had smaller homes on average (1,672 ft^2). Clusters 4 and 5 were primarily situated in the Northeast and Rust Belt, had air conditioning in 56 and 19% of homes, and were somewhat larger (2,098 ft^2 and 2,253 ft^2). In the latter three clusters, homes were built on average in 1954, 1959, and 1945. The results of Baxter and Sacks (2014) and Baxter et al. (2017), in a related study of short-term $PM_{2.5}$ exposure and mortality, support the

idea of a regional differences in building characteristics and health effects estimates based on north-south and east-west differences in housing clusters.

Vehicle AERs can be substantially higher than residential AERs, leading to rapid infiltration of on-road pollutants. Many factors affect vehicle AER, including whether windows are opened or closed, vehicle make and model, vehicle age, driving speed, and fan/recirculation setting on the vehicle ventilation system. The combined effect of these factors result in AERs that vary by more than two orders of magnitude, from less than 1 $hour^{-1}$ (approximately equivalent to a typical residential AER) to more than 100 $hour^{-1}$ (Hudda et al., 2011). In a model fit to AER measurements on 59 vehicles driven at three different speeds under recirculation conditions with closed windows, the most important variables were vehicle age, mileage, and speed, plus an adjustment for manufacturer (Fruin et al., 2011). Fan speed and vehicle shape were not influential variables.

More data have since been acquired to estimate F_{inf} for UFP since the Sarnat et al. (2006a) study. Sarnat et al. (2006a) found that F_{inf} reached a maximum for particles of 200 nm size and was sensitive to AER and PM composition. The smallest size they studied was 20 nm. Kearney et al. (2014) estimated daily F_{inf} for PM_1, $PM_{2.5-1}$, and UFP (NC estimated by the authors to have 80% smaller than 100 nm) in Edmonton, Ontario. They studied conditions in winter and summer and observed winter-time median F_{inf} of 0.45 for PM_1 (based on the SO_4^{2-} method) and of 0.19 for UFP (based on P-TRAK portable sampler measurements), a 58% reduction. During the summer, median F_{inf} was 0.79 for PM_1 and 0.51 for UFP, a 35% reduction. In addition to the influence of season, Kearney et al. (2014) also tested building age and ventilation characteristics and found that building age, airflow characteristics in the home, temperature differential, and wind speed influenced F_{inf} for PM_1 in winter, while furnace operation and wind speed influenced F_{inf} for UFP in winter. For summer, only wind speed influenced F_{inf} for PM_1, while portable air cleaner operation and window opening influenced F_{inf} for UFP. Rim et al. (2010) focused on UFP smaller than 100 nm and were able to measure particles as small as 4.4 nm (under open window conditions) and 9 nm (under closed window conditions) in their study of F_{inf} using an SMPS. For open window conditions, F_{inf} = 0.08 for particles in the 4.4−5.1 nm bin. For closed window conditions, F_{inf} = 0.03 for the 9−11 nm bin. For the 55−64 nm bin, F_{inf} was 0.16 for closed windows and 0.47 for open windows. The Rim et al. (2010) study also compared the C_{in}/C_{out} ratio with F_{inf}. Unlike for $PM_{2.5}$ and $PM_{10-2.5}$, the C_{in}/C_{out} ratio was very close in value to F_{inf} for UFP. These findings imply that very little PM in the smallest size fractions infiltrates the building envelope, suggesting that large errors would occur from assuming that concentrations measured at an ambient monitor were representative of indoor exposure to ambient UFP, especially as the particle size decreased.

Indoor air filtration using high-efficiency particulate air (HEPA) filters can reduce F_{inf} as well as indoor total and ambient $PM_{2.5}$ concentrations. Allen et al. (2011) conducted an intervention study by temporarily installing HEPA filters in 25 homes in British Columbia, Canada during winter and early spring. Indoor $PM_{2.5}$ concentrations were 59% lower on average during HEPA filter operation (4.6 vs. 11.2 $\mu g/m^3$). Reductions of similar magnitude were observed for outdoor-generated $PM_{2.5}$

(1.5 vs. 3.5 µg/m^3). Allen et al. (2011) estimated F_{inf} using the recursive method of Allen et al. (2003) and found that the average infiltration of $PM_{2.5}$ was reduced by 41% (0.20 vs. 0.34). These studies show a consistent effect of HEPA filtration in reducing $PM_{2.5}$ infiltration.

Several recent studies suggest that air conditioning may modify the association between $PM_{2.5}$ and health effects. Allen et al. (2012) used $PM_{2.5}$ and questionnaire data from the MESA-Air study to model F_{inf} as a function of air conditioning and heating use, window opening, and window insulation. During the summer, central air conditioning usage was the most important factor in the model, accounting for 80% of the overall model variability (model $R^2 = 0.70$). During the winter, the most important factor was 2-week average outdoor temperature, which accounted for 45% of the overall model variability (model $R^2 = 0.49$). These results suggest that the variability in $PM_{2.5}$ infiltration within and between cities may account for increased variability in estimation of $PM_{2.5}$ exposure and hence attenuation of the health effect estimate. Hodas et al. (2012) considered sensitivity of F_{inf} to $PM_{2.5}$ mass concentration, $PM_{2.5}$ component concentration, proximity to roadways, and income. Generally speaking, F_{inf} was higher when calculated for $PM_{2.5}$ mass concentration rather than individual components. F_{inf} was higher for both those living near roadways and for AER of 0.90 $hour^{-1}$, which was identified as the "typical" AER for low income homes compared with the general population. Hodas et al. (2012) suggested that variation in F may account for exposure misclassification in cases where variability in AER leads to assignment of incorrect F and for effect modification when conditions such as source proximity and poverty influence F.

Based on results of studies showing how F_{inf} varies under different conditions, Allen et al. (2012) suggested that infiltration could modify the health effect of $PM_{2.5}$ exposure; this idea was explored in other studies. Bell et al. (2009) tested if air conditioning prevalence (i.e., the proportion of homes with air conditioning in a given community as indicated by the American Housing Survey) modified the effect of $PM_{2.5}$ exposure concentration on cardiovascular and respiratory hospital admissions (HA) and of PM_{10} on mortality. Over the course of a year they observed decreases of 30% for the effect of short-term PM_{10} exposure on mortality and of 34% for the effect of short-term $PM_{2.5}$ exposure on cardiovascular HA when any air conditioning was in use. They observed an overall 45% increase in the effect of $PM_{2.5}$ on respiratory HA for those who use air conditioning, but a break-down of their data showed that there was a 75% decrease in effect of $PM_{2.5}$ on respiratory HA during the summer when air conditioning use would be most prevalent. Sarnat et al. (2013a) also explored how AER can be a modifier of the effect of $PM_{2.5}$, NO_X, and CO related to asthma ED visits in Atlanta neighborhoods. Parsing their data by low and high AER (0.25/hour threshold) and poverty level (8.5% threshold), Sarnat et al. (2013a) observed that the majority of locations with high levels of poverty also had high AER. They attributed this observation to old, drafty housing being more prevalent among those in poverty. Larger effect estimates were observed among those with high poverty and low AER, however. When effect modification was tested using an interaction term, a negative effect on ED asthma visits was observed despite increased $PM_{2.5}$ and AER being associated with increased ED visits. These results indicate that air conditioning may modify associations between $PM_{2.5}$ and health effects, but the results are not entirely consistent.

Many of the newer studies of PM infiltration focused on characterizing infiltration of UFP, clarification on the factors influencing infiltration, and examination of air conditioning usage or AER as an effect modifier of $PM_{2.5}$ exposure. UFP infiltration was found to decrease with decreasing particle size, likely due to particle diffusion to surfaces. Many new studies noted differences in infiltration for seasons or between northern and southern cities. Areas with prevalent air conditioning usage tended to have lower infiltration compared with areas where window opening is prevalent. Indoor-outdoor temperature gradients also likely influenced PM infiltration, with particles naturally following the warm-cold gradient. Some recent studies found that air conditioning may also modify the effect of short-term $PM_{2.5}$ exposure and health effects.

3.4.1.2 Indoor–Outdoor Concentration Relationships

The 2009 PM ISA (U.S. EPA, 2009b) largely focused on infiltration of PM in the $PM_{2.5}$ and $PM_{10–2.5}$ size ranges, finding that infiltration of PM indoors decreased with increasing particle size. This section builds on the literature review from the 2009 PM ISA with a focus on relationships between indoor and local outdoor PM concentrations in different size fractions, particularly $PM_{2.5}$ and UFP. Most of the studies published since the 2009 PM ISA that evaluated indoor-outdoor PM relationships were conducted outside the U.S., including studies in Europe, Canada, Mexico, South America, the Middle East, and Asia. Since PM levels, sources, and composition are likely to differ substantially in some areas from those typically encountered in the U.S., this section focuses on North American and European indoor-outdoor studies.

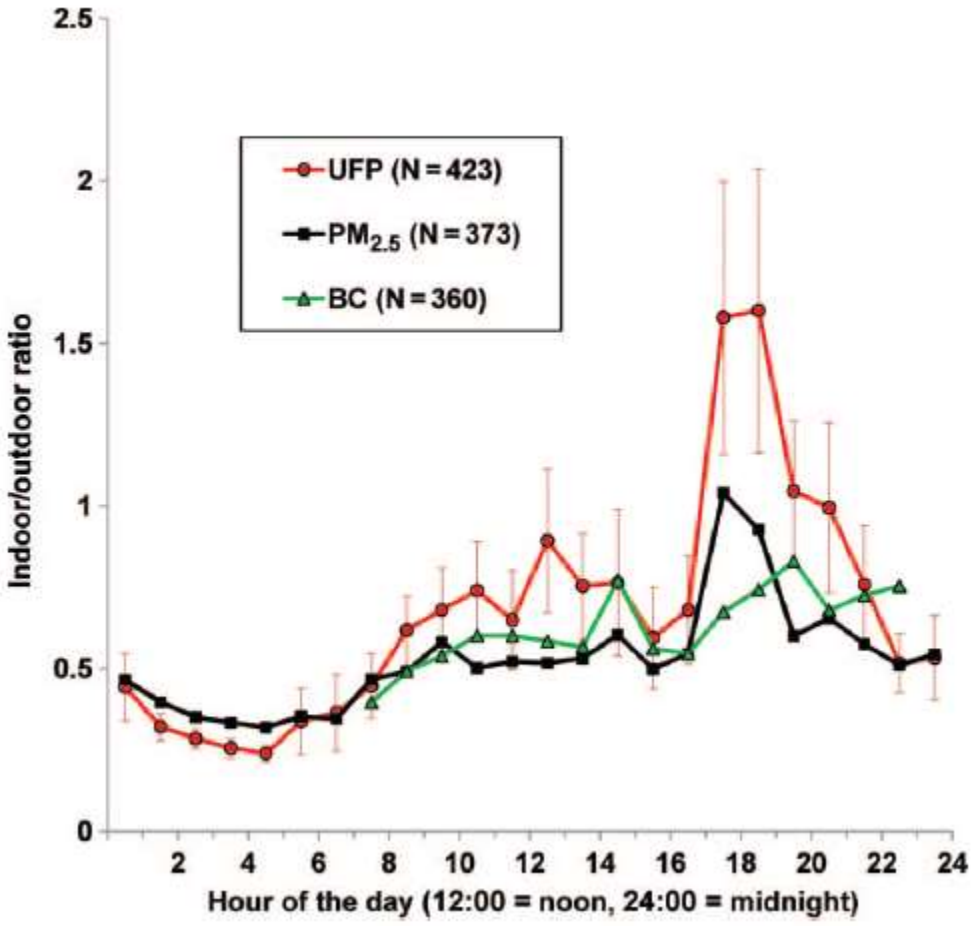
Recent literature has added data to the characterization of indoor-outdoor relationships across the $PM_{2.5}$ and $PM_{10–2.5}$ size fractions. A multicity study in Europe compared indoor and outdoor residential 24-hour average concentrations for NC (7−3,000 nm), $PM_{2.5}$, and $PM_{10–2.5}$ at 152 homes in Helsinki (Finland), Athens (Greece), Amsterdam (the Netherlands), and Birmingham (U.K.) (Hoek et al., 2008b). Median indoor-outdoor correlations for $PM_{10–2.5}$ were the lowest of the three PM metrics in all cities, ranging from 0.10−0.39. In Helsinki and Amsterdam, NC indoor-outdoor correlations were lower than $PM_{2.5}$ correlations (0.41 vs. 0.74 and 0.58 vs. 0.85, respectively), while in Athens and Birmingham, NC correlations were higher (0.80 vs. 0.63; 0.50 vs. 0.35). A common indoor source, gas cooking, was prevalent in both Amsterdam and Birmingham, cities with differing correlation magnitude, and so is unlikely to explain city-to-city differences in correlations. Consistent with observed low correlations, the regression slope of indoor on outdoor concentrations (a measure of infiltration, with a slope less than one indicating less infiltration) was lower for $PM_{10–2.5}$ than the other two PM metrics, ranging from 0.11−0.16. NC slopes ranged from 0.19−0.42 and were lower than $PM_{2.5}$ slopes (range: 0.39−0.48) in Amsterdam, Birmingham, and Helsinki, while the two slopes were roughly equivalent in Athens. Again, infiltration slope results were generally consistent with correlation results, being either both high or both low in a particular city. Buonanno et al. (2013a) reported I/O and the ratio of indoor to fixed-site monitors for three schools in Cassini, Italy and found I/O ranged from 0.63−0.74 while the indoor to fixed-site ratio

ranged from 0.47−1.53. These values are much higher than those reported in the Hoek et al. (2008b) study. Another important finding is that $PM_{10-2.5}$ exhibited the lowest infiltration and indoor-outdoor correlation of the three metrics, with NC and $PM_{2.5}$ infiltration behavior similar to one another. Semmens et al. (2015) measured NC in various size fractions ranging from 0.3−10 µm and found that correlations between indoor $PM_{2.5}$ and various NC size fractions were very high for NC less than 1 µm in size (0.94 and 0.93 for NC 0.3−0.49 µm and 0.5−0.99 µm, respectively). Correlations with $PM_{2.5}$ decreased monotonically for larger NC size fractions, with $PM_{2.5}$–$PM_{10-2.5}$ correlations of 0.46 for NC 2.5−4.99 µm and 0.35 for NC 5.0−9.99 µm. Correlations among indoor NC size fractions were highest for adjacent bins. Collectively, these results indicate that differences in source patterns, spatial concentration heterogeneity, housing stock, meteorology, and other factors contribute to different indoor-outdoor relationships in different urban areas, particularly for NC and $PM_{2.5}$.

Results for indoor-outdoor relationships for $PM_{2.5}$ concentration were not consistent across studies of the effect of season. Several single-city studies in the U.S. and Canada have evaluated indoor-outdoor relationships by season. For example, in Boston, median residential indoor-outdoor slopes for 24-hour average $PM_{2.5}$ were higher in summer than winter (0.74 vs. 0.53) for a panel of 25 participants studied in 2000 (Brown et al., 2008). Hsu et al. (2012) reported correlations between indoor and outdoor (outside residence and fixed-site monitors) concentrations of $PM_{10-2.5}$ and $PM_{2.5}$ in New York City, NY and Seattle, WA. For $PM_{10-2.5}$ in New York City (correlations not reported for Seattle), Spearman $R = 0.20$ for indoor-outdoor and 0.08 for indoor-fixed-site during the summer and Spearman $R = -0.12$ and −0.07 for indoor-outdoor and indoor-fixed-site during the winter. For $PM_{2.5}$ in New York City, Spearman $R = 0.44$ for both indoor-outdoor and indoor-fixed-site in winter and Spearman $R = 0.57$ and 0.53 for indoor-outdoor and indoor-fixed-site in summer. Hochstetler et al. (2011) measured $PM_{2.5}$, EC, and NC inside and outside three public schools in Cincinnati, OH and observed a lower slope and R^2 for $PM_{2.5}$ (I/O slope = 0.24, $R^2 = 0.08$), compared with EC (I/O slope = 0.44, $R^2 = 0.66$) and NC (I/O slope = 0.68, $R^2 = 0.72$). In Windsor, Ontario, Kearney et al. (2011) calculated the indoor-outdoor ratio (I/O) for UFP (20−100 nm), and found wide variation with median I/O of 0.19 (95th percentile: 0.64) and 0.27 (95th percentile: 0.61) for summer measurements for 2005 and 2006, respectively, and 0.25 (95th percentile: 0.45) for winter, 2006 measurements. Kearney et al. (2011) based these numbers on nighttime measurements, when it was assumed that there were no indoor sources of UFP so that I/O approximates F_{inf}; I/O estimates based on recursive and censoring models produced similar results. Daily I/O (not slopes) in Windsor were similar for $PM_{2.5}$ (0.5), BC (0.45), and 20−1,000 nm NC (0.55) at approximately 90 residences, averaging across summer and winter sampling seasons (Wheeler et al., 2011). Hourly I/O for NC were much higher during dinnertime (approximately 1.5), indicating indoor NC sources from cooking (Figure 3-2); this also contributed to a higher daily ratio relative to the other PM metrics. For $PM_{10-2.5}$ in Regina, Saskatchewan, 5-day geometric mean concentrations were lower indoors than outdoors during summer (4.3 vs. 8.8 µg/m^3) in a set of 100 residences, but the opposite was true for a set of 79 residences during winter, with higher indoor concentrations (3.7 vs. 2.5 µg/m^3). The spatial coefficient of variation for outdoor $PM_{10-2.5}$ concentrations was higher in winter than in summer.

Variation in indoor-outdoor relationships among different studies for warm and cold months may relate to different contributions from indoor sources, such as cooking and heating, between cities.

Time of day also influences I/O ratios, as shown in Figure 3-3 for data reported by Wheeler et al. (2011). In addition, Semmens et al. (2015) studied residences relying mainly on wood stoves for heating and found that I/O ratios were approximately 1.0−1.2 (indicating indoor sources) during daytime hours (6 a.m.–10 p.m.), indicating the wood stove or other indoor sources were contributing to indoor PM. Overnight (10 p.m.–6 a.m.) ratios were approximately 0.6. The relatively lower overnight I/O supports the finding that indoor sources were driving the high I/O values during the day.

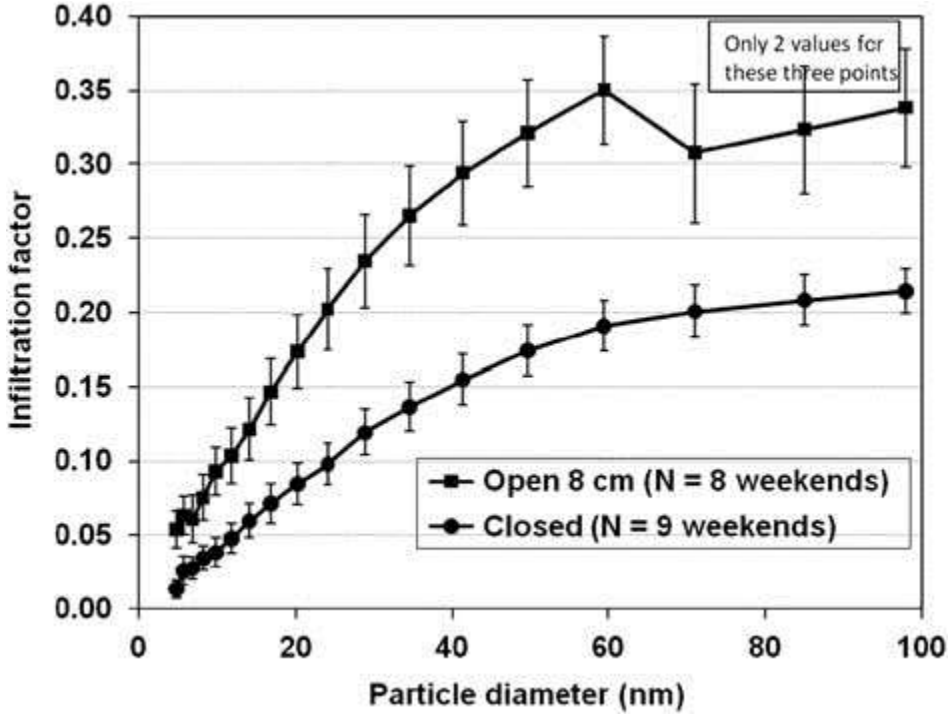


Note: Standard errors are only shown for the I/O for UFP. This figure was reproduced from Wheeler et al. (2011). The figure shows how the indoor-outdoor ratios change with hour of day for UFP, $PM_{2.5}$, and BC. Each type of PM has a peak indoor-outdoor ratio between 17:00 and 20:00. However, the peak indoor-outdoor ratio is much higher for UFP than for $PM_{2.5}$, which is slightly higher than for BC.

Source: Permission pending Wheeler et al. (2011).

Figure 3-2 Indoor-outdoor ratios for UFP, $PM_{2.5}$, and BC measured at 90 residences.

New research on UFP I/O suggest that I/O decreases with decreasing particle size within the ultrafine size range. Indoor-outdoor ratios were calculated for a manufactured house located on the National Institute for Standards and Technology (NIST) campus in Gaithersburg, MD to characterize infiltration to test how I/O varies across UFP size (Wallace and Ott, 2011). I/O generally increased with increasing UFP size (up through 100 nm) for both open and closed window conditions (Figure 3-3). Open window I/O was always higher and had greater variability than closed window I/O. This pattern is consistent with observations by Sarnat et al. (2006a) presented in the 2009 PM ISA (U.S. EPA, 2009b) in which F_{inf} increases with increasing particle size up to about 100 nm. Above 200 nm, Sarnat et al. (2006a) reported that F_{inf} declined with increasing particle size up to 8 µm. Across all experiments, Wallace and Ott (2011) estimated that ambient UFP exposure was responsible for 36% of total UFP exposure and that the contribution of outdoor UFP exposure to total UFP exposure would likely increase in urban environments.



Source: Permission pending Wallace and Ott (2011).

Figure 3-3 Indoor-outdoor ratios for UFP size obtained in a test house on the National Institute for Standards and Technology (NIST) facility for open and closed window conditions.

Recent studies reinforce previous conclusions that I/indoor-outdoor relationships are sensitive to particle size, with I/O typically decreasing in the $PM_{10-2.5}$ range. New studies add to the literature base for UFP, where I/O was found to decrease with decreasing particle size. UFP movement is more influenced by Brownian diffusion than are larger particles, which likely caused more UFP to diffuse to building surfaces instead of being transported indoors. Additional studies added to the characterization of indoor-outdoor relationships for different seasons and times of day. For most studies, I/O was higher during summer than winter and during daytime compared with nighttime.

3.4.1.3 Personal–Ambient Concentration Relationships

The new literature on personal-ambient relationships adds to findings from the 2009 PM ISA (U.S. EPA, 2009b), in which moderate correlations (0.3−0.7) were observed with median personal-ambient slope slightly higher than 0.5. The general understanding of these relationships is unchanged since the 2009 PM ISA. As with the previous section on indoor-outdoor relationships (Section 3.4.2), many of the studies published since the 2009 PM ISA that evaluated personal-ambient PM relationships were conducted outside the U.S., including studies in Europe, Mexico, South America, the Middle East, and Asia. Since PM levels, sources, and composition are likely to differ substantially in some areas from those typically encountered in the U.S., this section focuses on North American and European personal-ambient studies.

High correlations suggest that ambient concentrations are a good surrogate for personal exposure, while low correlations indicate exposure measurement error when using ambient concentration to represent personal exposure. Several studies, many of which were available at the time of the 2009 PM ISA (U.S. EPA, 2009b), have evaluated relationships between personal exposure and ambient PM concentrations in various U.S. cities, including: Baltimore, MD; Boston, MA; Chapel Hill, NC; Detroit, MI; and Steubenville, OH (Meng et al., 2012; Brown et al., 2009; Williams et al., 2008; Sarnat et al., 2006b; Koutrakis et al., 2005; Sarnat et al., 2005; Chang et al., 2000; Sarnat et al., 2000). These studies all evaluated 24-hour average exposures, except for Chang et al. (2000), which evaluated hourly exposures in a variety of microenvironments (e.g., indoor-home, indoor-other, outdoor-near-road, in-vehicle). Figure 3-4 shows personal-ambient correlations reported for Baltimore in Chang et al. (2000) and Sarnat et al. (2000) and New York City (Hsu et al., 2012). Both Baltimore studies evaluated $PM_{2.5}$, and Sarnat et al. (2000) reported personal-ambient correlations for PM_{10}, $PM_{10-2.5}$, and SO_4^{2-}. Hsu et al. (2012) also reported personal-ambient correlations for PM_{10}. Correlations ranged widely for $PM_{2.5}$, with a median of approximately 0.4 and an IQR of 0.3−0.7. PM_{10} correlations were similar to those for $PM_{2.5}$, while $PM_{10-2.5}$ correlations were somewhat lower, suggesting factors such as spatial variability and differential infiltration affect exposure to ambient $PM_{10-2.5}$. These results also suggest that PM_{10} was comprised primarily of $PM_{2.5}$ in these samples. Sulfate correlations were higher than those for $PM_{2.5}$. The recent findings of Hsu et al. (2012), in conjunction with older studies in the literature, indicate that a

greater portion of the variability in personal exposures is explained by variability in ambient PM for $PM_{2.5}$ and sulfate in $PM_{2.5}$, which tend to have lower spatial variability than $PM_{10-2.5}$ and UFP.

Figure 3-4 Correlations between personal exposure and ambient PM concentration in Baltimore, MD.

Regressing personal exposure on ambient PM concentration yields a slope factor expressing the fraction of personal exposure from ambient PM. Figure 3-5 presents personal-ambient slopes (i.e., the ratio of total personal exposure to ambient concentration) from studies in the four cities listed previously (Meng et al., 2012; Brown et al., 2009; Sarnat et al., 2006b; Koutrakis et al., 2005; Sarnat et al., 2005). Several of these studies evaluated EC and SO_4^{2-} in addition to $PM_{2.5}$. Median slopes for $PM_{2.5}$, EC, and SO_4^{2-} were between 0.5 and 0.6. The wide variability in personal-ambient slopes is likely due in part to the study design, which evaluated personal exposure in different seasons and with different building ventilation conditions (e.g., closed vs. open windows). The variability may have also been attributed to variation in penetration and deposition for the components and houses. Ryan et al. (2015a) and Brokamp et al. (2015) analyzed concentration data from outdoor concentrations (outside residence) and total personal exposure samples for $PM_{2.5}$ mass and 24 $PM_{2.5}$ trace metals (Ag, Al, As, Ba, Br, Ca, Cl, Cr, Cu, Fe, K, Mn, Ni, Pb, S, Sb, Se, Si, Sn, Sr, Ti, V, Zn, Zr) from the RIOPA study of homes in Los Angeles, CA, Houston, TX, and Elizabeth, NJ. They presented correlation and outdoor-personal ratios (O/P) for each $PM_{2.5}$ component. Correlations of Spearman $R > 0.8$ were reported for S and V, while Spearman $R < 0.4$ was reported for Ag, Al, As, Ba, Ca, Cl, Cr, Cu, Fe, K, Mn, Ni, Sb, Si, Sr, Ti, Zn, Zr, and for $PM_{2.5}$ mass. Median O/P > 1 was observed for As, Br, Sb, Se, and V and O/P < 1 for $PM_{2.5}$ and the other components. The results for $PM_{2.5}$ and $PM_{2.5}$–S contrast those presented in Figure 3-5. Data were unavailable for $PM_{10-2.5}$ or UFP in these studies. These findings indicate that variability in the personal-ambient slope reflects differences in ventilation and other localized conditions for $PM_{2.5}$ mass concentration, which is not very sensitive to $PM_{2.5}$ composition.

New studies agree with the previously published literature on personal-ambient relationships. Studies have examined personal-ambient correlations for different PM size fractions and found that a greater portion of the variability in personal exposures is explained by variability in ambient PM for $PM_{2.5}$ and sulfate in $PM_{2.5}$, compared with $PM_{10-2.5}$, which tends to have greater spatial variability than $PM_{2.5}$. Median personal-ambient slopes are generally slightly greater than 0.5, and they likely reflect differences in residential ventilation, time-activity patterns (Section 3.4.2.1), and other localized conditions.

3.4.2 Factors Contributing to Error in Estimating Exposure to PM

This section builds upon discussions from the 2009 PM ISA (U.S. EPA, 2009b) about factors having the potential to cause error in exposure concentration estimates. Time-activity patterns, spatial variability, instrument error, and model accuracy and precision are discussed below, because these topics were frequently examined in exposure measurement error discussions. Summaries of each factor's discussion from the 2009 PM ISA are included in Section 3.4.2.1, Section 3.4.2.2, Section 3.4.2.3, and Section 3.4.2.4.

3.4.2.1 Time–Activity Patterns

The 2009 PM ISA (U.S. EPA, 2009b) reviewed time-activity behaviors among the population and how time spent in different locations varies among age groups. Recent additions have been made to time-activity databases, and technological advances in geographic positioning system (GPS) technologies have also expanded the information base regarding time-activity. Such new tools have enabled examination of factors that influence time-activity patterns and errors in those relationships.

Updated data are available from the Consolidated Human Activity Database (CHAD) to compare time-activity among different population strata for 25,431 individuals (Isaacs, 2014). Across the population, 75% of time is spent indoors at the place of residence; 5.5% is spent in transit; 16% indoors at work, school, or other locations; and 2.9% outdoors (Table 3-6). Substantially more time (82 and 83%) is spent indoors at home for children younger than 6 years and for adults older than 64 years, while teens ages 12−19 years and adults 20−64 years spent the least amount of time indoors at home (72 and 71%, respectively). Similarly, young children spent the least amount of time in transit (4.0%), while adults 20−64 years spent the most time in transit (6.9%). Adults 20−64 also spent the largest proportion of the day outdoors (3.4%), while older adults spent the least amount of time outdoors (2.2%). Young children ages 0−5 years and children ages 6−11 years spent less time outdoors than adults (2.4 and 3.0%, respectively). When comparing time-activity data across race (Table 3-7), Hispanic study participants spent slightly more time indoors at home than average (78%), while White study participants spent the most time outdoors (3.3%) compared with Asian (2.0%), Black (2.1%), and Hispanic (2.3%) participants. Males spent more time outdoors compared with females (3.6 vs. 2.2%) (Table 3-8), and adults 20−64 years with low and high education both spent less times indoors at home (74 and 70%, respectively), more time indoors at work/school/other (16 and 19%), and more time outdoors (3.7 and 3.5%) compared with the 20−64 year-old adult population (3.4%) (Table 3-9). It is possible that missing education data corresponded with lower time spent outdoors. It was most surprising to find that children spent less time outdoors than adults, while sex-specific differences in time-activity data were anticipated.

Recent studies have focused on the use of GPS technologies, such as in smartphones, to develop detailed time-activity pattern data. For example, Glasgow et al. (2014) analyzed the frequency of Android-based smartphones in recording positional data among a panel of study participants and found that on average 74% of the data were collected over intervals shorter than 5 min, which is a marked improvement over many time-activity studies using diaries.

Table 3-6 Total and age-stratified time activity data from the Consolidated Human Activity Database.

Location Type	All	0−5 yr	6−11 yr	12−19 yr	0−19 yr	20−64 yr	65+ yr
Indoor-residential	75.1%	82.0%	74.4%	71.6%	76.2%	71.4%	82.9%
Transit	5.53%	3.96%	4.29%	5.13%	4.42%	6.92%	5.14%
Indoor-work/school/other	15.5%	10.1%	16.7%	19.9%	15.3%	17.9%	8.71%
Outdoor	2.87%	2.35%	2.96%	2.53%	2.62%	3.39%	2.18%
Uncertain or missing	0.97%	1.59%	1.65%	0.85%	1.40%	0.48%	1.05%

Table 3-7 Total and race/ethnicity-stratified time activity data from the Consolidated Human Activity Database.

Location Type	All	Asian	Black	Hispanic	White
Indoor-residential	75.1%	75.3%	74.8%	78.4%	74.8%
Transit	5.53%	5.01%	5.25%	5.05%	5.54%
Indoor-work/school/other	15.5%	16.3%	16.6%	13.4%	15.0%
Outdoor	2.87%	2.02%	2.09%	2.34%	3.30%
Uncertain or missing	0.97%	1.42%	1.26%	0.84%	1.45%

Table 3-8 Total and sex-stratified time activity data from the Consolidated Human Activity Database.

Location Type	All	Female	Male
Indoor-residential	75.1%	76.6%	73.4%
Transit	5.53%	5.47%	5.60%
Indoor-work/school/other	15.5%	14.8%	16.4%
Outdoor	2.87%	2.21%	3.64%
Uncertain or missing	0.97%	0.92%	1.04%

Table 3-9 Total and education-stratified time activity data from the Consolidated Human Activity Database, among adults 20−64 years.

Location Type	All 20−64 yr	Low Education	High Education
Indoor-residential	71.4%	73.7%	70.0%
Transit	6.92%	6.42%	7.12%
Indoor-work/school/other	17.9%	16.0%	19.1%
Outdoor	3.39%	3.73%	3.52%
Uncertain or missing	0.48%	0.22%	0.27%

Positional errors are a concern for GIS and GPS-based technologies. Several studies found that median positional errors based on smartphones were less than 26 m (Ganguly et al., 2015; Lane et al., 2013; Wu et al., 2010). Glasgow et al. (2014) observed much larger errors, with an overall median positional accuracy of 342 m and a range from 98 to 1,169 m using an Android-based smartphone, while Wu et al. (2010) observed much smaller errors when comparing two smartphones with three other GPS technologies. To test the impact of the positional errors on concentration estimates used in exposure assessment studies, Ganguly et al. (2015) compared R-LINE modeled residential $PM_{2.5}$ concentrations when the positions were estimated with GIS or GPS over buffers of 0−100 m, 100−200 m, 200−500 m, and >500 m. Median concentration measurement errors were 5% or less for each buffer for annual average concentrations and 6% or less for 24-hour max concentrations. Average errors were 10% or less for each buffer for both annual average and 24-hour max concentrations.

Survey tools to assess time-activity may be subject to recall error among the subjects. Spalt et al. (2015) administered a survey to all participants in the Multi-Ethnic Study of Atherosclerosis (MESA) Air Study to ascertain information about time spent indoors and outdoors at home, at work/volunteer/school, in transit, or in other locations. A subset of the study population was asked to complete a time-activity diary as well. Correlation for indoor locations was Spearman $R = 0.63$ for home, Spearman $R = 0.73$ for work/volunteer/school, and Spearman $R = 0.20$ for other locations. Correlation for outdoor locations was much lower, with Spearman $R = 0.14$ at home, Spearman $R = 0.20$ for work/volunteer/school, and Spearman $R = 0.10$ for other locations. In transit, Spearman $R = 0.39$. These results suggest that study participants have better recall of the times spent inside their home or work/volunteer/school compared to other activities, because time spent at home or at work/volunteer/school tends to occur at routine times.

Excluding time-activity patterns from exposure studies may lead to bias and uncertainty in the exposure estimate. Nyhan et al. (2018) combined GPS records from 407,435 individuals in the metropolitan Boston, MA area with a hybrid model using land use regression and satellite data to predict $PM_{2.5}$ concentration on an hourly basis. They compared the time-activity-based model with one that used the daily average $PM_{2.5}$ concentration (also based on the hybrid LUR-satellite model) at location of resident for each participant and found that the residence-based exposure model produced predictions that were 9% lower than the model accounting for time-activity when averaging the results over a year. This suggests that omission of time-activity data may lead to underestimation of the exposure.

Residential mobility is one factor leading to error in estimating exposure for long-term exposure studies. Using a single address to represent exposure concentration over a period of several years may result in either under- or over-estimating exposure during the study period. For example, Brokamp et al. (2015) analyzed residential mobility for a cohort of children over the first seven years of life in Cincinnati, OH and found that 54% of the children changed residential address during that time, resulting in a 4.4% decrease in the cohort's average traffic-related air pollution exposure concentration (defined as BC estimates from an LUR model). They also noted that if the birth address is used for exposure estimation during the entire study period, exposure misclassification is increased for those that move earlier (due to more years at the incorrect address) or are more highly exposed (due to a greater likelihood of moving). An epidemiologic study of asthma incidence at age seven showed that not accounting for residential mobility resulted in bias toward the null.

Recognizing that the CHAD database observed people (across population subgroups) spending approximately 5.5% of their time in vehicles, several studies have measured UFP concentrations in and immediately outside vehicles to estimate infiltration. Hudda et al. (2012) observed that I/O was positively associated with increasing AER for vehicles tested in Los Angeles, CA and Sydney, Australia each with recirculating air and outside air intakes. I/O increased with increasing vehicle speed and age, with a maximum of approximately 0.75 under recirculating conditions and of approximately 0.9 under outside air intake. Bigazzi and Figliozzi (2012) estimated I/O when a vehicle in Portland, OR was operated with windows down, windows up with outside air intake, and windows up with recirculating air. Under those

conditions, I/O decreased from 0.85 to 0.53 to 0.1−0.17, respectively. Knibbs et al. (2010) tested I/O for five vehicles and four ventilation settings (outdoor air intake with lowest and second lowest fan speed, recirculation on with lowest fan speed, recirculation on with fan off). Older model vehicles (prior to 2000) had I/O of 0.89−1.04 for the outdoor air intake settings and 0.29−0.47 for the recirculation settings. Models built after 2000 had I/O of 0.66−1.04 for outdoor air intake settings and 0.08−0.68 for recirculation settings. Yamada et al. (2016) took measurements along four road segments and inside one tunnel in the greater Tokyo, Japan area for particles smaller than and larger than 50 nm and using open air or recirculating air. When fresh air entered the vehicle, I/O ranged from 0.5 to 0.6 for particles smaller than 50 nm and from 0.8 to 0.9 for particles larger than 50 nm. When the test automobile's ventilation was operated in recirculation mode, infiltration ranged from 0.1 to 0.2 for particles smaller than 50 nm and from 0.2 to 0.9 for particles larger than 50 nm. In a tunnel in the greater Salzburg, Austria area, Madl et al. (2015) measured vehicle ventilation filtration efficiency for UFP, which can be used to interpret I/O by subtracting reported filtration efficiency from 1. They observed I/O of approximately 0.3 when the vehicle's standard ventilation setting was used, which reduced to 0.1 when the vehicle was put into recirculation mode. In all, these studies show that large variability in I/O occurs with both outdoor air intake and recirculation settings, but I/O tends to be higher for outdoor air intake.

Exposure to PM, particularly UFP, has been found to be elevated during bicycling and walking near roadways (Buonanno et al., 2013b; Hudda et al., 2012; Berghmans et al., 2009; Boogaard et al., 2009; Briggs et al., 2008). A study in Minneapolis, MN used city-wide traffic flows and a LUR model for particulate matter (including NC, BC mass, and $PM_{2.5}$) to analyze the relationship between bicycling or walking and PM exposure concentrations in different parts of the city (Hankey et al., 2017). The authors found that areas classified as high activity and high exposure made up approximately one-tenth of the total grid cells, but accounted for 20−44% of active travel.

Updated time-activity data and tools for assessing time-activity data have improved the general understanding of time-activity data and related uncertainties in recent years. Children were surprisingly found to spend less time outdoors than adults, but White respondents did spend more time outdoors than their Asian, Black, and Hispanic counterparts. New technologies to assess study participant location, errors related to study participant recall, and residential mobility have been used to determine that location-based errors are within 6% for short-term and long-term exposure assessment, while omission of residential mobility can result in a bias in the exposure estimate, resulting in biasing the health effect estimate for a study of long-term $PM_{2.5}$ exposure.

3.4.2.2 Spatial Variability in Concentrations

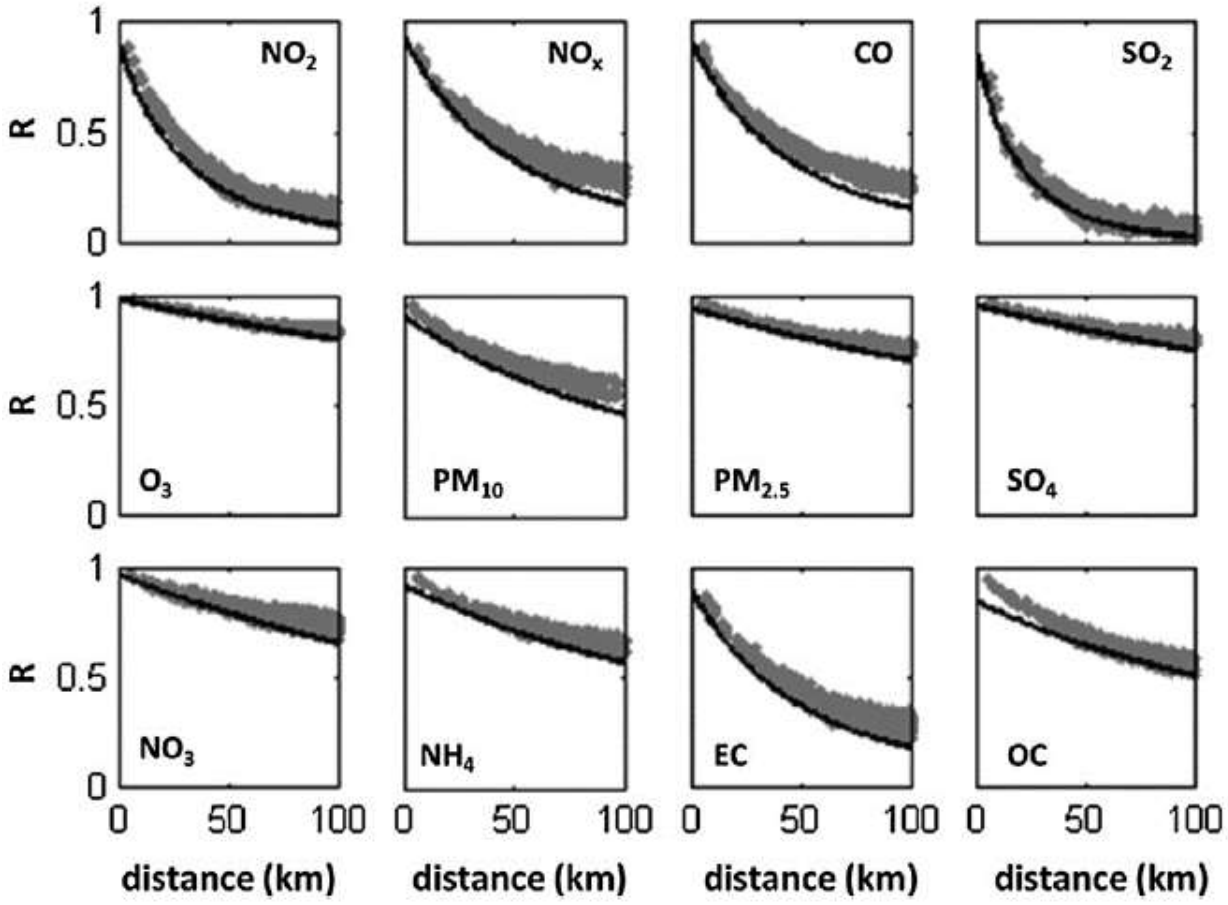
The 2009 PM ISA (U.S. EPA, 2009b) examined spatial relationships among $PM_{2.5}$ between AQS monitoring locations across neighborhood and urban scales. In general, this analysis suggested that correlations between monitors across space depended on the specific city's meteorology, topography, and

source mixture. For all cities studied, the between-monitor spatial correlations decreased with increasing distance between monitors. However, the correlation for $PM_{2.5}$ between Boston, MA monitor pairs was roughly Pearson $R = 0.8$ even when the monitors were 100 km apart. In contrast, correlation between $PM_{2.5}$ for Los Angeles monitor pairs was roughly Pearson $R = 0.2$ when the monitors were 100 km apart. The mountains and inversion patterns were thought to play a role in this comparatively low correlation. The 2009 PM ISA also investigated neighborhood scale monitor pair correlations among FRMs or FEMs in 15 CSAs or CBSAs and found that within 4 km, average correlation of Pearson $R = 0.93$ was maintained for a 4 km distance. At the time of the 2009 PM ISA, data were not available to study spatial variability in the concentration surface for $PM_{10–2.5}$ or UFP. Spatial distribution data for both UFP and $PM_{10–2.5}$ are still limited, especially for UFP. Data for UFP were available for two cities (Los Angeles, CA and Rochester, NY), and data from the Los Angeles study suggested that UFP had moderate spatial variability (coefficient of divergence [COD] between 0.2 and 0.6). It was thought that some background UFP reduced spatial variability, especially for particles larger than 40 nm (Section 2.5.1.2.4). Although some $PM_{10–2.5}$ data are available across the nation, micro-to-neighborhood scale data are not widely available at this size cut (Section 2.5.1.2.3). In cities where $PM_{10–2.5}$ measurements have been made in multiple locations, inter-monitor correlations were low. These limitations create uncertainty in characterizing spatial variability of exposure concentrations and its impact on interpreting results from epidemiologic studies, especially for long-term exposure to $PM_{10–2.5}$ and UFP.

Limitations in the use of ambient monitoring data to estimate exposure concentration arise when there is a lack of homogeneity and spatial autocorrelation of PM mass concentrations, which may occur for some size fractions and components (Baxter et al., 2013), causing the spatial range over which such estimates are used to vary widely. $PM_{10–2.5}$ and UFP concentration data tend to be more heterogeneous in space and hence more susceptible to spatial error (Section 2.5; Section 3.4.2.2). For large metropolitan areas, population exposure to primary anthropogenic components of PM (of any size fraction) may be substantially overestimated in terms of average concentration and temporal variation by the use of a fixed-site ambient monitor in close proximity to an industrial or energy generation source (Sarnat et al., 2015; Bell et al., 2011b). For example, traffic-related UFP and $PM_{2.5}$ components such as EC have elevated concentrations in close proximity to busy roadways (Zhu et al., 2009), potentially resulting in exposure misclassification (Ozkaynak et al., 2013; Bravo et al., 2012). Saturation sampling over longer time-scales may be used to ascertain spatial variation across an urban area, but at the expense of temporal resolution (Matte et al., 2013). Another limitation of using fixed-site ambient monitors to estimate exposure concentration is that ambient monitoring data can be incomplete due to missing data and sampling frequency limitations. Often missing data can be estimated using data from nearby monitors (e.g., by linear regression) or by temporal interpolation. Temporal interpolation can also be used for data analysis when the data are sampled with 1-in-3 or 1-in-6-day sampling frequencies (Junger and de Leon, 2015; Gomez-Carracedo et al., 2014; Junninen et al., 2004; Hopke et al., 2001), which is common for PM components. Interpolation schemes are used to capture hour-of-day and day-of-week trends. Estimates of mixing height using meteorological data and/or tracer component data are also used to improve the completeness of ambient monitor data.

Limited available $PM_{10-2.5}$ data for inter-site correlation and COD support previous statements that $PM_{10-2.5}$ tends to be spatially variable. Thornburg et al. (2009) measured correlation and COD in Detroit for personal multi-stage impactors measuring $PM_{10-2.5}$ and found Pearson R = 0.28−0.63 and COD = 0.17−0.41 during Summer and Pearson R = 0.03−0.76 and COD = 0.26−0.50 during Winter. Similarly, Lagudu et al. (2011) measured $PM_{10-2.5}$ using passive samplers and observed COD = 0.44−0.78 in the Spring and COD = 0.37−0.88 in the Fall. Neither the Thornburg et al. (2009) nor the Lagudu et al. (2011) studies included data for distances between specific monitors to ascertain if COD increased with increasing distance between samplers. This lack of data adds greater uncertainty to the characterization of $PM_{10-2.5}$ spatial variability.

Spatial variability of $PM_{2.5}$ components can vary among the components. Bell et al. (2011a) presented correlations for FRM or FEM pairs for seven $PM_{2.5}$ components (NH_4^+, EC, NO_3^-, OC, Si, Na^+, S) in a review paper. Bell et al. (2011a) observed that the bulk of the monitor-pair correlation is maintained relatively well (roughly Pearson R = 0.8) for NH_4^+, NO_3^-, and SO_4^{2-} (Figure 3-6). Other components had wider variability in correlations even when the monitor pairs were closer together, as was the case for EC, Si, and Na^+. OC correlations were more variable than for NH_4^+, NO_3^-, or SO_4^{2-} across monitor pair distances but not as variable as EC, Si, or Na^+. Dionisio et al. (2013) compared the coefficient of variation (CV = σ/μ) of six air pollutants' concentrations across space using a hybrid AERMOD-background model of concentrations in the Atlanta, GA metropolitan area. They observed the following ordinal relationship of the covariates' median CVs: NO_X (0.88) > CO (0.58) > EC (0.50) > $PM_{2.5}$ (0.13) > O_3 (0.07) > SO_4 (0.05) (see Figure 3-6). Likewise, Goldman et al. (2012) and Ivy et al. (2008) both used monitoring data from the Atlanta, GA metropolitan area to estimate spatial correlation functions, and they observed that the spatial correlograms for O_3, PM_{10}, $PM_{2.5}$, and the $PM_{2.5}$ components SO_4^{2-}, NO_3^-, NH_4^+, and OC were much less steep than for NO_2, NO_X, CO, SO_2, and EC. Hence, $PM_{2.5}$ was observed to be less spatially variable than copollutants frequently associated with traffic (NO_X, CO, EC) or industry (SO_2). Similarly, Goldman et al. (2012), Ivy et al. (2008) and Sajani et al. (2010) all observed less spatial variability of PM_{10} compared with NO_2 or NO_X. If PM_{10} were comprised primarily of $PM_{2.5}$, then these findings would be consistent with the Dionisio et al. (2013) results as well. These findings could reflect the influence of local sources and suggest that spatial variability of $PM_{2.5}$ components could have a large influence on monitor pair correlations for $PM_{2.5}$, with components with greater variation being influenced more by primary sources than components produced through secondary atmospheric chemistry.



Source: Permission pending Goldman et al. (2012).

Figure 3-6 Spatial correlation of $PM_{2.5}$ components for monitor pairs described in the review study.

It was known at the time of the 2009 PM ISA (U.S. EPA, 2009b) that spatial variability of $PM_{2.5}$ was lower than for $PM_{10–2.5}$ and UFP. Data to characterize $PM_{10–2.5}$ and UFP spatial concentration surfaces remain limited but generally support that comparison. More recent data for $PM_{2.5}$ components shows that components that are influenced by primary sources tend to be more spatially variable than components produced via atmospheric chemistry.

3.4.2.3 Instrument Accuracy and Precision

The influence of instrument error on health effect estimates from epidemiologic studies varies with study design. Inter-monitor comparison is often used to estimate instrument precision. Accuracy and

precision of ambient monitors is described in Section 2.5.4, and accuracy and precision for personal $PM_{2.5}$ monitors were described in the 2009 PM ISA (U.S. EPA, 2009b) and have not changed markedly since the last review.

More attention is given at present to $PM_{10–2.5}$, because those measurements were not as prevalent at the time of the 2009 PM ISA (U.S. EPA, 2009b). Errors associated with measurements of $PM_{10–2.5}$ are described in Section 2.4.2. Use of subtraction methods for estimating $PM_{10–2.5}$ concentration can lead to substantial errors. This is particularly true when the $PM_{10–2.5}$ is semivolatile. Clements et al. (2013) tested different methods for measuring PM_{10} and $PM_{2.5}$ and calculating $PM_{10–2.5}$ via subtraction methods and found that the nonvolatile PM endemic to Colorado were measured with less error by instruments that did not account for semivolatile losses. Biases in calculated $PM_{10–2.5}$ concentrations caused reductions in correlation coefficients across sites, leading to an incorrect picture of spatial variability in $PM_{10–2.5}$ concentration across the test area.

A number of studies have characterized errors associated with measuring UFP (Section 2.4.3). UFP concentrations are often referred to without specific reference to size distribution. Some studies report number count as UFP, while other studies use mobility methods to impose an upper particle size limit of 100 nm or 250 nm. CPCs typically have lower size detection limits of 10 nm (Liu and Kim, 1977), while mobility have lower size detection limits of 1 nm (Kangasluoma et al., 2015; Lehtipalo et al., 2014; Kuang et al., 2012; Jiang et al., 2011; Vanhanen et al., 2011; Iida et al., 2008). Hence, use of CPCs in an epidemiologic study of short or long-term exposure may lead to an underestimation of the UFP exposure concentration.

For epidemiologic studies of short-term exposure, Goldman et al. (2010) investigated instrument precision error at locations where ambient monitors were collocated. Correlations between collocated measurements of $PM_{2.5}$ mass and components (SO_4^{2-}, NO_3^-, NH_4^+, EC, OC) ranged from Pearson $R = 0.85$ for OC to Pearson $R = 0.97$ for $PM_{2.5}$ mass. Depending on specific conditions such as sampler type (e.g., passive vs. continuous), meteorological conditions, or presence of semivolatile PM, instrument errors may vary in total magnitude or direction so that error is not always positively correlated with concentration. Analysis of instrument error compared with measured and true (i.e., simulated) concentrations for the Goldman et al. (2010) study suggested that the error was not correlated with either measured or true concentrations. Hence, the instrument error was neither pure Berkson error nor pure classical error, but it probably retained Berkson-like and classical-like characteristics. If instrument error and concentration are positively correlated, then error in the exposure concentration estimates will be larger in locations where there are more prevalent or stronger primary sources or at times when PM emissions are higher for a given location. Moreover, if error is positively correlated with concentration, then it would be anticipated that the magnitude of the instrument error is largest at times of day when emissions are highest.

Instrumentation bias could be anticipated to influence exposure concentration estimates used in long-term PM exposure studies in some situations. For example, geostatistical or LUR models may

underestimate exposure concentration when the model is fit using data from samples that have experienced negative artifacts due to volatility. Ambient temperature and relative humidity would not be expected to vary greatly within a city. Because climate and ambient sources are more likely to differ among cities, instrumentation error occurring when warm temperatures exacerbate evaporation could have a larger influence on the comparison of exposure concentrations among cities.

3.4.2.4 Model Accuracy and Precision

Error in PM exposure model predictions leads to some error in the health effect estimates from epidemiologic studies in which they are used. However, the implications of the type of errors depends upon the application. In statistical models used in epidemiologic studies, spatial, temporal, or concentration biases and errors may align with the health data being used, leading to potential errors and increased uncertainties in the health effect estimates (NRC, 2007).

The performance of the exposure models in recreating exposure estimates can impact the ensuing health analyses. LOOCV is often used to assess the exposure concentration estimates (Section 3.3.2), particularly for LUR. One issue with LOOCV is that monitoring sites can be clustered, such that removing a monitor that is near other monitors does not "stress" the model, because the value from the nearby monitors will lead to an accurate replacement value. That issue, along with the majority of sites being clustered in urban areas, can lead to seemingly good performance metrics that are not indicative of how well the method can estimate exposure concentrations away from monitoring sites. Given that exposure models are developed, in part, to estimate levels away from observation locations it is informative to have approaches to evaluate how well the method can estimate exposures in such cases. One approach that has been developed is to remove multiple monitors that are spatially grouped such that they are not being influenced by nearby observations (Lv et al., 2016). A related issue arises in LUR modeling. If a hold-out technique uses 90% of the data to both build and train the model, a different set of independent variables may be chosen than those in the full model. Wang et al. (2014) argued that a preferable approach is to build the full model and retrain it with 90% of the data. Wang et al. (2015) found that the LUR model performance (R^2 ranged from about 0.3 to 0.9 for $PM_{2.5}$) was positively associated with the magnitude of the health effect estimate. Alexeeff et al. (2015) conducted a simulation study using high resolution fields developed from MAIAC satellite data as the "true" field, and developed simulated spatiotemporal fields by kriging and using LUR. R^2 of the kriging and LUR methods ranged from about 0.24 to 0.98. They linked poor performance (e.g., lower R^2) with bias in the health effect estimates. Goldman et al. (2011) and Goldman et al. (2010) also found in a simulation study that increased exposure measurement error led to negative bias in the health outcomes and increased uncertainty. These, and related studies, show the potential impact of the accuracy of the exposure concentration metrics on bias and uncertainty in the health effect estimates in an epidemiologic study.

A major issue in using concentration surfaces estimated by CTMs for epidemiologic analyses is that the errors in the model inputs [e.g., emissions, (Koo et al., 2015; Xu et al., 2015; Hao and Larkin, 2014; Larkin et al., 2014; Paulot et al., 2014; Urbanski et al., 2011; Zhang et al., 2010b), meteorology (Digar et al., 2011), and surface characteristics] and parameters (e.g., chemical reaction, thermodynamic, and turbulence descriptions) lead to output errors, including time- or location-varying biases (Hogrefe et al., 2015; Koo et al., 2015; Porter et al., 2015; Hogrefe et al., 2014; Rao et al., 2014; Appel et al., 2013; Appel et al., 2012; Simon et al., 2012; Napelenok et al., 2011; Civerolo et al., 2010; Foley et al., 2010; Zhang et al., 2010b; Swall and Foley, 2009). Meteorological models, which are typically used to provide inputs to air quality models, have similar issues with inputs and parameters, thus leading to uncertain output fields that also have errors and uncertainties. Arrandale et al. (2011) also noted that mean bias and correlation varied by region with distinct spatial patterns. Given the potential for such errors, understanding how well such models can reproduce PM (including size and components) concentration fields for exposure or exposure concentration modeling is important.

Errors can be large, particularly when considering individual PM components (e.g., OC) or size fractions (e.g., UFPs) (Koo et al., 2015; Stanier et al., 2014; Zhang et al., 2010b). In terms of model parameters, this is often due to a fundamental lack of understanding of the processes, for example knowledge of the chemical reactions and products involving organic compounds or nucleation (Donahue et al., 2013; Shiraiwa et al., 2013; Worton et al., 2013; Chen et al., 2011; Donahue et al., 2011; Hoyle et al., 2011; Pierce et al., 2011; Zhang et al., 2010a; Kulmala et al., 2009; Nieminen et al., 2009; Kroll and Seinfeld, 2008; Kuang et al., 2008; Kulmala and Kerminen, 2008). Koo et al. (2015) conducted an extensive evaluation of two CTMs (CMAQ and CAMx) for the same domain, and found that the models, overall, performed similarly for $PM_{2.5}$, but differences were found upon further investigation (e.g., performance for individual PM components, and how the errors varied based on region and time). The Koo et al. (2015) study demonstrated that the same model will perform differently, sometimes dramatically, depending upon domain and time period such that performance in one application is not definitive support that performance will be similar in a different application. The limited availability of sub-24-hour PM mass concentration and component data has inhibited the evaluation of CTMs for simulating the diurnal variation of PM. Koo et al. (2015) used diurnally varying $PM_{2.5}$ compositional information available from SEARCH (Hansen et al., 2006; Hansen et al., 2003) to further assess CMAQ and CAMx model performance and found that, in addition to a low bias in OC and ammonium, during the summer the models also simulated a drop during the daytime that was not found in the observations. This additional bias could impact studies that used temporally finer-scale $PM_{2.5}$ exposure concentration estimates.

Due to the various potential errors in using air quality models to develop exposure concentration fields, Marmur et al. (2006b) and Marmur et al. (2006a) concluded that the direct use of CTMs in epidemiologic studies of acute health endpoints would lead to attenuation in the observed outcomes. Spatially- and temporally-varying biases and errors would also lead to questions of their use in epidemiologic studies of long-term exposures as well if the fields are not modified (Bravo et al., 2012),

such as by blending with PM concentrations derived from satellite observations, as discussed in Section 3.3.3.

3.4.3 Costressor Relationships

To assess the independent effects of PM in an epidemiologic study of health effects, it is necessary to identify (Bateson et al., 2007): (1) which copollutants (e.g., NO_2, CO, BC) and additional exposures (e.g., noise, traffic levels) are potential confounders of the health effect-PM relationship so that their correlation with PM can be tested and, if needed, accounted for in the statistical model; (2) the time period over which correlations might exist so that potential confounders are considered appropriately for the time period relevant for the epidemiologic study design (e.g., pollutants or other factors that are correlated over the long term might not be important for a short-term exposure epidemiologic study); and (3) the spatial correlation structure across multiple pollutants, if the epidemiologic study design is for long-term exposure. Given that a covariate must be correlated with both the exposure and the health effect to be a confounder, the potential for confounding of PM-related health effects can vary by the health endpoint of interest.

For copollutants that do show high correlations, copollutant models may be appropriate to adjust the effect estimate for each pollutant for the potential confounding effects of another pollutant if each pollutant is associated with the health effect (Tolbert et al., 2007). If one copollutant is a surrogate for an etiologically linked pollutant, copollutant models may attribute the effect to the copollutant measured with less error, regardless of whether it is the etiologically linked pollutant. In copollutant models where PM is measured with more error than a copollutant, a differential effect occurs where the health effect estimate of PM exposure may be lower than the health effect estimate of the copollutant, even if PM is the true causal agent (Zeger et al., 2000), as discussed in the 2009 PM ISA (U.S. EPA, 2009b). If this occurs, the health effect related to PM exposure would be underestimated or potentially not detected. Positive correlation between PM and the copollutant and between the exposure measurement errors of PM and the copollutant can add more negative bias to the PM health effect estimate. Spatial variability of concentration differs among the particle size spectrum, and this may cause more exposure measurement error in $PM_{10-2.5}$ or UFP compared with $PM_{2.5}$ (Section 3.4.2.2). Hence, if $PM_{2.5}$ is measured with less error than copollutants, it is likely that the effect will be attributed to $PM_{2.5}$.

This section considers temporal copollutant correlations and how relationships among copollutants may change in space. Temporal copollutant correlations are computed from the time series of copollutant concentrations for two different collocated monitors. Temporal correlations are informative for epidemiologic studies of short-term PM exposure when the sampling interval is less than a month for each of the copollutants. Temporal correlations are informative for epidemiologic studies of long-term PM exposures when sampling intervals are months-to-years. Spatial relationships are evaluated by comparing within-pollutant variation across space for different pollutants. The following sections review

coexposures that can potentially confound the relationship between a health effect and PM exposure over different temporal and spatial resolutions.

3.4.3.1 Temporal Relationships among Ambient PM and Copollutant Exposures

AQS data presented in the 2009 PM ISA (U.S. EPA, 2009b) demonstrated most correlations between $PM_{2.5}$ and gaseous copollutants were typically between −0.2 and 0.8 with average and median values around 0.2 to 0.5. Correlations between $PM_{2.5}$ and $PM_{10–2.5}$ were observed in a similar range. Given limited data for $PM_{10–2.5}$ at the time when the 2009 PM ISA was written, correlations between $PM_{10–2.5}$ and gaseous copollutants were not presented.

To place the copollutant correlation discussion in the context of the epidemiologic studies, we present the correlation data for the epidemiologic studies in CHAPTER 5, CHAPTER 6, CHAPTER 7, CHAPTER 8, CHAPTER 9, CHAPTER 10, and CHAPTER 11 that reported correlations of $PM_{2.5}$, $PM_{10–2.5}$, or UFP with copollutants. Figure 3-7, Figure 3-10, and Figure 3-13 (for $PM_{2.5}$, $PM_{10–2.5}$, and UFP, respectively) plot study data for correlations with gaseous copollutants O_3, CO, SO_2, NO_2, and NO_X and with particulate copollutants. More data were available for $PM_{2.5}$ compared with $PM_{10–2.5}$ or UFP (as NC, based on the assumption that the majority of particles are smaller than 100 nm), and so Figure 3-7 is divided into four panels for all data combined, acute timescales within 1 hour, short-term timescales between 1 hour and 2 weeks (with most data obtained at a 24-hour timescale), and long-term timescales longer than 2 weeks. Only 24-hour data were available for $PM_{10–2.5}$ and UFP correlation data.

For acute and short-term timescales (within 1 hour and 2 weeks, respectively), median correlations of $PM_{2.5}$ with copollutants were ordered CO > NO_2 > SO_2 > NO_X > O_3 (Figure 3-7). Acute data were relatively sparse but produced median correlations that were lower than those for short-term. Because data were combined across studies, Figure 3-7 includes both Pearson and Spearman correlations. Short-term correlations for CO and NO_2 reached as high as $R = 0.9$, while roughly 20% of the short-term correlations between $PM_{2.5}$ and O_3 were negative. Correlation data between UFP and O_3 were limited to one study (Kearney et al., 2011), and three of four reported correlations were negative in contrast to the mostly positive correlations between $PM_{2.5}$ and O_3 (Figure 3-13). Data for short-term correlations of $PM_{2.5}$ with $PM_{10–2.5}$ and UFP were around $R = 0.5$, although data were also sparse for these comparisons. Median correlations of $PM_{10–2.5}$ and gases ranged between $R = 0.3$ and $R = 0.5$, although limited data were available for these comparisons. Correlations of $PM_{10–2.5}$ with CO and NO_2 were around $R = 0.5$, potentially indicating some commonality of sources, such as traffic emissions of CO and (indirectly) of NO_2 with $PM_{10–2.5}$ generated by brake dust (Section 2.4.2). For short-term correlations of UFP with copollutant gases and particles, median correlations were 0.5 for NO_2 and lower for everything else. It is possible that low correlations could be related to the short lifetime of UFP relative to other PM size fractions. However, because limited data for UFP correlations were available, few conclusions can be

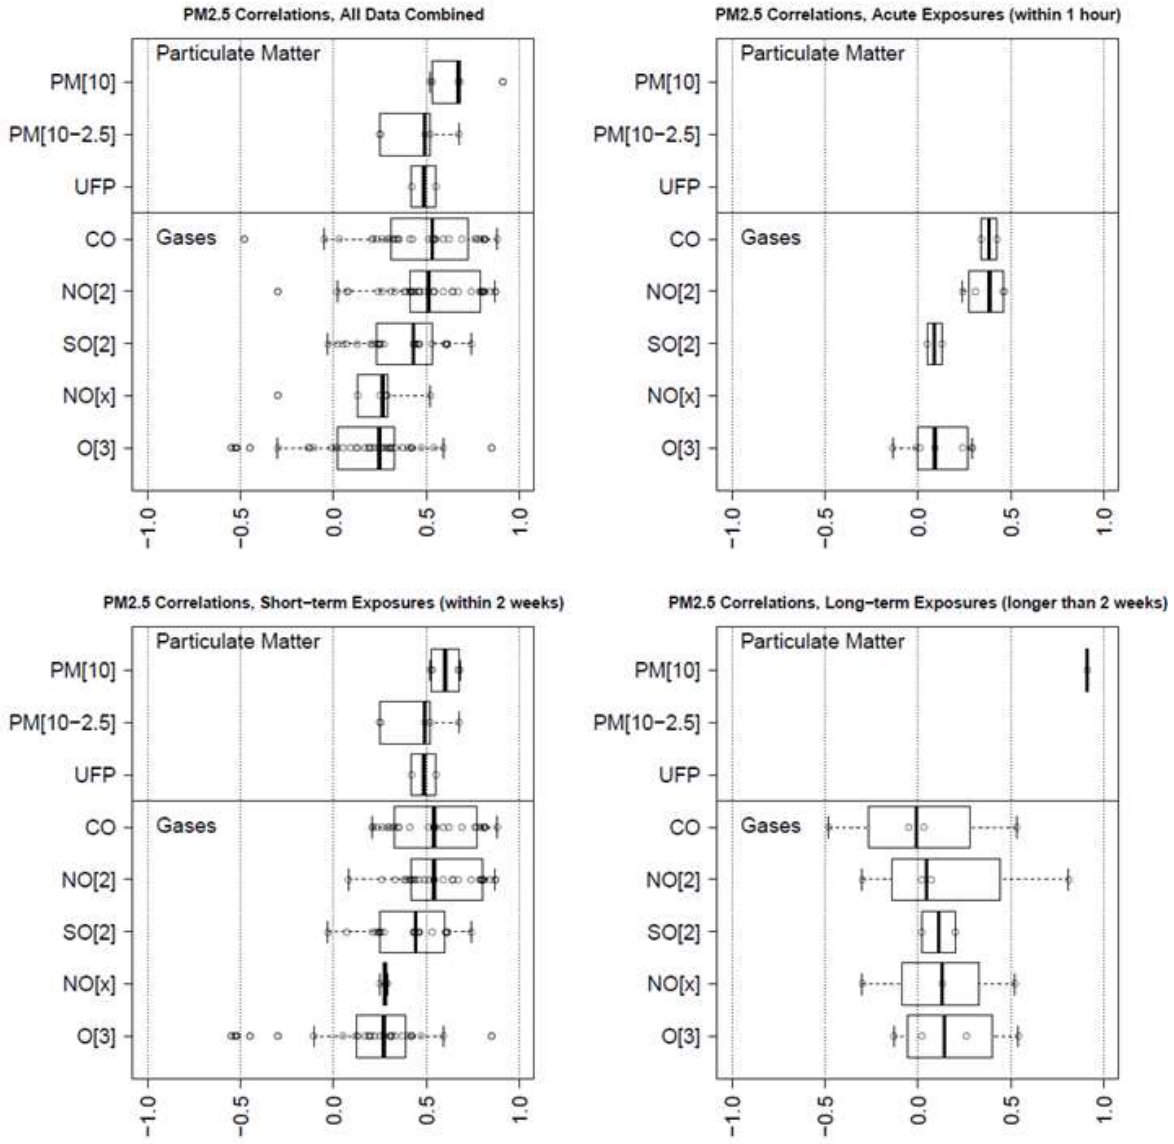
drawn. Because data were combined across studies, Figure 3-13 also includes both Pearson and Spearman correlations.

Median long-term correlations (i.e., longer than 2 weeks) between $PM_{2.5}$ and copollutants follow a pattern opposite to that for short-term correlations: $O_3 > NO_X > SO_2 > NO_2 > CO$ (Figure 3-7). Median correlations were between $R = 0$ and $R = 0.2$. Limited quantity of data existed for long-term correlations between $PM_{2.5}$ and copollutants and no data existed for long-term correlations of $PM_{2.5}$ with $PM_{10-2.5}$ or UFP. Moreover, overlapping 25th-to-75th percentile and 5th-to-95th percentile intervals reduce confidence in the comparison.

For comparison to the epidemiologic data, short-term (24-hour average) correlations of $PM_{2.5}$ and copollutants and of $PM_{10-2.5}$ and copollutants were studied using air quality data from collocated monitors reported within the U.S. EPA AQS repository system during 2013−2015. 438 sites met the 75% data completeness criteria presented in Section 2.5.1.1. Pearson correlations were used to evaluate temporal correlations among ambient $PM_{2.5}$ concentrations and NAAQS copollutant concentrations. Figure 3-8 displays the distribution of correlations between NAAQS copollutants and 24-hour $PM_{2.5}$ for annual data for 2013−2015, and Figure 3-9 displays the distribution of correlations broken down by season. For CO, SO_2, and NO_2, 1-hour daily max concentrations are used, while for O_3, 8-hour daily max concentrations are considered. Annual and seasonal copollutant correlation plots for 24-hour $PM_{10-2.5}$ are provided in Figure 3-11 and Figure 3-12.

Across seasons, 24-hour average $PM_{2.5}$ and $PM_{10-2.5}$ concentrations reported in the AQS consistently have the highest correlations with PM_{10} concentrations (median Pearson $R = 0.7-0.8$ for $PM_{2.5}$, median Pearson $R = 0.7-0.9$ for $PM_{10-2.5}$) (Figure 3-9, Figure 3-12). This could occur if $PM_{2.5}$ were a large contributor to PM_{10}, if $PM_{2.5}$ and $PM_{10-2.5}$ were of the same source, or if $PM_{2.5}$ and $PM_{10-2.5}$ were of different sources whose emissions were coordinated in time. Correlations between $PM_{2.5}$ concentrations and $PM_{10-2.5}$ concentrations are lower than either size fraction's correlation with PM_{10} across seasons (median Pearson $R = 0.2-0.5$), with lowest correlations in winter. This is consistent with observations from the epidemiology literature (Figure 3-7, Figure 3-10), although data for $PM_{10-2.5}$ correlations are limited. Figure 3-7 and Figure 3-10 do not distinguish between Pearson and Spearman correlations, because data are combined across studies. In the summer and spring, correlations of $PM_{2.5}$ with SO_2, NO_2, and CO are all roughly $R = 0.2$. In the fall and winter, however, correlations of $PM_{2.5}$ are ordered as $CO > NO_2 > SO_2$, consistent with correlations reported in the epidemiology literature (Figure 3-9). Higher correlations of CO and NO_2 with $PM_{2.5}$ may be indicative of combustion sources. Correlation of $PM_{2.5}$ and O_3 is highest during the summer (median Pearson $R \sim 0.45$) and is negative during the winter. High summer correlations could reflect photooxidation to produce simultaneously higher levels of O_3 and secondary PM (Section 2.3.2.3), (U.S. EPA, 2013). Median correlations of $PM_{10-2.5}$ with SO_2, NO_2, CO, and O_3 were all in the range of $R = 0.1-0.3$ across seasons. This may reflect the origin of $PM_{10-2.5}$ largely as dust rather than by combustion, other industrial processes, or photochemistry.

Correlation data from epidemiology studies (Figure 3-10) are higher for CO and NO_2, but only a limited number of studies reported those correlations.



Based on epidemiologic studies reporting correlations in CHAPTER 5, CHAPTER 6, CHAPTER 7, CHAPTER 8, CHAPTER 9, CHAPTER 10, and CHAPTER 11.

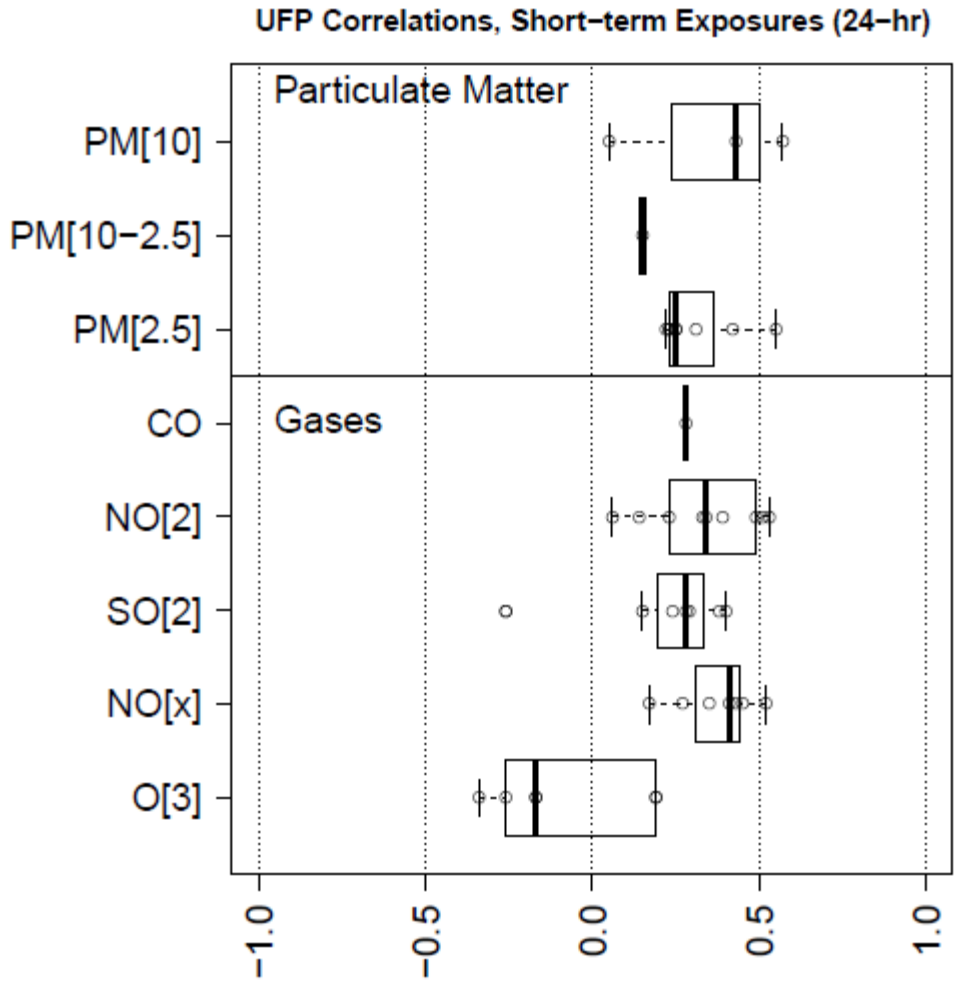
Limited data were available from the peer-reviewed literature for correlations of UFP concentration with concentrations of other PM size fractions or of gases (Figure 3-13). Median Pearson correlations around $R = 0.5$ were reported for UFP with $PM_{2.5}$ and with NO_2 and NO_X. Without more data to identify copollutant relationships for UFP, it is difficult to interpret these data.



Note: Only 24-hour data were available. Based on epidemiologic studies reporting correlations in Chapters 5−11.

3.4.3.2 Spatial Relationships among Ambient PM and Copollutant Exposures

When an epidemiologic study design relies on spatial contrasts to draw conclusions, such as for an epidemiologic study of long-term exposure, unmeasured spatial correlation between copollutants may lead to positive bias in the health effect estimate for each of the pollutants included in the model. Paciorek (2010) performed simulations and analyzed case study data (of the relationship between birth weight data and BC concentrations in eastern Massachusetts) to test the effect of spatial errors on health effect estimates in long-term exposure epidemiologic studies. In this study, Paciorek (2010) selected BC as a

PM component because it is spatially variable. He identified unmeasured spatial confounding as a key driver in biasing health effect estimates in a spatial regression. Paciorek (2010) maintained that bias can be reduced when variation in the exposure concentration metric occurs at a smaller spatial scale than that of the unmeasured confounder. The findings of Paciorek (2010) would be expected to be more significant for more spatially-variable $PM_{10-2.5}$, UFP, and BC than for $PM_{2.5}$, for which less spatial error would be anticipated.

3.4.3.3 Personal and Indoor Relationships between PM and Copollutant Exposures

No new studies on relationships among personal and ambient copollutants had been performed since the 2009 PM ISA (U.S. EPA, 2009b). Those data are presented graphically in Figure 3-14, Figure 3-15, and Figure 3-16. Figure 3-14 displays copollutant correlations among personal exposures to $PM_{2.5}$, toluene, O_3, and CO. The data from Chang et al. (2000) were obtained in Baltimore, MD in the summer of 1998 and winter of 1999. Median correlations were 0.39 for the personal-personal relationship for $PM_{2.5}$ versus CO, 0.32 for $PM_{2.5}$ versus toluene, and 0.045 for $PM_{2.5}$ versus O_3. Correlations were highest when personal measurements were obtained outdoors away from the road during the summer for $PM_{2.5}$ versus O_3 and $PM_{2.5}$ versus CO during the summer and for $PM_{2.5}$ versus toluene during the winter. The higher correlations obtained away from the road may reflect the secondary nature of much of the measured $PM_{2.5}$.

Median personal-ambient slopes between $PM_{2.5}$ and gaseous copollutants are generally between 0 and 0.5, as shown in Figure 3-15. These data were obtained from Koutrakis et al. (2005), Sarnat et al. (2005), Sarnat et al. (2001), and Sarnat et al. (2006b) from Boston, MA, Baltimore, MD, and Steubenville, OH. Median relationships of personal $PM_{2.5}$ exposure with ambient gaseous copollutant concentrations were higher with more variability than those of personal SO_4^{2-} exposures with ambient gas concentrations, indicating that nonambient $PM_{2.5}$ exposure may have amplified these relationships and added uncertainty. Data were more limited for relationships between personal EC concentration and ambient gaseous copollutant concentrations, but these tended to be lower as well. Greater variability occurred in some cases for the relationships between personal exposure to gaseous copollutants and ambient concentrations of $PM_{2.5}$, EC, and SO_4^{2-}, perhaps as a result of limited amounts of data.

Median slopes for the relationship between personal exposure to PM or SO_4^{2-} with gaseous copollutants (NO_2, O_3, and SO_2) tended to be between 0 and 0.5 (Figure 3-16). The exception was the relationship between $PM_{2.5}$ and SO_2, which was negative but of similar magnitude. These data were obtained from Koutrakis et al. (2005), Sarnat et al. (2005), and Sarnat et al. (2001). A slight reduction in median slope along with smaller data intervals were observed when personal SO_4^{2-} exposure was used in lieu of personal $PM_{2.5}$ exposure, suggesting that the nonambient component of personal exposure may have influenced these relationships. Nonambient sources of O_3 and SO_2 are much less prevalent, so it is unlikely that they would have influenced their respective relationships. Although NO_2 does have indoor

(indirect) sources, variability in these relationships was lower than for the other gaseous copollutant exposures.

3.4.3.4 Traffic-related Noise

The 2009 PM ISA (U.S. EPA, 2009b) did not consider the relationship of PM with traffic-related noise levels. Recent evidence is inconsistent regarding the correlations of PM concentrations with traffic and noise levels (HEI, 2010). There are differences among the studies exploring the health effects of PM and noise regarding size cut of PM measured, road type, and surrounding features. Hence, the role of traffic and noise as confounders or independent variables in the relationship between health effects and PM exposure is unclear.

Several studies have examined the relationship of traffic-related noise with PM concentrations. Kheirbek et al. (2014) added noise level meters to the dense New York, NY monitoring project described in Ross et al. (2013) and observed that 1-week average noise level (measured as dB[A]), obtained at 60 locations during Fall 2012, correlated with Pearson $R = 0.45$ for $PM_{2.5}$ concentration and Pearson $R = 0.62$ for BC concentration. Boogaard et al. (2009) measured UFP, $PM_{2.5}$, and noise (measured as dB[A]) while bicycling on scripted 10- to 20-minute routes for ten cities in The Netherlands and found a median correlation of Pearson $R = 0.34$ across cities for UFP and noise while the median correlation was Pearson $R = 0.009$ for $PM_{2.5}$ and noise. Gan et al. (2012b) calculated the correlations among air pollutants and noise from road traffic and aircraft using 5-minute data from 103 sites in Vancouver, BC, Canada during 2003 (dates not stated). They observed lower correlations for $PM_{2.5}$ concentration with road traffic noise (Spearman $R = 0.14$) compared with that for BC (Spearman $R = 0.45$). However, correlations between $PM_{2.5}$ and aircraft noise were higher (Spearman $R = 0.31$) than for BC (Spearman $R = -0.07$). Over a 5-year average, Gan et al. (2012a) reported the correlation between $PM_{2.5}$ concentration and noise from road traffic to be Spearman $R = 0.14$. Reported correlation of 5-year average BC concentration with BC concentration had a Spearman $R = 0.44$. These findings are consistent with the short-term observations reported in Gan et al. (2012b).

Ross et al. (2011) also examined relationships of different frequency noises with $PM_{2.5}$ and EC concentrations using continuous monitors collecting 48,000 samples per second for six 24-hour periods in August 2009. Ross et al. (2011) measured the relationships between traffic level, noise, and concentrations of $PM_{2.5}$ and EC in New York, NY as part of the Ross et al. (2013) study. Unweighted noise of all frequencies was uncorrelated with $PM_{2.5}$ concentration (Spearman $R = 0.20$) but correlation increased for EC concentration (Spearman $R = 0.35$) for all times. Correlations were higher for medium frequency noise ($PM_{2.5}$: Spearman $R = 0.20$; EC: Spearman $R = 0.39$) compared with high frequency noise ($PM_{2.5}$: Spearman $R = 0.14$; EC: Spearman $R = 0.15$) but were similar for low frequency noise ($PM_{2.5}$: Spearman $R = 0.19$; EC: Spearman $R = 0.32$). Correlations between $PM_{2.5}$ and low frequency noise (Spearman $R = 0.3$) were higher during rush hour than at night for low frequency noise or for any time for medium and high frequency noise. At night, high frequency noise had a higher correlation with EC concentration (Spearman $R = 0.4$).

Distance to road has also been observed to influence the relationship between noise and PM concentration as a surrogate for exposure concentration. The Gan et al. (2012b) study described above

also reported Spearman correlations between 5-minute average. A-weighted equivalent noise (i.e., noise level that is adjusted to noise perception by the human ear) and concentrations of $PM_{2.5}$ and BC for buffers of 50 m and 150 m of a highway (defined as A1 and A2 roads) and a major road (defined as A1, A2, and A3 roads). Correlations for $PM_{2.5}$ and noise were Spearman R = 0.02 within 50 m of the highway, Spearman R = 0.03 within 150 m, and Spearman R = 0.17 when further than 150 m. For a major road, correlations for $PM_{2.5}$ and noise were Spearman R = 0.24 within 50 m, Spearman R = 0.15 within 150 m, and Spearman R = 0.14 when further than 150 m. Results for correlations between BC and noise were higher than for correlations between $PM_{2.5}$ and noise, and they were more consistent between highways (within 50 m: Spearman R = 0.17, within 150 m: Spearman R = 0.38, further than 150 m: Spearman R = 0.41) and major roads (within 50 m: Spearman R = 0.26, within 150 m: Spearman R = 0.46, further than 150 m: Spearman R = 0.31). Allen et al. (2009) studied the relationship between UFP concentration, and 5-minute average A-weighted equivalent noise for 105 locations in Chicago, IL and Riverside, CA using measurements taken in December 2006 and April 2007. After adjustment for regional unspecified air pollutant concentration gradients, correlation of UFP with noise was Pearson R = 0.31 for Chicago and Pearson R = 0.41 for Riverside. Correlation of noise with UFP concentrations was higher within a 100-m buffer of the road (Chicago: Pearson R = 0.37; Riverside: Pearson R = 0.58) compared with outside the buffer (Chicago: Pearson R = 0.08; Riverside: Pearson R = 0.50).

3.4.4 PM Composition and Exposure Assessment

Compositional differences in ambient PM and ambient PM that has infiltrated indoors were discussed briefly in the 2009 PM ISA (U.S. EPA, 2009b). Several studies cited in the 2009 PM ISA found that SO_4^{2-} comprised the largest proportion of ambient $PM_{2.5}$ exposure in studies from the eastern U.S., while a study in Denver found NO_3^- to be the largest contributor to $PM_{2.5}$. Studies of differential infiltration of $PM_{2.5}$ by BC or OC found that BC contributed more to indoor $PM_{2.5}$ compared with OC. 2013−2015 composition data across the U.S. shows that, while there is still more SO_4^{2-} in the east compared with the west, OC now is the most prevalent component of $PM_{2.5}$ in many areas across the country (Section 2.5.1.1.6).

This section provides new information on PM composition for $PM_{2.5}$, $PM_{10-2.5}$, and UFP from the peer-reviewed literature. Section 3.4.4.1 presents correlations between PM mass and composition from AQS and from the peer-reviewed literature. Section 3.4.4.2 is a new section of the ISA that presents data on studies of ROS exposure in the literature.

3.4.4.1 Composition

Select epidemiologic studies of the health effects of PM exposure have examined potential associations between health effects and exposure to PM components (CHAPTER 5, CHAPTER 6,

CHAPTER 7, CHAPTER 8, CHAPTER 9, CHAPTER 10, and CHAPTER 11). These studies compare the effect estimates for exposure to PM components with health effect estimates for exposure to total PM, measured as ambient mass concentration (MC), NC, or personal exposure concentration. This section presents relationships between concentrations of total PM with PM components.

Figure 3-17 displays correlations for 24-hour ambient $PM_{2.5}$ mass concentration with mass concentration for select components of $PM_{2.5}$ measured from the AQS during 2013−2015 on an annual basis, and Figure 3-18 displays the correlations on a seasonal basis. Median correlations with $PM_{2.5}$ were ordered as OC > SO_4^{2-} > EC > NO_3^- > Cl > Si, with correlations above Pearson R = 0.5 for OC, SO_4^{2-}, EC, and NO_3^-. Sulfate, NO_3^-, and OC are most commonly a product of chemical reactions of air pollutants in the atmosphere, and PM produced during atmospheric chemistry is often in the fine size range (Section 2.2). The median correlation of $PM_{2.5}$ with Cl and Si was approximately Pearson R = 0.2. On a seasonal basis, correlations between $PM_{2.5}$ and NO_3^- were lower during the spring and summer months, perhaps coinciding with less home heating fuel use during the summer. In the peer-reviewed literature (Figure 3-19), correlations of ambient $PM_{2.5}$ with ambient SO_4^{2-} and NO_3^-, used as exposure concentration surrogates, were similarly high (Ito et al., 2011; Ostro et al., 2010; Ostro et al., 2009), but much greater variability in correlations were observed for ambient OC and more so for EC or BC (which were combined for presentation purposes). Median correlations were around 0.5 for most trace metals, but higher correlations were observed for S, Zn, and V in New York (Ito et al., 2011) and Southern California (Ostro et al., 2010; Polidori et al., 2009). The higher correlations for S are likely explained by SO_4^{2-}. Ito et al. (2011) and Polidori et al. (2009) attributed elevated correlations with Zn and V to residential oil combustion.

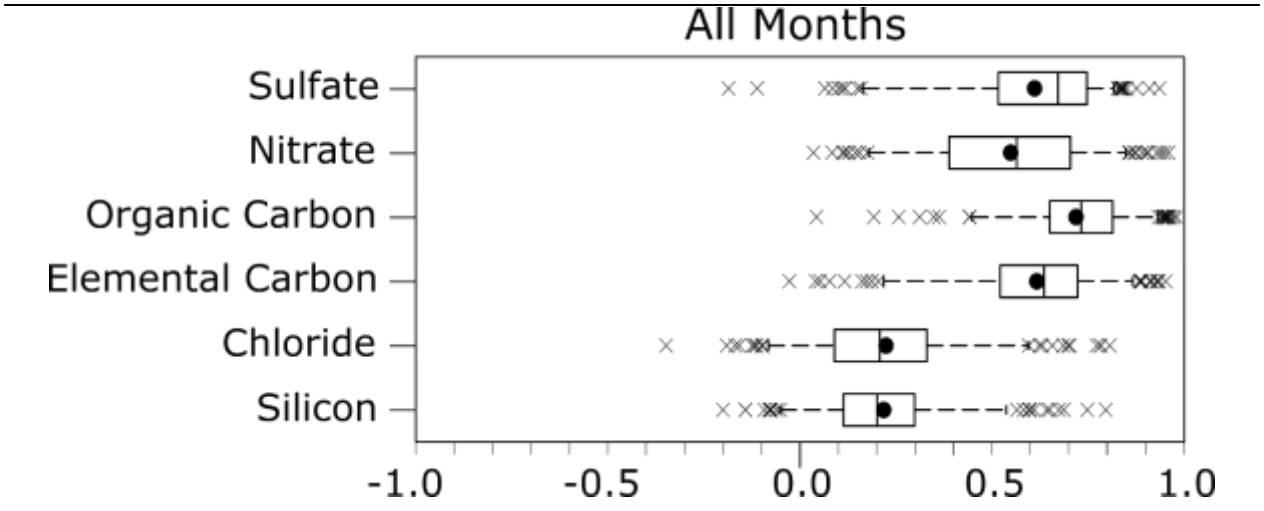

Figure 3-17 Distribution of Pearson correlation coefficients for annual 24-hour average $PM_{2.5}$ mass concentration with mass concentration of $PM_{2.5}$ components from the Air Quality System during 2013−2015.

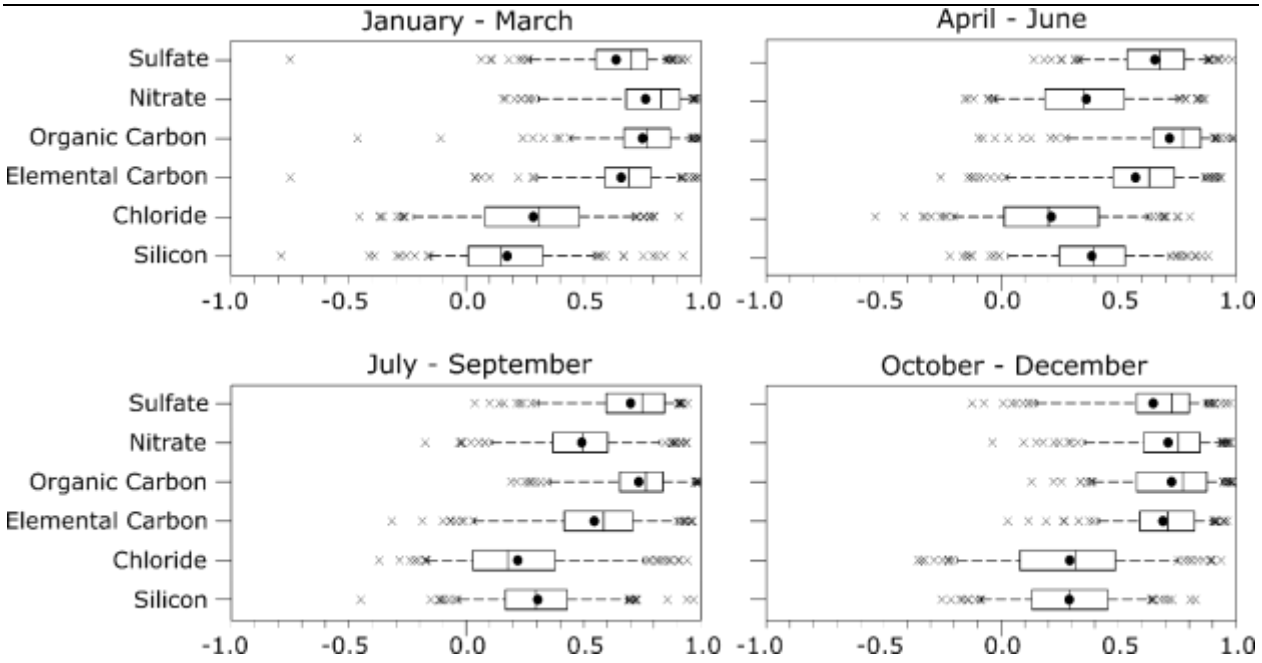

Figure 3-18 Distribution of Pearson correlation coefficients for comparison of seasonal 24-hour average total $PM_{2.5}$ mass with mass concentration of $PM_{2.5}$ components from the Air Quality System during 2013−2015.

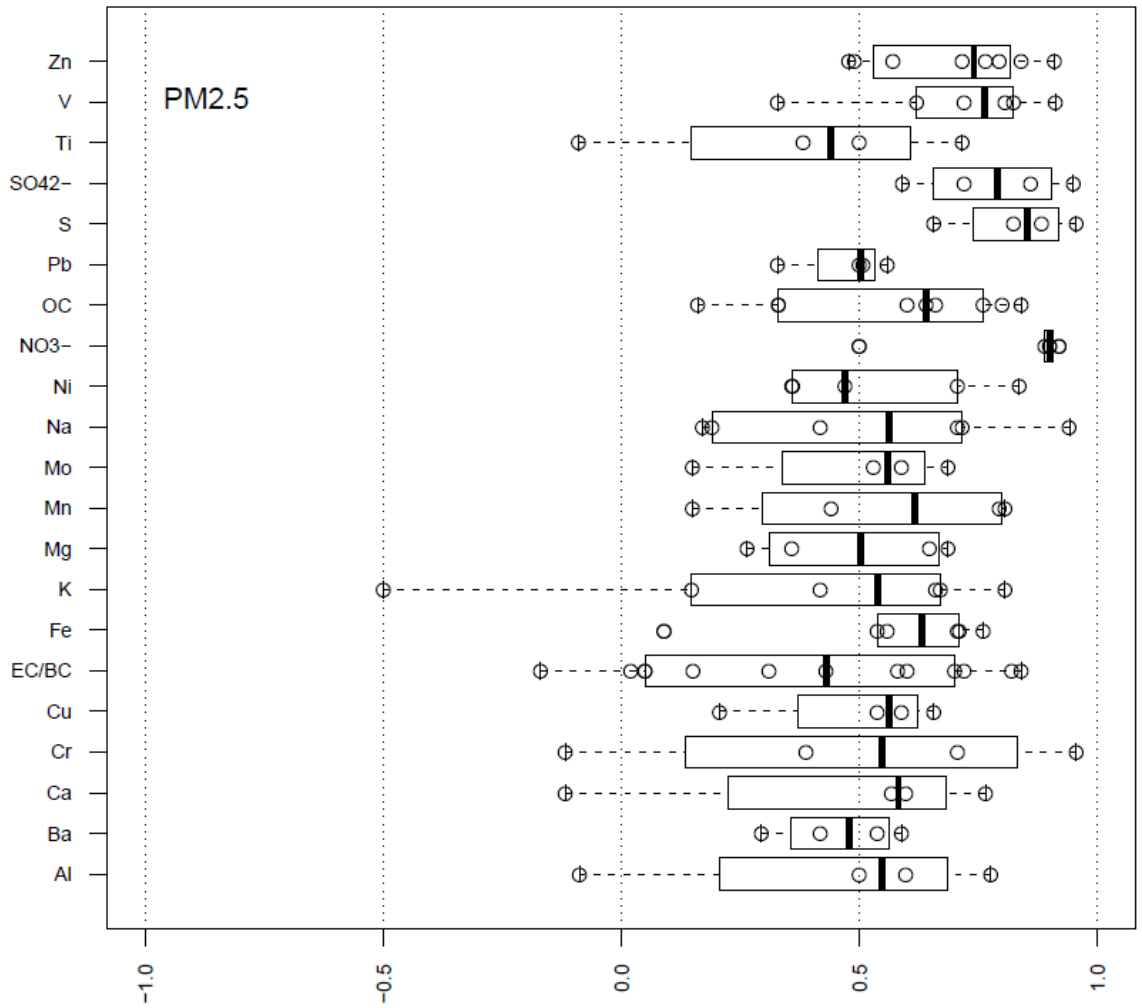

Source: Permission pending, Polidori et al. (2009); Ito et al. (2011); Ostro et al. (2009); Raysoni et al. (2013); Zhang et al. (2016); Delfino et al. (2013); Delfino et al. (2010); Ostro et al. (2010).

Figure 3-19 Distribution of Pearson correlation coefficients for annual 24-hour average total $PM_{2.5}$ mass concentration with mass concentration of $PM_{2.5}$ components from the peer-reviewed literature during 2013−2015.

For SO_4^{2-}, OC, NO_3^-, and EC, site-specific correlations range from near Pearson $R = 1$ down to near Pearson $R = 0$ (Figure 3-17). This suggests spatial variability of the correlations between $PM_{2.5}$ and each component (Figure 3-20). Maps of Pearson correlations at AQS sites measuring $PM_{2.5}$ and components illustrate the level of variability for the four components. Correlations between $PM_{2.5}$ and SO_4^{2-} are highest in the northeastern and Midwestern portions of the U.S. Correlations between $PM_{2.5}$ and NO_3^- are highest in the West and markedly lower throughout the Southeast and Midwest. Correlations between $PM_{2.5}$ and EC appear highest in the West, possibly due to the influence of wildfire on $PM_{2.5}$ concentrations (Section 2.5.1.1.6).

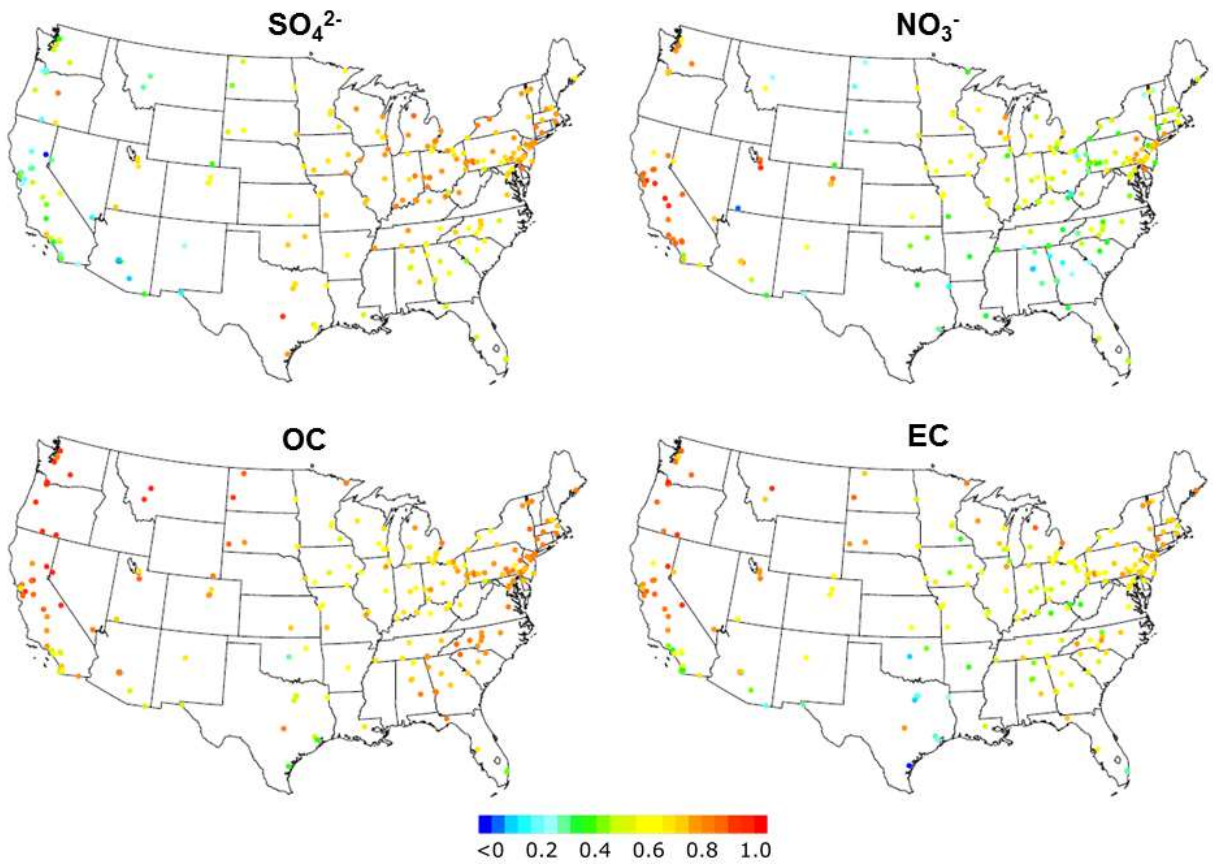

Figure 3-20 Maps illustrating national-scale variability of Pearson correlation coefficients for comparison of seasonal 24-hour average total $PM_{2.5}$ mass concentration with mass concentration of $PM_{2.5}$ components from the Air Quality System during 2013−2015.

Figure 3-21 displays annual correlations for 24-hour ambient $PM_{10-2.5}$ mass concentration with mass concentration for select components of $PM_{10-2.5}$ measured from the AQS during 2013−2015, and Figure 3-22 displays seasonal correlations. Median correlation of $PM_{10-2.5}$ mass concentration with Si was slightly lower than Pearson $R = 0.7$, while median correlations of $PM_{10-2.5}$ mass concentrations with the other $PM_{10-2.5}$ components were between Pearson $R = 0$ and Pearson $R = 0.3$. The difference between correlations for Si with those for the other components holds across seasons, with the highest correlation for Si and lowest correlations for all other components evident during the fall months (Figure 3-22). The higher correlation of $PM_{10-2.5}$ mass concentration and Si in $PM_{10-2.5}$ was likely due to the influence of dust, particularly in the Southwestern U.S. (Section 2.5). Figure 3-24 shows higher correlations in the Southwest, in support of this claim. Data for correlations between ambient $PM_{10-2.5}$ mass concentration and Si in $PM_{10-2.5}$ (for each of these studies, ambient $PM_{10-2.5}$ and components were measured by fixed-site monitors outside the location where personal samples were obtained, but no correlations were reported for personal samples) were not available in the literature for comparison (Raysoni et al., 2013; Delfino et al., 2010; Polidori et al., 2009), but median correlations for components reported were all less than Pearson $R = 0.5$ (Figure 3-23).

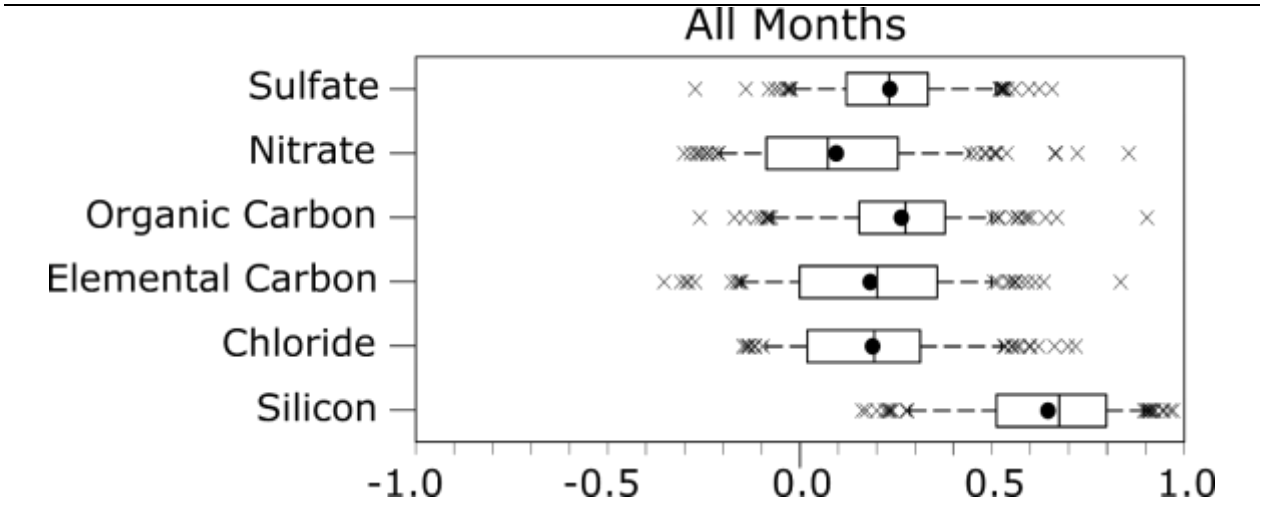

Figure 3-21 Distribution of Pearson correlation coefficients for annual 24-hour average total mass concentration of $PM_{10-2.5}$ with mass concentration of $PM_{10-2.5}$ components from the Air Quality System during 2013−2015.

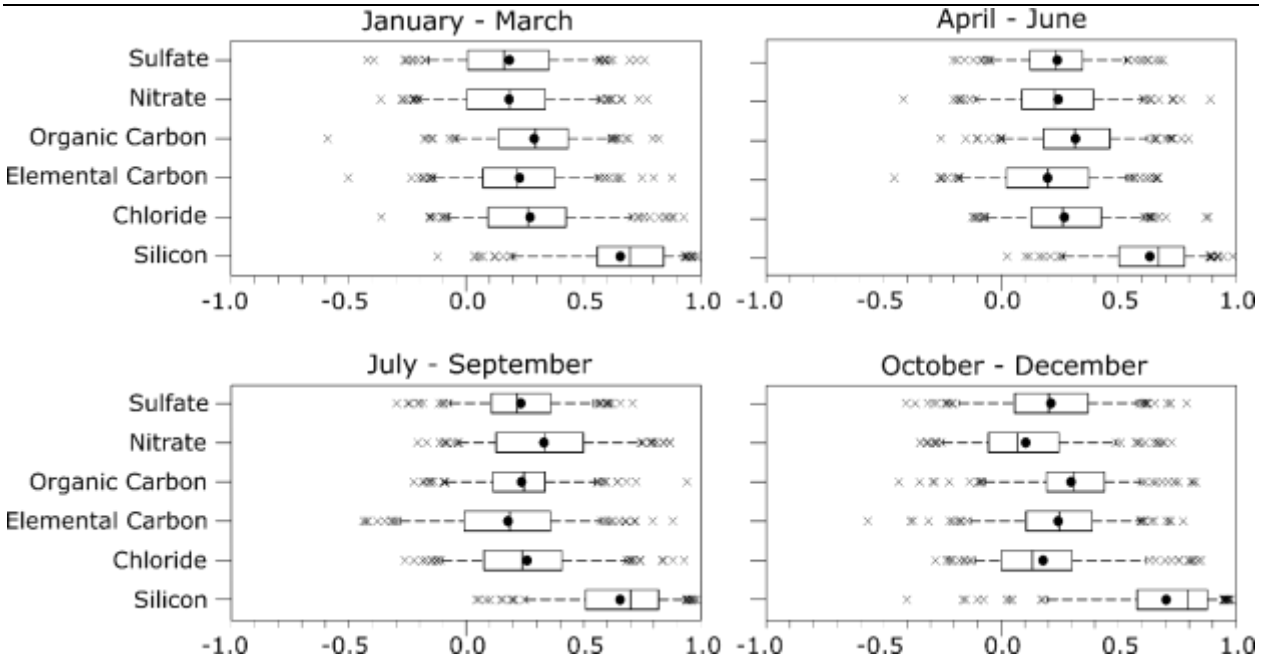

Figure 3-22 Distribution of Pearson correlation coefficients for comparison of seasonal 24-hour average total $PM_{10-2.5}$ mass concentration with mass concentration of $PM_{10-2.5}$ components from the Air Quality System during 2013−2015.

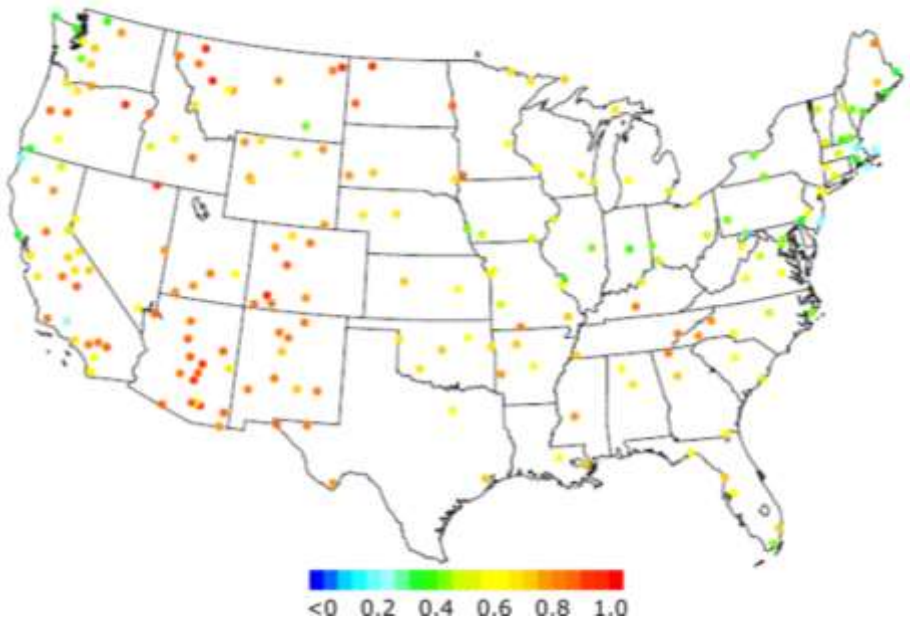

Figure 3-24 Map illustrating national-scale variability of Pearson correlation coefficients for comparison of seasonal 24-hour average total $PM_{10-2.5}$ mass concentration with mass concentration of Si in $PM_{10-2.5}$ from the Air Quality System during 2013−2015.

Exposure to UFP composition is informed by considering data for correlations of mass concentration for PM smaller than 250 nm ($PM_{0.25}$). These samples were measured using a cascade impactor, with concentrations of $PM_{0.25}$ components were calculated based on ambient fixed-site measurements for monitors placed outside retirement communities as surrogates for exposure concentration in Polidori et al. (2009) and Delfino et al. (2010), as shown in Figure 3-25. The highest median correlation was between $PM_{0.25}$ and V (Spearman R = 0.8), which tends to be present in heating oil and industrial waste (Polidori et al., 2009). Correlation between $PM_{0.25}$ and V was near Spearman R = 1 in the cool season and near Spearman R = 0.7 during the warm season, which is consistent with heating oil use. Medium correlations near Spearman R = 0.5 were reported for several components, including S (correlations with SO_4^{2-} were not reported at the $PM_{0.25}$ size cut), Pb, OC, Ni, Na, Mo, Fe, EC/BC, Ba, and Al. Both studies took place in 2005−2007, and ultra-low sulfur diesel fuel was phased in between 2006 and 2010. Moderate correlations for $PM_{0.25}$ with S, EC/BC, OC, and Ba could be related to traffic (Polidori et al., 2009).

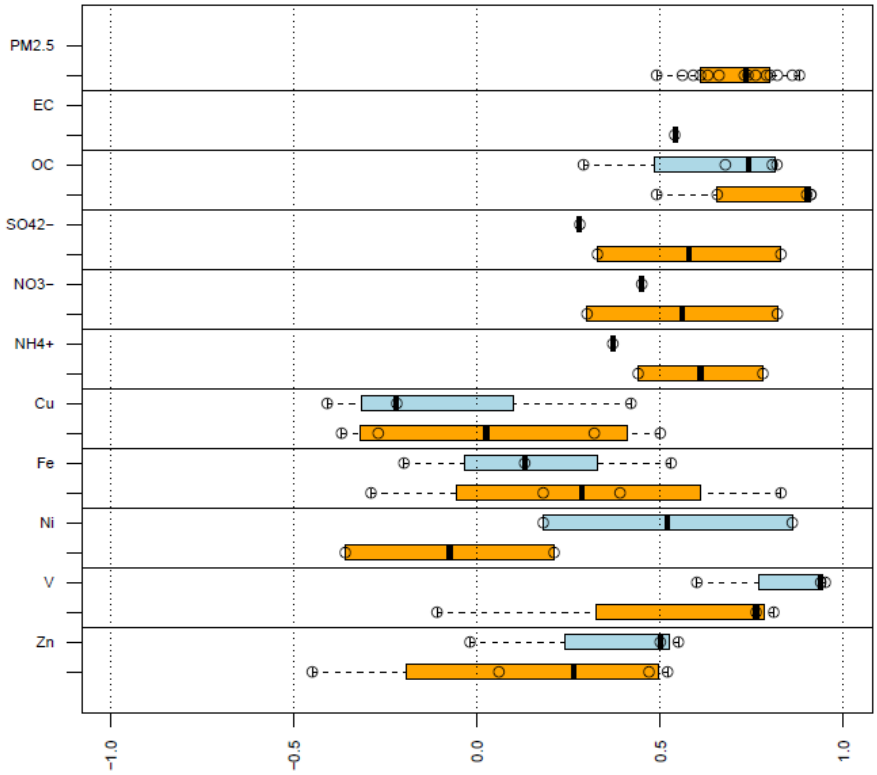
3.4.4.2 Reactive Oxygen Species

Recent exposure assessment studies inform biological plausibility discussions (Section 5.2.1, Section 5.3.1, Section 6.2.1, Section 6.3.1, and Section 10.2.1) because they measure oxidative potential

as a surrogate for oxidative stress. Oxidative stress and inflammation may be initiated by PM exposure, when a target site does not have enough antioxidant reserve to counteract the ROS. Oxidative stress can occur directly through redox reaction, or it can occur indirectly, where redox-inactive metals can form complexes with antioxidants so that the cell is then vulnerable to oxidation. The dithiothreitol (DTT) assay for measuring ROS inform PM's ability to cause oxidative stress directly [see Cho et al. (2005), Section 3.3.1.2]. Macrophage ROS assays [see Landreman et al. (2008), Section 3.3.1.2] provide a model of both direct and indirect oxidative stress, because both may occur in the model cell.

ROS activity for ambient PM is shown in Figure 3-26 through correlations of ROS macrophage and DTT assay results with mass concentration of $PM_{2.5}$, prevalent components (EC, OC, SO_4^{2-}, NO_3^-, and NH_4^+), and select trace metals (Cu, Fe, Ni, V, Zn) (Bates et al., 2015; Fang et al., 2015; Verma et al., 2009; Hu et al., 2008). Correlations between $PM_{2.5}$ mass concentration and DTT activity ranged from Pearson R = 0.49 to 0.88. No studies presented correlations between $PM_{2.5}$ mass and ROS activity based on the macrophage ROS assay, and limited data were available for the components presented. Most correlations were greater than 0.3 for EC, OC, SO_4^{2-}, NO_3^-, and NH_4^+. For trace metals, correlations ranged from positive to negative, where negative correlations imply that the ROS activity goes down with increasing concentration of the PM components or vice versa. In most cases, boxplots overlapped for the DTT and macrophage ROS assay, suggesting that both types of assay results covary similarly with measures of concentration for $PM_{2.5}$ components, despite the inability of DTT to capture indirect oxidation processes. These findings suggest that mass concentration of ambient $PM_{2.5}$ components may inform epidemiologic studies of oxidative stress and related effects. However, oxidative potential approaches are limited as a model of oxidative stress, because they do not reproduce the oxidative stress mechanisms. Moreover, macrophage ROS assay data are needed to correlate with ambient $PM_{2.5}$ mass concentration to consider if ambient $PM_{2.5}$ mass concentration is associated with direct and indirect ROS activity.



$PM_{2.5}$ = particulate matter with 50% aerodynamic diameter less than a nominal diameter of 2.5 µm; EC = elemental carbon; OC = organic carbon; SO_4^{2-} = sulfate; NO_3^- = nitrate; NH_4^+ = ammonium; Cu = copper; Fe = iron; Ni = nickel; V = vanadium; Zn = zinc.

Note: For each element, correlations obtained through the dithiothreitol assay are shown in orange at the bottom of each box and correlations obtained through the reactive oxygen species macrophage ROS assay are shown in light blue at the top of each box.

Figure 3-26 Pearson correlations of ambient air measures of oxidative potential with $PM_{2.5}$ mass and $PM_{2.5}$ components.

Personal exposure measurements were correlated to ROS activity for three studies of PM exposures in a school (Delfino et al., 2013) and retirement communities (Zhang et al., 2016; Delfino et al., 2010). In the school study, correlations ranged from Spearman R = 0.77 to 0.85 for the DTT assay's relationship to $PM_{2.5}$ mass, EC, OC, and water-soluble OC exposure concentrations. Similarly, correlations ranged from Spearman R = 0.66 to 0.86 for the same components for the macrophage ROS assay's relationship to $PM_{2.5}$ mass, EC, OC, and water-soluble OC exposure concentrations. The first retirement home study occurred between 2005 and 2007 and included Spearman correlations of macrophage ROS activity with $PM_{10–2.5}$, $PM_{2.5–0.25}$, and $PM_{0.25}$ mass exposure concentrations, along with

NC and components of EC, OC, BC, primary OC (POC), and secondary OC (SOC). Correlations of macrophage ROS activity with $PM_{10-2.5}$ and $PM_{2.5-0.25}$ were Spearman R = 0.09 and 0.07, respectively. Correlations of ROS activity with $PM_{0.25}$ mass exposure concentration (Spearman R = 0.41) and for NC (Spearman R = 0.23) were higher by comparison. EC, OC, BC, and POC had correlations of Spearman R = 0.31 to 0.40, while the correlation for SOC with ROS activity was 0.08.

Assays to measure ROS activity were recently evaluated for particles near the UFP size range. Zhang et al. (2016) correlated ROS activity of particulate matter smaller than 180 nm ($PM_{0.18}$) or of particulate matter between 180 and 250 nm ($PM_{0.25-0.18}$) with $PM_{2.5}$, BC, and components' exposure concentrations within the $PM_{0.18}$ and $PM_{0.25-0.18}$ size ranges. Correlation was Spearman R = −0.17 and 0.05, respectively for the DTT and macrophage ROS assays, for the correlation of $PM_{2.5}$ exposure concentration with ROS activity of $PM_{0.18}$. Correlation was Spearman R = 0.20 and 0.45 for the correlation of $PM_{2.5}$ exposure concentration with ROS activity of $PM_{0.25-0.18}$, so that ROS activity of $PM_{0.25-0.18}$ correlated more with $PM_{2.5}$ exposure concentration than did ROS activity of $PM_{0.18}$. Correlations among components of $PM_{0.18}$ exposure concentrations were higher for ROS activity of $PM_{0.18}$, but that pattern did not hold for ROS activity of $PM_{0.25-0.18}$. Additionally, larger differences were observed when correlations between exposure to mass concentration and ROS activity were measured by DTT (for DTT of $PM_{0.18}$, Spearman R = 0.50 to 0.86, and of $PM_{0.25-0.18}$, Spearman R = 0.25 to 0.62) than when they were measured by the macrophage ROS assay (for ROS of $PM_{0.18}$, Spearman R = −0.02 to 0.45, and of $PM_{0.25-0.18}$, Spearman R = 0.09 to 0.41). This may imply that for $PM_{0.25}$, mass exposure concentration of components may be associated with direct redox activity but not with indirect oxidation via antioxidant complexation. No correlations of $PM_{0.25-0.18}$ or $PM_{0.18}$ total mass exposure concentration were provided in the Zhang et al. (2016) study. However, the Delfino et al. (2010) study did provide correlation data for $PM_{0.25}$ and NC and found low-moderate correlations (Spearman R = 0.41 for $PM_{0.25}$ and Spearman R = 0.23 for NC), consistent with the correlations of the $PM_{0.18}$ and $PM_{0.25-0.18}$ components' mass exposure concentrations with the macrophage ROS assay results. Hence, multiple studies indicate that the macrophage ROS assay is a reliable indicator of oxidative potential.

3.4.5 Influence of Exposure Errors on Results from Epidemiologic Studies of Different Designs

Exposure measurement error, which refers to the biases and uncertainties associated with using concentration metrics as surrogates for the actual exposure of an individual or population (Section 3.2.1, Exposure Terminology), can be an important contributor to error in epidemiologic study results. Time-series studies assess the daily health status of a population of thousands or millions of people over the course of multiple years (i.e., thousands of days) across an urban area by estimating people's exposure using a short monitoring interval (hours to days). In these studies, the community-averaged concentration of an air pollutant measured at ambient monitors is typically used as a surrogate for individual or population ambient exposure. In addition, panel studies, which consist of a relatively small sample

(typically tens) of study participants followed over a period of days to months, have been used to examine the health effects associated with short-term exposure to ambient concentrations of air pollutants [e.g., Delfino et al. (1996)]. Panel studies may also apply a microenvironmental model to represent exposure to an air pollutant. A longitudinal cohort epidemiologic study, such as the American Cancer Society (ACS) cohort study, typically involves hundreds or thousands of subjects followed over several years or decades [e.g., Jerrett et al. (2009)]. Ambient concentrations are generally aggregated over time and by community as exposure surrogates.

Exposure error can bias epidemiologic associations between ambient pollutant concentrations and health outcomes and tends to widen confidence intervals around those estimates (Sheppard et al., 2005; Zeger et al., 2000). The importance of exposure error varies with study design and is dependent on the spatial and temporal aspects of the design. Other factors that could influence exposure estimates include topography of the natural and built environment, meteorology, instrument errors, use of ambient PM concentration as a surrogate for exposure to ambient PM, and the fact PM is one part of a complex mixture of pollutants. The following sections will consider various sources of error and how they affect the interpretation of results from epidemiologic studies of different designs.

3.4.5.1 Short-Term Exposure Studies

3.4.5.1.1 Time-Series Studies

As discussed in the 2009 PM ISA (U.S. EPA, 2009b), in most short-term exposure epidemiologic studies, the health effect endpoint is modeled as a function of ambient exposure, E_a, which is defined as the product of C_a and α, a term encompassing time-weighted averaging of microenvironmental exposures and infiltration of PM (Section 3.2.2, conceptual model). Time-series epidemiologic studies capturing the exposures and health outcomes of a large cohort frequently use the ambient concentration at a fixed-site monitor or an average of ambient concentrations across monitors as a surrogate for E_a in a statistical model (Strickland et al., 2011; Wilson et al., 2000). This is necessary due to the infeasibility of measuring personal exposures for studies involving thousands of participants. Moreover, for time-series epidemiology studies of short-term exposure, the temporal variability in concentration is of primary importance to relate to variability in the health effect estimate (Zeger et al., 2000). C_a can be an acceptable surrogate if the ambient monitor captures the temporal variability of the true air pollutant exposure. Spatial variability in PM concentrations across the study area could attenuate an epidemiologic health effect estimate if the exposures are not correlated in time with C_a when ambient monitoring is used to represent exposure in the statistical model. If exposure assessment methods that more accurately capture spatial variability in the concentration distribution over a study area are employed, then the confidence intervals around the health effect estimate may decrease.

In a time-series study of ED visits for cardiovascular disease, Goldman et al. (2011) simulated the effect of classical and Berkson errors due to spatiotemporal variability among ambient or outdoor (i.e., an ambient monitor situated outside the home) air pollutant concentrations over a large urban area. For 24-hour average $PM_{2.5}$, the relative risk (RR) per unit mass was negatively biased in the case of classical error (1.0094 compared to the base case of 1.0139) and negligibly positively biased in the case of Berkson error (1.0144). Negative bias means that the health effect estimate underestimates the true health effect. The 95% confidence interval range for RR per ppm of $PM_{2.5}$ was wider for Berkson error (0.0144) compared with classical error (0.0097). Similar results were obtained for $PM_{2.5}$ components (SO_4^{2-}, NO_3^-, NH_4^+, EC, and OC).

Recent studies have explored the effect of spatial exposure error on health effect estimates to test the appropriateness of using ambient monitoring for time-series studies. Goldman et al. (2010) simulated spatial exposure error based on a semivariogram function across monitor sites with and without temporal autocorrelation at 1- and 2-day lags to analyze the influence of spatiotemporal variability among ambient or outdoor concentrations over a large urban area on a time-series study of ED visits for cardiovascular disease. A random term was calculated through Monte Carlo simulations based on the data distribution from the semivariogram, which estimated the change in spatial variability in exposure with distance from the monitoring site. The average of the calculated random term was added to an ambient monitoring time series (considered in this study to be the base case) to estimate population exposure to $PM_{2.5}$ subject to spatial error. For the analysis with temporal autocorrelation considered, RR per ppm for 24-hour average $PM_{2.5}$ dropped slightly to 1.0126 (95% CI: 1.0113, 1.0139) when it was compared with the ambient monitor RR per ppm = 1.0139.[41] When temporal autocorrelation was not considered, RR per unit mass similarly dropped to 1.0123 for 24-hour average $PM_{2.5}$. The results of Goldman et al. (2010) suggest that spatial exposure error from use of ambient monitoring data results in biasing the health effect estimate towards the null to underestimate the true health effect, but the magnitude of the change in effect was small.

In another study analyzing the influence of spatiotemporal variability among ambient or outdoor concentrations over a large urban area on health effect estimates, Goldman et al. (2012) evaluated the effect of different types of spatial averaging on bias in the health effect risk ratio and the effect of correlation between measured and "true" ambient concentrations of $PM_{2.5}$ and PM_{10} and other air pollutant measures. Concentrations were simulated at alternate monitoring locations using the geostatistical approach described above (Goldman et al., 2010) for the 20 county Atlanta metropolitan area for comparison with measurements obtained directly from monitors at those sites. Geostatistical-simulated concentrations were considered by the authors to be "true" in this study, and other exposure assessment methods were assumed to have some error. Five different exposure assessment approaches were tested: (1) using a single fixed-site ambient monitor, (2) averaging the simulated

[41] Note that 95% CIs were not reported for the ambient monitor RR or for the cases where temporal autocorrelation was not considered.

exposure concentrations across all monitoring sites, (3) performing a population-weighted average across all monitoring sites, (4) performing an area-weighted average across all monitoring sites, and (5) population-weighted averaging of the geostatistical simulation (see Table 3-10). Goldman et al. (2012) observed that the exposure error was somewhat correlated with both the measured and "true" values, reflecting both Berkson and classical error components. For the single fixed-site ambient monitor, the exposure errors had a moderate positive correlation with the measured value. For the other exposure concentration estimation methods, the exposure errors were moderately negatively correlated with the "true" value, while having positive but lower magnitude correlation with the measured value. Additionally, the exposure bias, given by the ratio of the exposure error to the measured value, was higher in magnitude at the single fixed-site monitor than for the spatial averaging techniques for $PM_{2.5}$. Hence, compared with other exposure assessment methods, the health effect estimate would likely have greater bias towards the null (i.e., underestimation of the true health effect estimate) with reduced precision when a single fixed-site monitor is used to measure $PM_{2.5}$ concentration as a surrogate for exposure. However, exposure error is likely to cause some bias and imprecision for other exposure surrogate methods as well.

Table 3-10 The influence of exposure concentration metrics on error in health effect estimates.

Exposure Estimation Approach	Bias[(Z−Z*)/Z][a]	R^2(Z, Z*)[b]	*R*[(Z−Z*), Z*][c]	*R*[(Z−Z*), Z][c]
$PM_{2.5}$				
Fixed-site monitor	0.21	0.76	−0.10	0.41
Unweighted average	0.05	0.85	−0.28	0.14
Population-weighted average	0.05	0.84	−0.28	0.14
Area-weighted average	0.04	0.84	−0.29	0.13
Geostatistical model—population-weighted average	N/A	0.87	−0.38	0.00065

N/A = not applicable.

[a]Data provided by the authors for Figure 5 of Goldman et al. (2012).

[b]Data provided by the authors of Figure 4 of Goldman et al. (2012).

[c]Pearson correlation.

Note: Model errors were based on comparisons between measured data and simulated data at several monitoring sites. Errors were estimated for a single fixed-site ambient monitor, various monitor averages, and values computed from a geostatistical model. Z denotes the measured concentration, and Z* denotes the "true" concentration, considered here to be from the geostatistical model. Bias in the exposure concentration metric is given as the proportion of error between the measurement and true value to the measurement.

Source: Permission pending, Goldman et al. (2012).

In addition to the effect of the correlations and ratios themselves, spatial variation in their values across urban areas also impacts time-series epidemiologic results. The Goldman et al. (2010) and Goldman et al. (2012) findings suggest more Berkson error in the spatially resolved exposure concentration metrics compared with the fixed-site ambient monitor and more classical error for the fixed-site ambient monitor estimate compared with the other exposure assessment techniques. Hence, more bias would be anticipated for the health effect estimate calculated from the fixed-site ambient monitor, and more variability would be expected for the health effect estimate calculated with the more spatially resolved methods. Differences in the magnitude of exposure concentration estimates are not likely to cause substantial bias, but they tend more to widen confidence intervals and thus reduce the precision of the effect estimate (Zeger et al., 2000). The more spatially variable air pollutants studied in Goldman et al. (2012) also had more bias in the health effect estimates. This occurred across exposure assessment methods but was more pronounced for the fixed-site ambient monitoring data. Note that the Goldman et al. (2010), Goldman et al. (2011), and Goldman et al. (2012) studies were performed only in Atlanta, GA. These simulation studies are informative, but similar simulation studies in additional cities would aid generalization of these study results.

Dionisio et al. (2014) evaluated differences in $PM_{2.5}$ effect estimates derived from ambient monitors, an AERMOD air quality model to capture spatial variability, and a SHEDS personal exposure model incorporating infiltration and time-activity patterns for ZIP codes in Atlanta. They found that personal exposure model-based estimates were lower than ambient monitor and air quality model estimates, which were relatively similar to one another. The study also evaluated attenuation of health effect estimates in single-pollutant and copollutant models using a classical error attenuation factor relating the observed health effect estimate and health effect estimate that was designated by the authors to be "true". In single-pollutant models, using a fixed-site monitor reduced the size of the health effect estimate to about 80% of the effect estimate from the air quality model. The health effect estimate based on the fixed-site monitor was much more attenuated to approximately 25% of the health effect estimate when the personal exposure model was used for the exposure concentration estimate. The degree of attenuation was slightly greater in copollutant models with SO_4^{2-} and O_3, and slightly less in a copollutant model with NO_X. Due to the more regional nature of PM, little spatial variability in the health effect estimates and degree of attenuation was observed. The findings of this study also suggest that PM is not as susceptible to spatially varying exposure error as locally-emitted pollutants such as CO and NO_X.

To account for temporal variability in exposure, Dominici et al. (2004) used spline functions to control for the temporal trend in exposure concentration and outcome in time-series studies. Szpiro et al. (2014) compared a version of this method with an approach to pre-adjust the exposure to account for the time trend, without need to account for the trend in the outcome, to reduce bias in the effect estimate. This method is particularly applicable for repeated-measure cohort studies, since it takes advantage of the additional exposure data available from more frequent pollutant measurements compared to the infrequent outcome and covariate measures.

Section 3.4.2.4 also describes the influence of instrument accuracy and precision on the relationship between ambient PM concentrations and personal exposure to ambient PM. Exposure measurement error related to instrument precision has a smaller effect on health effect estimates in time-series studies compared with error related to spatial gradients in the concentration because instrument precision would not be expected to modify the ability of the instruments to respond to changes in concentration over time. Goldman et al. (2010) investigated the influence of instrument error on health effect estimates in a time-series epidemiology study by studying differences in exposure concentration estimates and health effect estimates obtained using collocated monitors. In this study, a random error term based on observations from collocated monitors was added to an ambient monitor's time series to simulate population estimates for ambient air concentrations subject to instrument precision error in 1,000 Monte Carlo simulations. Virtually no change in the risk ratio was observed for 24-hour average $PM_{2.5}$; the RR per ppm with simulated instrument precision error was 1.0138 compared with RR per ppm = 1.0139 for the ambient monitor. The amount of bias in the health effect estimate related to instrument precision was very small.

As described in the 2009 PM ISA (U.S. EPA, 2009b), nonambient sources of PM include indoor combustion, cooking, cleaning, and other activities. However, such exposure is unlikely to be temporally correlated with ambient PM exposure (Wilson and Suh, 1997), and therefore would not affect epidemiologic associations between ambient PM and a health effect in a time-series study. In simulations of a nonreactive pollutant, Sheppard et al. (2005) concluded that nonambient exposure does not influence the health outcome effect estimate if ambient and nonambient concentrations are independent. Because personal exposure to ambient PM is some fraction of the ambient concentration, it should be noted that effect estimates calculated based on personal exposure rather than ambient concentration will be positively biased in proportion to the ratio of ambient concentration to ambient exposure, and daily fluctuations in this ratio can widen the confidence intervals in the ambient concentration effect estimate. Uncorrelated nonambient exposure will not bias the effect estimate but may also widen the confidence intervals (Sheppard et al., 2005; Wilson and Suh, 1997).

3.4.5.1.2 Panel Studies

Panel or small-scale cohort studies involving dozens of individuals may use more individualized concentration measurements, such as personal exposures, residential fixed-site indoor or outdoor measurements, or concentration data from local study-specific monitors. Modeled concentrations are not typically used as exposure surrogates in panel epidemiologic studies. Probabilistic, distribution-based approaches are not designed to estimate exposures for specific individuals, such as might be needed for panel epidemiologic studies. Another main disadvantage of the modeling approach is that the results of modeling exposure assessment must be compared to an independent set of measured exposure levels (Klepeis, 1999). In addition, resource-intensive development of evaluated and representative model inputs

is required, such as human activity patterns, distributions of air exchange rate, and deposition rate. Therefore, modeled exposures have been used much less frequently in panel epidemiologic studies.

Panel studies using hourly or other subdaily measurements are used to evaluate subclinical health effects, such as biomarkers of inflammation [e.g., Dubowsky et al. (2006)]. Sensitivity to averaging time may be tested by fitting models with various averaging times to identify the time period most associated with effects. However, temporal variations in exposure and covariates (e.g., temperature, other pollutants) can lead to temporal variability in exposure measurement error. Malloy et al. (2010) proposed a wavelet approach to add time-varying data into the statistical model used in an epidemiologic study. Simulations adding exposure measurement error to an hourly $PM_{2.5}$ data set indicated that the fine-scale wavelets describing shorter-frequency variation captured most of the exposure error, with little error accounted for by the coarse wavelets. The standard moving average approach of fitting models with successively longer averaging times showed the greatest exposure error at shorter averaging times (less than 20−60 hours), while the effect of simulated error was similar across averaging times wavelet approach showed similar error over averaging times of 10 hours or greater. This suggests that the wavelet approach may be better able to identify associations with health effects over short averaging times (e.g., 24 hours or less).

To evaluate the effect of small-scale intraurban spatial variability on health effect estimates, Sarnat et al. (2012) considered the influence of local exposure concentration metrics on respiratory effect estimates for a panel of school children. This study was conducted along the U.S.-Mexico border in El Paso, TX and Ciudad Juarez, Mexico, and 48-hour average concentrations measured from fixed-site ambient monitors, monitors outside the children's schools, and monitors inside the children's schools were all used as surrogates for PM exposure concentration. For $PM_{2.5}$, slightly higher health effect estimates were observed for indoor monitors compared with outdoor and fixed-site ambient monitors (2.7, 2.3, and 2.4%, respectively), although confidence intervals overlapped. $PM_{10–2.5}$ had a higher health effect estimate for indoor than outdoor monitors (2.8 vs. 2.0%), again with overlapping confidence intervals. No fixed-site ambient $PM_{10–2.5}$ data were available. For both $PM_{2.5}$ and $PM_{10–2.5}$, multivariate models with both indoor and outdoor concentration only showed associations for indoor concentration. This effect was more pronounced for $PM_{10–2.5}$, which exhibits greater urban spatial variability than $PM_{2.5}$. The authors suggested that exposure measurement error could result in biasing the health effect estimate toward the null to underestimate the health effect, given the finding of higher health effect estimate for the outdoor $PM_{2.5}$ monitor compared with the outdoor $PM_{10–2.5}$ monitor.

3.4.5.2 Long-Term Exposure Cohort Studies

For cohort epidemiologic studies of long-term human exposure to PM, where the difference in the magnitude of the concentration is of most interest, if C_a is used as a surrogate for E_a, then α can be considered to encompass the exposure measurement error related to uncertainties in the time-activity data and infiltration. Spatial variability in PM concentrations across the study area could lead to bias in the

health effect estimate if C_a is not representative of E_a. This could occur if the study participants are clustered in a location where their PM exposure is higher or lower than the exposure estimated at a modeled or measurement site. There is limited information regarding whether C_a is a biased exposure surrogate in the near-road environment for epidemiologic studies of long-term exposure.

Choice of exposure surrogate can influence error in the health effect estimate. For example, Baxter et al. (2010) calculated bias and RMSE for health effect estimates based on different exposure estimation methods including evaluated regression models, distance from a major road, and an indoor exposure model that accounts for factors such as seasonality in infiltration of ambient $PM_{2.5}$ and EC. The simulated indoor concentrations produced unbiased health effect estimates, while the other exposure surrogates typically (but not always) biased the health effect estimate towards the null to underestimate the true health effect and inflated the RMSE relative to that of the indoor model. Distance surrogates had much larger biases and RMSE compared with models containing $PM_{2.5}$ or EC concentration measures. Kioumourtzoglou et al. (2014) developed linear mixed effects models to calibrate exposure surrogates (fixed-site ambient monitor and monitor outside a residence) against what was considered by the authors to be "true" personal exposure to ambient $PM_{2.5}$, estimated by multiplying the fixed-site ambient $PM_{2.5}$ measurement by the ratio of personal to ambient SO_4^{2-}. The calibration coefficients indicated that the fixed-site ambient monitor only captured 31% of the "true" personal exposure to ambient $PM_{2.5}$, and the outdoor monitor captured 54% of the "true" personal exposure to ambient $PM_{2.5}$. Hence, in both cases, the exposure surrogate was lower than the sulfate-derived personal exposure.

Researchers have recently compared the choice of ground-based or satellite-based estimation methods on epidemiologic effect estimates. Jerrett et al. (2016) compared several residential exposure concentration estimation methods using ground-based data (i.e., monitor, meteorological, land use, or spatial information) or satellite data for a large subset of the ACS cohort (668,629 individuals). The authors found that although the various methods yielded similar median $PM_{2.5}$ exposure concentration estimates (approximately 12 $\mu g/m^3$), effect estimates for circulatory mortality during 1982−2004 were much lower for the satellite methods than the ground-based methods. Of the seven methods tested, the highest effect estimate was produced by a ground-data-only two-stage model consisting of LUR followed by a BME kriging model of the residuals; this method also had the best model fit. This model produced a relative risk (95% CI) of 1.14 (1.11−1.17) per 10 $\mu g/m^3$ $PM_{2.5}$, while the lowest relative risk was observed with one of the two satellite-only methods (RR = 1.02, 95% CI = 1.00−1.04). Jerrett et al. (2016) calculated the Akaike Information Criterion (AIC) to assess model fit and found a negative association between HR and AIC (R^2 = 0.94), which suggests that use of the satellite method alone produced an attenuated effect estimate. The LUR-BME method estimated exposure concentrations on a 30 × 30 m (0.03 × 0.03 km) grid, while this satellite-only method provided estimates on a 1 × 1 km grid. The results of the Jerrett et al. (2016) study suggest that exposure estimation methods incorporating locally available ground data may introduce less exposure error than remote sensing methods alone, but that satellite methods have the capability to identify associations when ground data are lacking.

Spatial resolution of the exposure concentration estimates has been evaluated to examine the influence of spatial exposure error in cohort studies. For example, Alexeeff et al. (2015) fit kriging and LUR models based on 100 or 500 monitoring sites [derived from a satellite downscaling approach described in Kloog et al. (2014) and Section 3.3.3] and estimated bias and uncertainty for each exposure concentration model used to compute health effect estimates for linear and logistic health effect simulations. For the LUR models, which had the highest model R^2 (71 to 84%) compared with the satellite-downscaling estimates, the effect estimates were biased away from the null to overestimate the health effect estimate in all cases. Bias in the linear models was reduced from 4−5% for LUR fit with 100 monitors to 1% for the LUR fit with 500 monitors, and confidence interval coverage increased from 48 to 68%. Bias in the logistic models was reduced from 3−4% for LUR fit with 100 monitors to 2% for LUR fit with 500 monitors, and confidence interval coverage increased from 91 to 94%. The kriging models had much lower model R^2 (24−44%). One kriging model fit to long-term average monitor data also produced bias away from the null to overestimate the health effect estimate that reduced with number of monitors, but with larger magnitude biases. The other produced bias mostly towards the null to underestimate the health effect estimate, with magnitude of bias increasing with increased number of monitors.

Gryparis et al. (2009) noted that smoothing of the true exposure concentration surface can cause Berkson error in the effect estimate. Gryparis et al. (2009) simulated three spatial surfaces of increasing variability and then tested five types of exposure concentration modeling approaches: plug-in exposure concentration estimation where the "true" exposure concentrations (as designated by the authors) are predicted by a smoothing model; plug-in exposure concentration estimation with variance correction; regression calibration using hold-out predictions, covariates, and observations; and two types of Bayesian surface models (full Bayesian and two-stage Bayesian approaches) fitting a joint model for the health and exposure concentration data. Simulation results produced negative biases to underestimate the health effect for the plug-in exposure concentration estimation methods with and without variance correction, and those biases became larger in magnitude with increasing spatial variability (for the plug-in method with variance correction, simulation results produced −57% bias for the smoothest surface and −419% bias in the most spatially variable surface). Likewise, the mean squared error (MSE) increased and confidence interval coverage decreased with increasing variability of the "true" exposure concentration surface. Biases and MSEs were much smaller in magnitude for the regression calibration and Bayesian exposure concentration assignment methods, and those biases were positive and so overestimated the health effect (maximum bias was 23% for the two-stage Bayes method for the most spatially variable exposure concentration surface). MSE for the regression calibration and Bayesian methods also increased with increasing variability of the "true" exposure concentration surface. Regression methods have also been applied to correct ambient monitor data or spatial modeling estimates of $PM_{2.5}$ exposure based on indoor SO_4^{2-} to ambient $PM_{2.5}$ ratios in studies all-cause mortality (Hart et al., 2015a) and lung cancer (Hart et al., 2015b). In each study, the health effect estimate was lower when no exposure error correction method was applied. This implies that the smoother, non-corrected method introduced error into the exposure estimate that resulted in negative bias to underestimate the health effect.

The greater spatial characterization of $PM_{2.5}$ exposure concentration estimates from a combined satellite-LUR method with 50 m resolution developed by Kloog et al. (2011) resulted in higher mortality effect estimates compared with cohort studies using city-wide concentrations for the entire population based on a 10 km resolution grid (Kloog et al., 2013). This is consistent with a reanalysis of the ACS cohort conducted by Willis et al. (2003), which found that a subset analysis including only individuals living in a county with a sulfate monitor yielded an all-cause mortality effect estimate twice that for the entire cohort (1.5 vs. 1.25). The Kloog et al. (2013) study also found an effect of monitor distance, with a higher effect estimate for the population living within 20 km of a monitor than for those living farther away. This spatial influence on epidemiologic effect estimates is consistent with the null bias resulting from classical error.

The influence of spatial exposure error on health effect estimates varies with the study parameters, such as exposure model selection and location. Wu et al. (2011) compared health effect estimates for birth outcomes from four hospitals in Los Angeles and Orange Counties, CA given $PM_{2.5}$ concentrations as estimated using nearest monitors and the CALINE4 dispersion model. For preeclampsia, crude and adjusted odds ratios were consistently lower when the nearest monitor was used to estimate exposure concentration instead of the more spatially resolved dispersion model. Differences in the odds ratio for the two exposure concentration estimation methods were larger for Los Angeles County compared with Orange County. For Los Angeles County, the odds ratios were also below one when the nearest monitor was used, in contrast with Orange County, where the odds ratios were both above one. However, for preterm (<37 weeks gestation) and very preterm births (<30 weeks gestation), odds ratios were lower for the nearest monitor exposure concentration estimation method compared with the dispersion model in Los Angeles, but in Orange County, the opposite was observed. These findings indicate that higher spatial resolution may improve estimation of health effects.

Exposure error in studies of long-term exposure has the potential to be larger for $PM_{2.5}$ components than for $PM_{2.5}$ mass concentration, since the spatial variability of $PM_{2.5}$ components tends to be greater than for $PM_{2.5}$ mass concentration (Sun et al., 2013). Within components, the reported concentrations were also sensitive to the methods of measurement, with nearest monitor typically producing greater relative variability (measured as IQR/median) compared with IDW and city-wide average concentrations, respectively. Sun et al. (2013) compared statistical models of cardiovascular disease biomarkers associated with long-term exposure to $PM_{2.5}$ mass, EC, OC, Si, and S concentration using the nearest monitor, IDW, and city-wide average metrics. In general, effect estimates with city-wide averages tended to be lower in magnitude compared with the nearest monitor or IDW approaches for both the $PM_{2.5}$ mass and component metrics for one biomarker (CIMT) and for another biomarker (CAC) only for the Si component. Using finer-scale concentration estimates to approach the same problem, Kim et al. (2014) observed CIMT effects for Si but not EC. Little bias with $PM_{2.5}$ mass or S (as an indicator of SO_4^{2-}) concentration suggests that the less spatially variable metrics are less subject to bias related to exposure measurement error.

When a spatial concentration model, such as LUR or a spatiotemporal model, is used to develop a set of exposure concentration estimates for input into a long-term exposure epidemiologic study, minimizing error in the exposure or exposure concentration estimate does not always minimize error in the health effect estimate (i.e., β). Szpiro et al. (2011a) used simulation studies to evaluate the bias and uncertainty of the health effect estimate obtained when using correctly specified and misspecified exposure concentration models. The correct exposure concentration model was a spatiotemporal model with three geographic covariates while the misspecified model included only two of these three geographic covariates. In practice, covariates in spatiotemporal models may include variables such as population within a given buffer, proximity to industrial sources or highways, or building density. Szpiro et al. (2011a) did not explicitly state what the covariates were; as a statistical simulation study, the objective was to explore the impact of removing from the model a geographic covariate that may influence the exposure concentration. They estimated the exposure concentration model parameters using monitor data and predicted exposure concentrations at subject locations. They studied two conditions: where the variation in the third covariate was identical in the monitor and subject data versus where it was much smaller in the monitor data than in the subject data. Szpiro et al. (2011a) showed that prediction accuracy of the exposure concentration estimate was always higher for the correctly specified model compared with the misspecified model. The health effect estimate had better properties (lower RMSE) for the correct model when the third covariate had identical variability in the monitor and subject data. However, when the third covariate was much less variable in the monitor data, then the health effect estimate had better properties for the misspecified model. The results of Szpiro et al. (2011a) demonstrate one situation where use of a more accurately defined exposure concentration metric does not improve the health effect estimate.

Another simulation study evaluating the influence of exposure estimation methods on bias in health effect estimates considered the joint effect of exposure measurement error and confounding (Cefalu and Dominici, 2014). Exposure measurement error due to spatial variability in ambient concentrations or land use variables is often accounted for by exposure prediction models, such as LUR. Health effect models then may adjust for some of these same covariates as a means of reducing confounding of the effect estimate. Cefalu and Dominici (2014) demonstrated that if covariates are included in the exposure prediction model, but not the health effect model, the magnitude of bias in the health effect estimate is always increased relative to the simulated "true" exposure (as designated by the authors). The bias may be in either direction, depending on which covariates are omitted. To eliminate this bias, all potential confounders included in the health model must be included in the exposure prediction model, unless they are uncorrelated with exposure. Their simulation compared models with increasing numbers of covariates, and they found that in some situations the bias increased despite an increase in R^2, a similar result to the Szpiro et al. (2011a) study in which an improved exposure concentration metric did not improve the health effect estimate. One difficulty in applying these results to interpret epidemiologic study results is the uncertainty regarding the proper set of confounders to be included in the exposure and health models. While the Szpiro et al. (2011a) and Cefalu and Dominici (2014) simulations were for a generic air pollutant, they are relevant to spatially variable $PM_{10-2.5}$ or UFP.

Preferential sampling may occur when the exposure concentration model is fit to a set of spatial data, and exposures at other locations in the domain are not well represented. Sheppard et al. (2012) performed a series of simulations to study successively greater spatial correlations between monitors and study participants using kriging and nearest monitor to estimate $PM_{2.5}$ exposure concentration. Bias between the health effect estimate of the "true" exposure concentration (as designated by the authors) was compared with that derived from the kriged or nearest monitor exposure concentration estimates. Sheppard et al. (2012) found that bias decreased as spatial correlation between the "true" exposure concentration and the modeled exposure concentration increased. Both the kriging and nearest monitor exposure concentration models caused the coverage of the 95% confidence interval to be underestimated, but the underestimation was greater for nearest monitor. Furthermore, underestimation of the confidence interval became smaller with increasing spatial dependence of the "true" and modeled exposure concentrations. These results suggest that correlation between the "true" and modeled exposure reduces bias in the health effect estimate and reduces underestimation of variability in the health effect estimate. Lee et al. (2015) simulated several scenarios in which spatial variability explained successively larger portions of the exposure concentration variability to test for the effect of preferential sampling. Lee et al. (2015) also compared geospatial models of $PM_{2.5}$ components EC and S fit with the national network (urban and rural), CSN (urban), and IMPROVE (rural) networks and found large differences in the modeled exposure concentration surface. These results support the point that the nature of the monitors is important in deriving the surface. In general, Lee et al. (2015) found that the more preferential sampling occurred, the larger the relative bias and standard error of the effect estimate. In practice, studies of LUR have shown that fitting a model in one city and then applying it to another city can lead to large errors (U.S. EPA, 2016). The results of Lee et al. (2015) would imply that this practice would add error to the effect estimate.

Error correction is a relatively new approach to estimate the correct the classical-like standard error of exposure estimates and potentially to correct for bias in the exposure estimates used in statistical models for longitudinal cohort studies (Szpiro et al., 2011b). Szpiro and Paciorek (2013) and Bergen and Szpiro (2015) established that two conditions must hold for the health effect estimate to be predicted correctly: the exposure concentration estimates from monitors must come from the same underlying distribution as the true exposure concentrations, and the health effect model adjusts for confounding in the population. Szpiro and Paciorek (2013) performed several simulations to investigate what happens when these conditions are violated. In one set of simulations, the distribution of the exposure concentration was varied. When the assigned exposure concentration measurements were set to be uniform across space, the health effect estimate was biased away from the null (i.e., overestimated the health effect) with different standard error compared with the case when the exposure subjects were collocated with the study participants. When the model was misspecified, the health effect estimate was biased towards the null (i.e., underestimated the health effect) with different standard errors compared with the correctly specified model. Bias correction and bootstrap calculation of the standard errors improved the model prediction, even when the "true" model (as designated by the authors) contained several degrees of freedom. Spiegelman (2013) noted that the new measurement error correction methods developed by Szpiro and

Paciorek (2013) are a version of regression calibration. Bergen et al. (2013) applied error correction to models of long-term exposure to $PM_{2.5}$ components (EC, OC, Si, and S). They found that exposure errors in the EC and OC models were almost pure Berkson errors, so that the bootstrap calculation of the standard errors did not improve the estimates. Si and S were influenced by Berkson-like error, and bootstrap simulation of the standard errors was used for error correction. Absence of notable bias supports the observation of negligible classical-like error in the Si and S exposure concentration estimates.

In the case of long-term exposure cohort studies, nonambient contributions to the total personal exposure measurements would be expected to widen the confidence interval around the health effect estimates by adding noise to the exposure signal. Also, addition of any non-negative nonambient component to the personal exposure measurement would result in an underestimate of exposure to ambient PM, because the average total personal PM exposure would have to be either equal to or greater than the average personal exposure to ambient PM. This exposure error could bias the health effect estimate towards the null to underestimate the true health effect.

3.5 Summary

The exposure assessment chapter in the 2009 PM ISA (U.S. EPA, 2009b) synthesized a plethora of new research on PM, most of which focused on $PM_{2.5}$. The exposure assessment chapter in the 2009 PM ISA found that $PM_{10–2.5}$ tended to be more spatially variable than $PM_{2.5}$ at microscale, neighborhood scale, and urban scale, because $PM_{10–2.5}$ was more sensitive to local sources and loss processes, such as gravitational setting. UFP was also noted to be more spatially variable due to growth processes, but fewer data were available. Secondary production of $PM_{2.5}$ was noted to contribute to the relatively lower heterogeneity in its spatial concentration distribution. Similarly, infiltration was found to vary with particle size fraction, with the greatest infiltration factors occurring for $PM_{2.5}$ and infiltration decreasing with increasing particle size, due to surface impaction of $PM_{10–2.5}$ during the infiltration process. Source apportionment studies for SO_4^{2-}, as a marker of ambient $PM_{2.5}$, were presented as a method for distinguishing personal exposure to ambient $PM_{2.5}$ from total $PM_{2.5}$ exposure. Other components, such as EC and OC, were found not useful for apportionment of ambient $PM_{2.5}$ exposure, given their indoor sources. Spatial variability in PM concentration was noted to add uncertainty to exposure estimates.

Errors and uncertainties in the exposure assessment methods can add bias and uncertainty to health effect estimates from epidemiologic studies on the health effects of PM exposure. With regard to use of exposure surrogates in epidemiologic studies, the 2009 PM ISA (U.S. EPA, 2009b) noted that separating total PM exposure into ambient and nonambient components reduces uncertainty in health effects estimates. The 2009 PM ISA also noted that time-series studies of short-term $PM_{2.5}$ exposure generally use concentration data from fixed-site monitors as surrogates for exposure concentration, based on the assumption that temporal variability is captured at the monitor. Panel studies utilizing personal $PM_{2.5}$ exposure measurements found associations between short-term ambient $PM_{2.5}$ exposure and health

effects, and those findings were strengthened by focusing on the ambient component of exposure. It was noted that long-term $PM_{2.5}$ exposure studies produced health effects estimates that were most accurate when the PM concentration distribution does not vary substantially in space. Findings from the recent literature build from these results.

Fixed-site monitoring is still frequently utilized for exposure concentration surrogates for $PM_{2.5}$ (Section 3.3.1.1). Fixed-site monitoring data for $PM_{10–2.5}$ must be used with more caution. Generally, dichotomous samplers produce the most reliable measurements of $PM_{10–2.5}$ for use in exposure studies. Collocated PM_{10} and $PM_{2.5}$ monitors used to calculate $PM_{10–2.5}$ concentration by difference can have higher errors and uncertainties due to differences in flow rates for the two instruments, while differences between PM_{10} and $PM_{2.5}$ taken over a county or city to estimate $PM_{10–2.5}$ concentration has higher errors and uncertainties. CPCs are most commonly used to measure UFP. Some portion of the UFP size distribution may be omitted when using CPCs, since they do not typically measure particles smaller than 10 nm.

Substantial advances to exposure modeling have been made in recent years (Section 3.3.2). Spatial interpolation methods, LUR, dispersion models, and CTMs were already commonly used to estimate $PM_{2.5}$ exposure concentration. Improvements in modeling the OC component of $PM_{2.5}$ have improved the accuracy of CTMs in recent years. Additionally, hybrid approaches drawing input from CTMs, satellite observations of AOD, surface measurements of PM concentration, and land use variables data have been combined into spatiotemporal models. Microenvironmental exposure models have also been applied with input concentrations from these methods for comparison in epidemiology studies. The majority of studies using these methods are applied to model $PM_{2.5}$. These methods are employed less frequently to estimate $PM_{10–2.5}$ and UFP exposure concentration, related in part to less availability of input data. Epidemiologic study design influences selection of exposure concentration estimation methods.

Copollutant confounding of the PM health effect estimate may occur if exposure to the copollutants and their relationships to the health effect of interest are both correlated with PM exposure (Section 3.4.3). Median correlations of 24-hour ambient $PM_{2.5}$ with concentrations of ambient CO, NO_2, and O_3 during 2013−2015 were as high as Pearson $R = 0.5$, and upper correlations reached near 1. Copollutant correlation varied with season (highest for O_3 in summer and for CO and NO_2 in winter). Median correlations of 24-hour ambient $PM_{10–2.5}$ concentrations during the same time period were as high as Pearson $R = 0.4$, and upper correlations typically below Pearson $R = 0.7–0.8$. Median correlations between $PM_{2.5}$ and $PM_{10–2.5}$ range between 0.2 and 0.5, with higher values in summer and fall. Correlation data for UFP were very limited, but they indicate correlations as high as Pearson $R = 0.5$ for NO_2 and NO_X, which are also traffic-related pollutants. Moderate-to-strong correlations may introduce a greater degree of confounding into epidemiologic study results, depending on the relationship between the copollutants and the health effect of interest.

Ambient PM data from fixed-site monitors continue to be commonly used in health studies as a surrogate for PM exposure concentration (Section 3.3.1.1). Advantages to using fixed-site monitoring

data are that they provide a long-term record of concentration trends and they undergo rigorous quality assurance if FRMs or FEMs are used. The concentration profile of $PM_{2.5}$ tends to be less variable across the urban or neighborhood scale compared with $PM_{10–2.5}$ or UFP. Therefore, ambient $PM_{2.5}$ concentrations estimated at fixed-site monitors often provide a reasonable representation of exposure concentrations throughout the study area (Section 3.4.2.2). However, the higher degree of spatial variability in ambient $PM_{10–2.5}$ and UFP across an urban area may not be captured by a fixed-site monitor. Uncharacterized variability in a time-series of exposure concentrations across space, resulting from use of fixed-site monitoring data, in a time-series study of $PM_{10–2.5}$ or UFP exposure may attenuate health effect estimates, so that the health effect estimate underestimates the true health effect (Section 3.4.5.1). Bias may occur in either direction for long-term exposure studies, depending on whether the fixed-site monitor is over- or underestimating ambient $PM_{10–2.5}$ or UFP exposure concentration for the population of interest (Section 3.4.5.2). In all study types, use of fixed-site monitoring ambient $PM_{10–2.5}$ or UFP concentrations in lieu of the true exposure is expected to widen confidence intervals beyond what would be obtained if the true exposure were used. Personal monitors directly measure PM exposure, but they produce a relatively limited data set, making them most suitable for panel epidemiologic studies (Section 3.4.5.1.2). Without accompanying time-activity data, ambient PM exposure cannot be distinguished from personal PM exposure in personal monitoring studies (Section 3.4.2.1).

When spatial variability of exposure concentration surfaces is not accurately modeled, the health effect estimate tends to be biased towards the null with decreased probability that the confidence intervals contain the true health effect. Bias towards the null means that the health effect estimate is underestimating the true health effect. This is particularly true when the actual spatial variability is much higher than what is represented by the model (Section 3.4.5.2). Hybrid models typically have good cross-validation, especially for $PM_{2.5}$, and have the potential to reduce exposure measurement error and resulting bias and uncertainty in health effect estimates produced by epidemiologic models of long-term exposure to PM, even for spatially-varying size fractions and components. Bias correction and bootstrap calculation of standard errors have also been shown to improve health effect estimate prediction from spatiotemporal models when the exposure estimates have a classical-like error structure. When the exposure estimates have a Berkson-like error structure, health effect estimates would only be expected to improve when model covariates are chosen so that the statistical distribution of the modeled exposure concentrations is close to the distribution of the true exposure concentrations.

In summary, exposure error tends to produce underestimation of health effects in epidemiologic studies of PM exposure, although bias in either direction can occur. New developments in PM exposure assessment, including hybrid spatiotemporal models that incorporate satellite observations of AOD, land use variables, surface monitoring data from FRMs, and/or CTMs, have led to improvements in spatial resolution of the $PM_{2.5}$ concentration surface. These advancements have reduced bias and uncertainty in health effects estimates. However, high correlations with some gaseous copollutants necessitate evaluation of the impact of confounding on health effects estimates, using two-pollutant models to ascertain robustness of epidemiologic study results. $PM_{10–2.5}$ and UFP concentrations are typically more

spatially variable than $PM_{2.5}$ concentrations, and concentration data for those size fractions are less frequently available as model input or for use in validating hybrid models. As a result, there is typically less uncertainty in health effect estimates derived from both monitored and modeled exposure estimates for $PM_{2.5}$ compared with $PM_{10-2.5}$ and UFP.

CHAPTER 4 DOSIMETRY OF PARTICULATE MATTER

Overall Conclusions regarding the Dosimetry of Particulate Matter (PM)

- Our basic understanding of the mechanisms of particle deposition and clearance has not changed since the last PM ISA (U.S. EPA, 2009). However, comparisons of deposition across species have improved. Evidence in this review also better quantifies the fraction of inhaled particles reaching the lungs and particle translocation from the respiratory tract.
- Evidence included in this review shows a smaller fraction of inhaled air enters though the nose of children relative to adults. This, in combination with lower nasal particle deposition efficiency in children compared to adults, results in a greater fraction of inhaled PM reaching and potentially depositing in the lungs of children relative to adults.
- New dosimetric information shows that PM_{10} overestimates the size of particles likely to enter the human lung. New dosimetric information that improves interspecies extrapolations, quantifies the fraction of inhaled PM entering the lungs of humans and rodents.
- New information, altering a conclusion in the last PM ISA, shows that particle translocation from the olfactory mucosa via axons to the olfactory bulb may be important in humans.
- New data show translocation of gold nanoparticles from the human lung into circulation. Of deposited particles, a small fraction (0.05%) eliminated via urine is quantitively similar between humans and rodents. New rodent data show that the fraction (≤0.2% for particles 5−200 nm) of nanoparticle translocation from the lungs is particle size dependent and that gastrointestinal tract absorption of particles is a minor route into circulation.

4.1 Introduction

Particle dosimetry refers to the characterization of deposition, translocation, clearance, and retention of particles and their components within the respiratory tract and extrapulmonary tissues. This chapter summarizes basic concepts presented in dosimetry chapters of more recent PM AQCDs (U.S. EPA, 2004, 1996) and the PM ISA (U.S. EPA, 2009), and updates the state of the science based upon new literature appearing since publication of these PM assessments. Although the basic understanding of the mechanisms governing deposition and clearance of inhaled particles has not changed, there is significant additional information on the role of certain biological determinants such as sex, age, and lung disease on deposition and clearance.

Relative to the last PM ISA (U.S. EPA, 2009), extra emphasis is placed on differences between children and adults. In general, children breathe less through the nose and have less deposition in the extrathoracic airways than adults. This leads to a relatively higher concentration of PM reaching the lower airways of children than adults. Much of the literature described in this chapter supporting differences in route of breath as a function of age and sex comes from older literature that was not included in prior reviews. Additionally, substantially more particle translocation data have become available on the extent of inhaled material is detected in organs. Some studies have evaluated whether translocation is due to direct air-blood barrier translocation from the lung versus gastrointestinal uptake of particles or solubilization with subsequent movement to organs. There are also limited data on transplacental

movement of particles. Although only a small portion of insoluble particles translocate to extrapulmonary organs, their translocation can be rapid (<1 hour) and is size dependent. Translocation of particles depositing on the olfactory epithelium to the olfactory bulb is also now recognized as a potentially important route of movement to the brain for insoluble particles (<200 nm) or soluble components of any sized particle in humans as well as rodents.

The dose from inhaled particles deposited and retained in the respiratory tract is governed by a number of factors. These include exposure concentration and duration, activity and breathing conditions (e.g., nasal vs. oronasal and minute ventilation), and particle properties (e.g., particle size, hygroscopicity, and solubility in airway fluids and cellular components). The basic characteristics of particles as they relate to deposition and retention, as well as anatomical and physiological factors influencing particle deposition and retention, were discussed in depth in CHAPTER 10 of 1996 PM AQCD and updated in CHAPTER 6 of the 2004 PM AQCD. Species differences between humans and rats in particle exposures, deposition patterns, and pulmonary retention were also reviewed by Brown et al. (2005). New to this review, similarities in particle deposition among several species are provided. Other than a brief overview in this introductory section, the disposition (i.e., deposition, absorption, distribution, metabolism, and elimination) of fibers and unique nano-objects (e.g., hollow spheres, rods, fibers, tubes) is not reviewed herein (see Section P.3.1). Substantial exposures to fibers and unique nano-objects generally occur in the occupational settings rather than the ambient environment.

The deposition by interception of micro-sized fibers was briefly discussed in the 1996 and 2004 PM AQCD, but fiber retention in the respiratory tract was not addressed. Airborne fibers (length/diameter ratio ≥3), can exceed 150 μm in length and appear to be relatively stable in air. This is because their aerodynamic size is determined predominantly by their diameter, not their length. Fibers longer than 10 μm can deposit by interception and when aligned with the direction of airflow may penetrate deep into the respiratory tract. Once deposited, macrophage mediated clearance is the primary mechanism of removing micro-sized particles from the pulmonary region. The length of fibers can, however, affect their phagocytosis and clearance. For example, fibers of >17 μm in length are too long to be fully engulfed by rat alveolar macrophages and can protrude from macrophages (i.e., macrophage frustration) (Zeidler-Erdely et al., 2006). The ability of fibers, particularly small ones (<5 μm length and <0.25 μm diameter), to translocate from the lungs to the parietal pleura, liver, and kidney is reviewed by Miserocchi et al. (2008). Further discussion of the fiber disposition in the respiratory tract is beyond the scope of this chapter.

The term “ultrafine particle” has traditionally been used by the aerosol research and inhalation toxicology communities to describe airborne particles or other laboratory generated aerosols used in toxicological studies that are ≤100 nm in size (based on physical size, diffusivity, or electrical mobility). Generally consistent with the definition of an ultrafine particle (UFP), the International Organization for Standardization (ISO) define a nanoparticle as an object with all three external dimensions in the nanoscale, i.e., from approximately 1 to 100 nm (ISO, 2008). The ISO also defined a nano-object as a

material with one or more external dimensions in the nanoscale. The terms, nanoparticle and UFP, have been used rather synonymously in the toxicological literature. Within this chapter the usage of UFP or nanoparticle is restricted to particles have physical diameter or mobility diameter (the size of a sphere having the same diffusivity or movement in an electrical field as the particle of interest) less than or equal 100 nm, whereas other chapters may extend the definition to <0.30 µm (Section P.3.1 and Section 2.4.3.1).

4.1.1 Size Characterization of Inhaled Particles

Particle size is a major determinant of the fraction of inhaled particles depositing in and cleared from various regions of the respiratory tract. The distribution of particle sizes in an aerosol is typically described by the lognormal distribution (i.e., the situation in which the logarithms of particle diameter are distributed normally). The geometric mean is the median of the distribution, and the variability around the median is the geometric standard deviation (GSD or σ_g).

The particle size associated with any percentile of the distribution, d_i, is given by:

$$d_i = d_{50\%}\,\sigma_g^{z(P)}$$

Equation 4-1

where: z(P) is the normal standard deviate for a given probability. In most cases, the aerosols to which people are naturally exposed are polydisperse. By contrast, most experimental studies of particle deposition and clearance in the lung use monodisperse particles (GSD <1.15). Ambient aerosols may also be composed of multiple size modes, each mode should be described by its specific median diameter and GSD.

Aerosol size distributions may be measured and described in various ways. When a distribution is described by counting particles, the median is called the count median diameter (CMD). On the other hand, the median of a distribution based on particle mass in an aerosol is the mass median diameter (MMD). Impaction and sedimentation of particles in the respiratory tract depend on a particle's aerodynamic diameter (d_{ae}), which is the size of a sphere of unit density that has the same terminal settling velocity as the particle of interest. The size distribution is frequently described in terms of d_{ae} as the mass median aerodynamic diameter (MMAD), which is the median of the distribution of mass with respect to aerodynamic equivalent diameter. Alternative descriptions should be used for particles with actual physical sizes below ≈0.5 µm because, for those sized particles, aerodynamic properties become less important and diffusion becomes ever more important. For these smaller particles, their physical diameter or CMD are typically used since diffusivity is not a function of particle density. For small irregular shaped particles and aggregates, the diameter of a spherical particle that has the same diffusion coefficient in air as the particle in question is appropriate, i.e., a thermodynamic diameter. Unless stated otherwise, all particle diameters in the text of this chapter that are ≥0.5 µm are aerodynamic diameters.

All particle diameters ≤0.1 µm are a thermodynamic diameter. A few studies provide UFP deposition data and continue to monitor deposition to diameters of 0.2 to 0.3 µm. Those larger 0.2 to 0.3 µm particles should be assumed to be thermodynamic diameters. Within this chapter, plots of predicted particle deposition with particles between 0.1 and 0.5 µm were simulated assuming unit density spheres so that the physical, thermodynamic, and aerodynamic diameters are the same.

A number of papers have become available that assess the deposition and translocation of very small nanoparticles below 10 nm in diameter (see Section 4.3.3). Calculation of particle surface area for micron sized particles have are general calculated as πd^2. Specific surface area (i.e., normalized to particle mass) is $6/(\rho d)$, where ρ is particle density. However, when particle diameter is below 10 nm, this means of estimating surface area become imprecise. Below 10 nm, it becomes necessary to consider the angularity of the surface in particles consisting of a small number of atoms (Janz et al., 2010). It is also interesting to consider the number of atoms in some of the newer nanoparticle literature. For instance, considering gold nanoparticles, a 1.2 nm particles contain 35 gold atoms, a 1.4 nm particle has 55 gold atoms, and a 1.8 nm particle has 150 gold atoms (Pan et al., 2007).

4.1.2 Structure and Function of the Respiratory Tract

4.1.2.1 Anatomy

The basic structure of the human respiratory tract is illustrated in Figure 4-1. In the literature, the terms extrathoracic (ET) region and upper airways or upper respiratory tract are used synonymously. The terms lower airways and lower respiratory tract are used to refer to the thoracic airways, i.e., the combination of the tracheobronchial (TB) region which is the conducting airways and the alveolar region which is the functional part or parenchyma of the lung. A review of interspecies similarities and differences in the structure and function of the respiratory tract is provided by Phalen et al. (2008). Although the structure varies, the illustrated anatomic regions are common to all mammalian species with the exception of the respiratory bronchioles. Respiratory bronchioles, the transition region between ciliated and fully alveolated airways (i.e., alveolar ducts and sacs), are found in humans, dogs, ferrets, cats, goats, and monkeys (Phalen et al., 2008; Phalen and Oldham, 1983). Respiratory bronchioles are absent in rats and mice and abbreviated in hamsters, guinea pigs, rabbits, oxen, sheep, and pigs (Phalen et al., 2008; Phalen and Oldham, 1983). The branching structure of the ciliated bronchi and bronchioles also differs between species from being a rather symmetric and dichotomous branching network of airways in humans to a more monopodial branching network in other mammals including monkeys.

Figure 4-1. Diagrammatic representation of human respiratory tract regions.

The development of the lung is not complete at birth. Prior to the work of Dunnill (1962), there were two competing opinions as to whether the lung was: (1) fully developed at birth and simply increased in volume by increasing dimensions of the airways and alveoli or (2) increased in volume by the creation of new units (alveoli and alveolar sacs) within the distal lung. Based on postmortem morphometric analysis of 20 lungs from 10 children, Dunnill (1962) concluded there was continued creation of new alveolar sacs and alveoli from birth to 8 years of age. This conclusion, in part, was based on the observation that the number of alveoli in the 8-year-old child was close to that observed in an adult male. After about 8 years of age, the continued increase in lung volume was presumed due to increased airway and alveolar dimensions. In a larger study 36 boys and 20 girls ranging from 6 weeks to 14 years of age, Thurlbeck (1982) concluded that the creation of new alveoli continued until at least 2 years of age,

but that there is considerable variability in the number of alveoli among individuals and a considerably larger number of alveoli than observed by Dunnill (1962). This variability and larger number of alveoli lead Thurlbeck (1982) to question whether the lungs of 8 year old child in the Dunnill (1962) study would have continued to grow with creation of additional alveoli. Although it was clear from these studies that new alveoli were created in humans postnatally, it was unclear when this process ceased.

Recent work shows postnatal creation of alveoli into young adulthood occurs in multiple mammalian species. The prenatal and postnatal creation of alveoli is synonymously termed alveogenesis, alveologenesis, and alveolarization in the literature (Bourbon et al., 2005). Lewin and Hurtt (2017) review six stages of lung development (i.e., embryonic, pseudoglandular, canlicular, saccular, alveolar, and microvascular maturation) across several mammalian species as well as some aspects of immune function development and some causes of impaired lung development. Here, a few points related to the structural development of the lung are noted based largely on Lewin and Hurtt (2017). The canlicular stage is completed about 25 gestational weeks in humans and is marked by the completion of tracheobronchial airways branching structure. Alveolar cells become identifiable during the saccular stage at about 24 weeks in human fetus and about 19 days in rat fetus. Subsequently, terminal bronchioles end in sac-like structures. Rats and mice are born at this stage of respiratory development, whereas alveolarization begins prenatally with 10−20% of adult alveoli found at birth in humans, rabbits, and sheep. Rapid alveolarization occurs during the first 3 weeks of life in rats and first 2−3 years in humans (Herring et al., 2014). Following the period of rapid alveolarization there is evidence for a more gradual increase that may occur to until young adulthood for multiple species including rodents, dogs, monkeys, and humans (Lewin and Hurtt, 2017; Herring et al., 2014; Narayanan et al., 2012; Hyde et al., 2007). This is consistent with the period of increasing in lung volume in humans with age (and height) until around 18 years of age in females and 20 years of age in males (Hankinson et al., 1999).

4.1.2.2 Breathing Rates

Some general species information relevant to particle dosimetry (e.g., breathing parameters and respiratory surface areas) is provided in Table 4-1. The data in this table are for gross comparison among resting adults since specific strains are not individually characterized nor are changes with animal age characterized. Additional data for rats on respiratory tract volumes and breathing rates as a function of animal weight are available from Miller et al. (2014). Across species, ventilation rates increase with increases in activity. Within species, there are also differences among strains in breathing patterns and rates. Furthermore, stress due to experimental protocols may alter breathing patterns differentially among species. In rats, Mauderly and Kritchevsky (1979) reported restraint to cause increased breathing frequency (f) and decreased tidal volume (V_T), while minimally affecting overall minute ventilation. In mice, Mendez et al. (2010) reported restrained animals to have approximately 2.4 times the minute ventilation of unrestrained animals (27 and 64 mL/min, respectively). Most of this increase in minute ventilation came from a doubling of f from 145 min^{-1} to 290 min^{-1}. However, in a study of four mouse

strains, DeLorme and Moss (2002) consistently observed decreased breathing frequency and minute ventilation in restrained mice (*f*, 335 min^{-1}; minute ventilation, 70 mL/min) relative to unrestrained mice (*f*, 520 min^{-1}; minute ventilation, 120 mL/min). These findings are consistent with Alessandrini et al. (2008), who reported a breathing frequency of 500 min^{-1} and minute ventilation of 106 mL/min in unrestrained mice. Thus, even within one species there can be large differences in breathing conditions between studies. Breathing patterns and minute ventilation must both be considered to accurately assess particle deposition fractions and dose rates.

Table 4-1. Typical respiratory parameters and body weights among animals and humans.

Species	Breathing Frequency min^{-1}	Tidal Volume mL	Minute Ventilation mL/min	Functional Residual Capacity mL	Alveolar surface Area m^2	Body Weight kg
Mouse (restrained)	290[a]	0.22[a]	64[a]	0.5[e]	0.05[f]	0.02[f]
Mouse (unrestrained)	145[a]	0.19[a]	27[a]	0.5[e]	0.05[f]	0.02[f]
Rat	102[b]	2.1[b]	214[b]	3.5[e]	0.4[f]	0.4[f]
Dog	22[c]	175[c]	3,600[c]	500[c]	52[f]	16[f]
Human (male)	12[d]	625[d]	7,500[d]	3,300[d]	140[d]	73[d]
Human (female)	12[d]	444[d]	5,330[d]	2,700[d]	100[g]	60[d]

Table 4-1 shows considerable variation among species in adults. The effect of activity on ventilation rates is discussed in Section 4.2.4.1 in relation to the effect of activity in adults on particle deposition. Minute ventilation changes with age and growth [for humans see U.S. EPA (2011)]. Breathing patterns of humans are well recognized to change with increasing age, i.e., V_T increase and respiratory rates decrease (Tobin et al., 1983a; Tabachnik et al., 1981). Some guidance for humans with regard to changing breathing patterns with age and activity are provided by ICRP (1994). Recent data show median *f* decreases linearly from 44 min^{-1} in infants to 30 min^{-1} at 2 years of age and linearly from 22 min^{-1} at 6 years to 15.5 min^{-1} at 18 years (Fleming et al., 2011). Allometric scaling can be used to adjust breathing

patterns of immature animals as a function body weight (BW, kg). Breathing frequency (min^{-1}) from Piccione et al. (2005) is $82*BW^{-0.287}$ and aligns well with breathing frequency for rats, but for mice provides a value between that of restrained and unrestrained animals. Minute ventilation (L/min) from Bide et al. (2000) is $0.499*BW^{0.809}$ and aligns well with minute ventilation for rats, but for mice provides a value lower than that of unrestrained animals. Allometric predictions for mice can be scaled (observed ÷ predicted value) to match those of adults in Table 4-1 and tidal volume may be estimated as minute ventilation divided by breathing frequency.

The ICRP indicated a 3-month-old infant might be expected to breathe with a minute ventilation of 1.5 L/min (V_T, 39 mL; *f*, 38 min^{-1}) at rest/sleep and 3.2 L/min (V_T, 66 mL; *f*, 48 min^{-1}) during light activity/exercise. Some more recent data suggest higher respiratory rates for 3-month-olds with a median *f* of 42 min^{-1} with 10th to 90th percentiles of 34 and 56 min^{-1}, respectively (Fleming et al., 2011). For their in vitro investigation of nasal versus oral particle penetration into the lower respiratory tract, Amirav et al. (2014) used minute ventilations of 2.0 and 3.2 L/min (50 and 80 mL V_T at 40 min^{-1}) for 5month-olds as well as for 14-month-olds and minute ventilations of 2.4 and 3.6 L/min (80 and 120 mL V_T at 30 min^{-1}) for 20-month-olds based on the recent literature. Normalized to body mass, median daily ventilation rates (m^3/kg-day) decrease over the course of life (Brochu et al., 2011). This decrease in ventilation relative to body mass is rapid and nearly linear from infancy through early adulthood. Relative to normal-weight male and female adults (25−45 years of age; 0.271 m^3/kg-day), ventilation rates normalized to body mass are increased 1.5 times in normal-weight children (7−10 years of age; 0.402 m^3/kg-day) and doubled in normal-weight infants (0.22−0.5 years of age; 0.538 m^3/kg-day).

4.1.2.3 Epithelial Lining Fluid

The site of particle deposition within the respiratory tract has implications related to lung retention and surface dose of particles as well as potential systemic distribution of particles or solubilized components. There are progressive changes in airway anatomy with distal progression into the lower respiratory tract. In the bronchi there is a thick liquid lining and mucociliary clearance rapidly moves deposited particles toward the mouth. In general, in the bronchi, only highly soluble materials moving from the air into the liquid layer will have systemic access via the blood. With distal progression, the protective liquid lining diminishes and mucus clearance rates slow. Soluble compounds and some poorly soluble UFPs may potentially cross the air-liquid interface to enter the tissues and the blood, especially in the alveolar region.

The epithelial lining fluid (ELF) over most of the tracheobronchial region may generally be described as consisting of two layers: an upper mucus layer and a periciliary layer, which surrounds the cilia (Button et al., 2012; Widdicombe, 2002; Widdicombe and Widdicombe, 1995; Van As, 1977). The length of motile human cilia is about 7 μm in the distal nasal airways, trachea, and bronchi and around 5 μm in the bronchioles (Yaghi et al., 2012; Song et al., 2009; Clary-Meinesz et al., 1997; Widdicombe

and Widdicombe, 1995). In the healthy lung, the thickness of the periciliary layer is roughly the length of the cilia (Song et al., 2009; Widdicombe and Widdicombe, 1995). This periciliary layer forms a continuous liquid lining over the tracheobronchial airways; whereas the upper mucus layer is discontinuous and diminishes or is absent in smaller bronchioles (Widdicombe, 2002; Van As, 1977). The periciliary layer may be the only ELF layer (i.e., there is little to no overlaying mucus) in the ciliated airways of infants and healthy adults who are unaffected by pathology related to disease, infection, or other stimuli (Bhaskar et al., 1985).

The ELF covering the alveolar surface is considerably thinner than the periciliary layer found in the tracheobronchial region. The alveolar ELF consists of two layers: an upper surfactant layer and a subphase fluid (Ng et al., 2004). Bastacky et al. (1995) conducted a low temperature scanning electron microscopy analysis of rapidly frozen samples (9 animals; 9,339 measurements) of rat lungs inflated to approximately 80% total lung capacity. The alveolar ELF was found to be continuous, but of varied depth. Three distinct ELF areas were described: (1) a thin layer (0.1 μm median depth, GSD ~ 2.16; GSDs were calculated from 25th, 50th, and 75th percentiles of the distributions) over relatively flat areas and comprising 80% of the alveolar surface, (2) a slightly thinner layer (0.08 μm, GSD ~ 1.79) over protruding features and accounting for 10% of the surface, and (3) a thick layer (0.66 μm, GSD ~ 2.18) occurring at alveolar junctions and accounting for 10% of the surface. Based on these distributions of thicknesses, 10% of the alveolar region is covered by an ELF layer of 0.04 μm or less. Presuming that these depths would also occur in humans at 80% total lung capacity and assuming isotropic expansion and contraction, depths should be expected to be 20−40% greater during normal tidal breathing (rest and light exercise) when the lung is inflated to between 50−60% total lung capacity averaged across the respiratory cycle. During tidal breathing, a median ELF depth of 0.12−0.14 μm would be expected over 80% of the alveolar surface with 10% of the alveolar surface having a median depth of around 0.05 μm or less. Considering the entire distribution of depths during tidal breathing, about 30, 60, and 90% of the alveolar surface would be estimated to have a lining layer thickness of less than or equal to 0.1, 0.2, and 0.5 μm, respectively.

4.1.3 Route of Breathing

As humans, we breathe oronasally, i.e., through both our nose and mouth. In general, we breathe through our nose when at rest and increasingly through the mouth with increasing activity level. Few people breathe solely through their mouth. In contrast to humans, rodents are obligate nose breathers. Brown et al. (2013) found that the penetration of particles greater than 1 μm into the lower respiratory tract of humans was more affected by route of breathing than age, sex, activity level, or breathing pattern (i.e., V_T and f). This section describes how route of breathing, also referred to as "respiratory mode" or "breathing habit" in the literature, is affected by age, sex, activity level, and upper respiratory tract anomalies. Based on literature that is decades old but that has not been included in prior PM ISA or

AQCDs, this section will show that children breathe more though the mouth than adults and that across all ages, males breathe more through their mouth than females.

One of the more commonly referenced studies in dosimetric papers is Niinimaa et al. (1981). This paper is referenced in all prior PM reviews back to 1982 PM AQCD (U.S. EPA, 1982) as the primary data source on route of breathing. Niinimaa et al. (1981) examined route of breathing in a group of healthy individuals (15−35 years of age; 14 M, 21.6 ± 3.8 years; 16 F, 22.9 ± 5.4 years) recruited via advertisements posted on the University of Toronto campus. The investigators found that most individuals, 87% (26 of 30) in the study, breathed through their nose until an activity level was reached where they switched to oronasal breathing. Thirteen percent (4 of 30) of the subjects, however, were oronasal breathers even at rest. These two subject groups (i.e., the 87 and 13% of subjects) are commonly referred to in the literature [e.g., ICRP (1994)] as "normal augmenters" and "mouth breathers," respectively. More recently, Bennett et al. (2003) reported a more gradual increase in oronasal breathing with males (n = 11; 22 ± 4 years) tending to have a greater oral contribution than females (n = 11; 22 ± 2 years) at rest (87 vs. 100% nasal, respectively) and during exercise (45 vs. 63% nasal at 60% maximum workload, respectively).

Consistent with this trend for women to have a greater nasal contribution (Bennett et al., 2003), in a large study of children (63 M, 57 F; 4−19 years), Leiberman et al. (1990) reported a statistically greater nasal fraction during inspiration in girls relative to boys (77 and 62%, respectively; $p = 0.03$) and a marginally significant difference during expiration (78 and 66%, respectively; $p = 0.052$). Another large study (88 M, 109 F; 5−73 years) also reported females as having a significantly greater fraction of nasal breathing than males (Vig and Zajac, 1993). This effect was largest in children (5−12 years) with an inspiratory nasal fraction of 66% in males and 86% in females during resting breathing. This study also reported that the partitioning between the nose and mouth was almost identical between inspiration and expiration. In children and adults, sex explains some interindividual variability in route of breathing with females breathing more through the nose than males.

A few studies have attempted to measure oronasal breathing in children as compared to adults (Bennett et al., 2008; Becquemin et al., 1999; James et al., 1997; Vig and Zajac, 1993). James et al. (1997) found that children (n = 10; 7−16 years) displayed more variability than older age groups (n = 27; 17−72 years) with respect to their oronasal pattern of breathing with exercise. Becquemin et al. (1999) found that children (n = 10; 8−16 years) tended to display more oral breathing both at rest and during exercise than adults (n = 10; 27−56 years). The highest oral fractions were also found in the youngest children. Similarly, Bennett et al. (2008) reported children (n = 12; 6−10 years) tended to have a greater oral contribution than adults (n = 11; 18−27 years) at rest (68 vs. 88% nasal, respectively) and during exercise (47 vs. 59% nasal at 40% maximum workload, respectively). Vig and Zajac (1993) reported a statistically significant effect of age on route of breathing which was most apparent in males with the fraction of nasal breathing increasing from 67% in children (5−12-year-olds) to 82% in teens (13−19-year-olds), and 86% in adults (20−73 years). Females had a nasal fraction of 86% in children and

teens and 93% in adults. Based on these studies, the nasal fraction appears to increase with age until adulthood.

Several large studies have reported an inverse correlation ($r = -0.3$ to -0.6) between nasal resistance and nasal breathing fraction (Vig and Zajac, 1993; Leiberman et al., 1990; Leiter and Baker, 1989). However, neither pharmaceutical constriction nor dilation of the nasal passages affected the nasal fraction (Leiberman et al., 1990; Leiter and Baker, 1989). Nasal resistance decreases with age and is lower in females than males (Vig and Zajac, 1993; Becquemin et al., 1991). These differences in nasal resistance may account for larger nasal fractions in adults than children and females than males. Smaller studies (n = 37) have not found a significant correlation between nasal resistance and nasal fraction but have noted that those having high resistance breathe less through the nose (James et al., 1997). Bennett et al. (2003) reported a tendency for lower nasal resistance in African-American blacks (5 M,6 F; 22 ± 4 years) relative to Caucasians (6 M, 5 F; 22 ± 3 years). The nasal fraction in blacks tended to be greater at rest and 40% maximum workload and achieved statistical significance relative to Caucasians at 20 and 60% maximum workload. Leiter and Baker (1989) reported that of the 15 mouth-breathing children as identified by a dentist, pediatrician, or otolaryngologist in their study, the three having greatest nasal resistance breathed 100% through the mouth. These investigators also reported that the nasal fraction was negatively correlated ($p \leq 0.004$) with nasal resistance during both inspiration and expiration. However, the correlation appears driven by the three individuals with 100% mouth breathing. In a study of 102 children (evenly divided by sex) aged 6 to 14 years, Warren et al. (1990) reported that both nasal cross-sectional area and the fraction of nasal breath both increased with age, but did not report the association between these parameters or assess the effect of sex. The average nasal breathing fraction increased linearly from about 47% at 6 years of age to 86% at 14 years of age. Overall, breathing habit appears related to nasal resistance, which may explain some of the effects of age and sex on breathing habit.

Diseases affecting nasal resistance may also affect breathing route. Chadha et al. (1987) found that the majority (11 of 12) of patients with asthma or allergic rhinitis breathe oronasally even at rest. James et al. (1997) also reported the subjects (n = 37; 7−72 years) having hay fever, sinus disease, or recent upper respiratory tract symptoms tended to the have a greater oral contribution relative to those absent upper respiratory tract symptoms. James et al. (1997) additionally observed that two subjects (5.4%) breathed solely through the mouth but provided no other characteristics of these individuals. Greater oral breathing may occur due to upper respiratory tract infection and inflammation.

Some studies of children suggest obesity also affects breathing habit. Using MRI, Schwab et al. (2015) examined anatomic risk factors of obstructive sleep apnea in children (n = 49 obese with sleep apnea, 38 obese control, 50 lean controls; 11−16 years of age). In obese children with sleep apnea, adenoid size was increased relative to both obese and lean controls not having sleep apnea. The size of the adenoid was also increased in male obese controls (n = 24) relative to male lean controls (n = 35), whereas adenoid size was similar between female obese controls (n = 14) and female lean controls

(n = 15). Both nasopharyngeal cross-sectional area and minimum area were similar between lean and obese controls, but decreased in obese children with obstructive sleep apnea. In a longitudinal study of children (n = 47 F, 35 M) assessed annually from 9 to 13 years of age, Crouse et al. (1999) found nasal cross-section was minimal at 10 years of age. The authors speculated this may be due to prepubertal enlargement of the adenoids. In a 5 year longitudinal study of children (n = 17 M, 9 F) following adenoidectomy, Kerr et al. (1989) reported a change in mode of breathing from oral to nasal. These studies suggest the obese children, especially boys, may have increased oral breathing relative to normal weight children.

In summary, breathing habit is affected by age, sex, nasal resistance, and possibly obesity. Numerous studies show children to inhale a larger fraction of air through their mouth than adults. Across all ages, males also inhale a larger fraction of air through their mouth than females. Other factors that increase nasal resistance such as allergies or acute upper respiratory infections can also increase the fraction of oral breathing. Obesity, especially in boys, may also contribute to increased nasal resistance and an increased oral fraction of breathing relative to normal weight children.

4.1.4 Ventilation Distribution

Ventilation distribution refers to how an inhaled breath becomes divided in the lung. Ventilation distribution affects the partitioning or mass transport of inhaled aerosols between lung regions and the residence time within these regions. The effects of ventilation distribution on particle deposition are discussed in Section 4.2.4.6. In large mammals such as humans, there is a gravity induced gradient which causes the volume of alveoli in dependent lung regions (i.e., the lowest areas in the lungs) to be smaller than those in nondependent lung regions. During normal tidal breathing, dependent regions may have somewhat increased ventilation relative to nondependent regions. As a breath is distributed, so too may be associated airborne particles. Some experimental data are available on the association between regional deposition of ultrafine, fine, and coarse particles and regional ventilation in the healthy and diseased lung. Ventilatory inhomogeneity due to obstructive disease generally exceeds normal gravity induced gradients.

The distribution of ventilation has been studied in a number of animal species. There is a pronounced gravitation gradient in the ventilation distribution of standing horses with the dependent (ventral) regions receiving more of each breath than the nondependent (dorsal) regions (Amis et al., 1984). In standing Shetland ponies, late-term pregnancy has been reported to increase ventilation to the nondependent regions possibly due to intra-abdominal pressure on the dependent (ventral) regions (Schramel et al., 2012). In contrast to horses, data out to 20 days postpartum showed equal ventral-dorsal ventilation in these ponies. In the supine position, dogs and sloths show increased ventilation of the dependent (dorsal) regions relative to the nondependent (ventral) regions (Hoffman and Ritman, 1985). However, in the prone position there is essentially uniform ventral-dorsal ventilation in both the dogs and sloths. Thus, the position in which rats are exposed may influence the regional delivery and deposition of

inhaled aerosols. In rats, the nondependent region of the lung has been reported to be better ventilated, whether positioned supine, prone, or on either side (Dunster et al., 2012; Rooney et al., 2009). In humans, ventilation patterns are affected by both body position and lung inflation.

Milic-Emili et al. (1966) showed apical (nondependent) to basal (dependent) differences in pleural pressure can affect ventilation distribution in healthy individuals. In upright humans, the apical lung receives the majority of an inhaled air at low lung volumes (less than 20% vital capacity). Above this volume, the vertical proportioning of ventilation is relatively constant across a breath with basal regions (dependent part) having somewhat increased ventilation relative to apical regions (Milic-Emili et al., 1966). The effect of gravity is shifted by changes in body position. For instance, while lying on the left side, aerosols inhaled at low lung volumes will be preferentially transported into and deposited in the right lung (Bennett et al., 2002). In upright individuals at high lung volumes (70% or more of total lung capacity), particles are transported preferentially into and deposit in the left lung (Bennett et al., 2002). A more uniform left-right distribution of particle deposition is observed for inhalations closer to functional residual capacity (FRC). Left-right asymmetry in particle deposition at high lung volumes is primarily due to differences in ventilation between the lungs (Möller et al., 2009). The effect of gravity-induced gradients on ventilation and left-right asymmetry in upright individuals described here for healthy individuals, however, are small relative to the ventilatory heterogeneity caused by obstructive lung disease (Suga et al., 1995).

4.1.5 Particle Inhalability

In order to potentially become deposited in the respiratory tract, particles must first be inhaled. The inspirable particulate mass fraction of an aerosol is that fraction of the ambient airborne particles that can enter the uppermost respiratory tract compartment, the head (Soderholm, 1985). The American Conference of Governmental Industrial Hygienists (ACGIH) and the International Commission on Radiological Protection (ICRP) have established inhalability criteria for humans (ACGIH, 2005; ICRP, 1994). These criteria are indifferent to route of breathing and assume random orientation with respect to wind direction. They are based on experimental inhalability data for $d_{ae} \leq 100$ μm at wind speeds of between 1 and 8 m/s. For the ACGIH criterion, inhalability is 97% for 1 μm particles, 87% for 5 μm, 77% for 10 μm, and plateaus at 50% for particles above ~40 μm. The ICRP criterion, which also plateaus at 50% for very large d_{ae}, does not become of real importance until 5 μm where inhalability is 97%. Dai et al. (2006) reported slightly lower nasal particle inhalability in humans during moderate exercise than rest (e.g., 89.2 vs. 98.1% for 13 μm particles, respectively). Nasal particle inhalability is similar between an adult and 7-year old child (Hsu and Swift, 1999). Inhalability into the mouth from calm air in humans also becomes important for d_{ae} >10 μm (Anthony and Flynn, 2006; Brown, 2005). Unlike the inhalability from high wind speeds which plateaus at 50% for d_{ae} greater than ~40 μm, particle inhalability from calm air continues to decrease toward zero with increasing d_{ae} and is affected by route of breathing.

Inhalability data in laboratory animals, such as rats, are only available for breathing from relatively calm air (velocity ≤ 0.3 m/s). For nasal breathing, inhalability becomes an important consideration for particles larger than 1 μm in rodents and 10 μm in humans (Ménache et al., 1995). The inhalability of particles of 2.5, 5, and 10 μm is 80, 65, and 44% in rats, respectively, whereas it only decreases to 96% for an d_{ae} of 10 μm in humans during nasal breathing (Ménache et al., 1995). Asgharian et al. (2003) suggested that an even more rapid decrease in inhalability with increasing d_{ae} may occur in rats, particularly for faster breathing rates. Asgharian et al. (2014) extended his model to calculate inhalability for mice which had a slightly more rapid decline in inhalability with increasing particle size than rats. Inhalability and nasal deposition are particularly important considerations influencing how much PM makes it into the lower respiratory tract of rodents relative to humans.

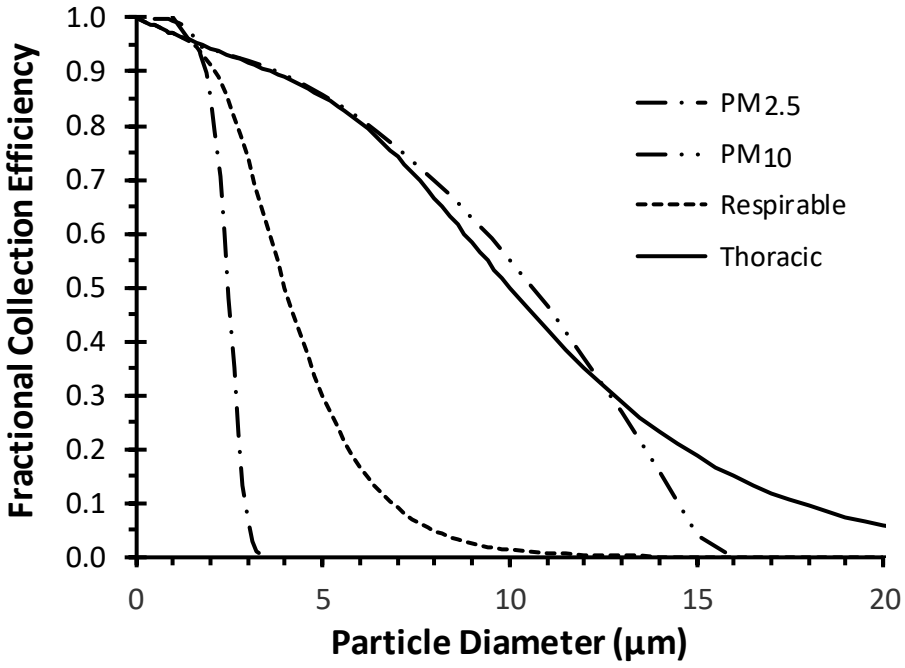
Kim et al. (2014) provide some computational fluid dynamics (CFD) simulations of inhalability for a 7-month old. Although the simulations were for an infant under a hood for drug delivery, these simulations may reasonably approximate inhalability from calm air. For a child sitting while quietly breathing (Q, 5 L/min), nasal inhalability decreased from 83% for 1 μm to 63% for 5 μm particles. For oronasal breathing, with 65% of air entering the mouth, inhalability was about 93% for 1 to 5 μm particles. These data suggest that particle inhalability of infants is much less than expected in adults.

4.1.6 Thoracic and Respirable Particles

This section describes sampling conventions that are used by in ambient and occupational settings. The particle sampling conventions are compared to demonstrate their similarities and differences. Finally, modeling is used to illustrate how the size of particles entering the lower respiratory tract (i.e., the thorax) is affected by route of breathing (see Section 4.1.3) and differs among species.

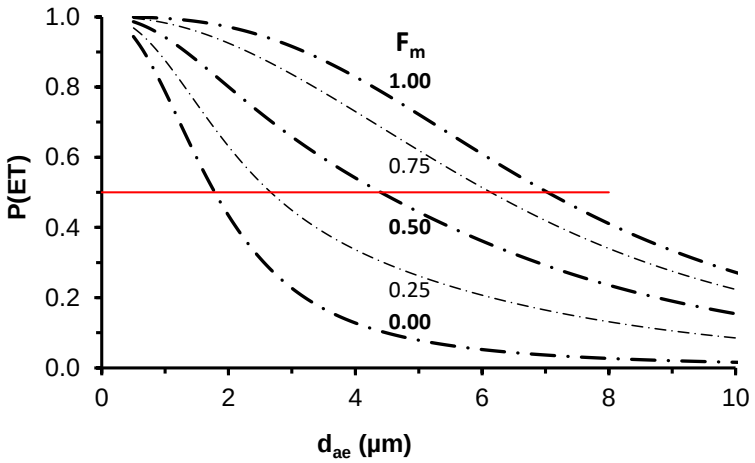
The terms thoracic particles and respirable particles refer to the fraction of particles that are able to enter the thoracic and gas exchange region of the lung, respectively. The European Committee for Standardization (CEN) specifically defines the thoracic fraction as the mass fraction of inhaled particles penetrating beyond the larynx (CEN, 1993). They further define the respirable fraction as the mass fraction of inhaled particles penetrating into the unciliated airways. More typically, the literature has defined the respirable fraction in relation to the fraction of particles entering the gas-exchange region or the fraction penetrating through the tracheobronchial region, the ciliated airways, or conducting airways. Relative to total airborne particles, the particle size having 50% penetration for the thoracic and respirable fractions are 10 μm and 4.0 μm (aerodynamic diameters), respectively (CEN, 1993). These criteria were specifically developed for workplace atmospheres. In 1987, the EPA adopted PM_{10} as the indicator of PM for the National Ambient Air Quality Standards (NAAQS) to delineate the subset of inhalable particles (referred to as thoracic particles) that were thought small enough to penetrate to the thoracic region (including the tracheobronchial and alveolar regions) of the respiratory tract.

Figure 4-2 illustrates the thoracic fraction and EPA's PM_{10} sampler collection efficiencies discussed above. These criteria are similar for particles smaller than 10 μm. However, the curves diverge between 12−13 μm, with a dramatic drop in collection efficiency for EPA's PM_{10} versus a more gradual decrease in sampler collection efficiency for the thoracic fraction criterion. The occupational respirable particle sampling convention and EPA's $PM_{2.5}$ are also illustrated in Figure 4-2. In 1997, EPA extended size-selective sampling to include fine particles indicated by $PM_{2.5}$ and retained PM_{10} as an indicator for the purposes of regulating the thoracic coarse particles or coarse fraction particles (i.e., the inhalable particles that remain if $PM_{2.5}$ particles are removed from a sample of PM_{10}). The selection of $PM_{2.5}$ by the EPA was mainly to delineate the atmospheric fine (combustion derived, aggregates, acid condensates, secondary aerosols) and coarse (crustal, soil-derived dusts) PM modes and for consistency with community epidemiologic health studies reporting various health effects associated with $PM_{2.5}$ (U.S. EPA, 1997). Although Miller et al. (1979) recommended a particle size cut-point of ≤2.5 μm as an indicator for fine PM based on consideration of particle penetration into the gas-exchange region, the selection of $PM_{2.5}$ was not based on dosimetric considerations and was not intended to represent a respirable particle sampling convention. The thoracic sampling convention intentionally over represents the true penetration of particles into the thoracic region (compare Figure 4-1 and Figure 4-3). The American Conference of Governmental Industrial Hygienist (ACGIH) committee that recommended a 50% cut-point at 10 μm for the thoracic fraction considering uncertainty related to individual biological variability in respiratory health status, breathing patterns (rate and route), and airways structure as well as differences in work rates, all of which can cause differences in inhaled aerosol deposition and dose. Facing those uncertainties, the committee afforded extra protection to exposed workers by choosing a 50% cut-point at 10 μm rather than in the range of 5−7 μm where experimental studies showed 50% penetration of particles into the lower respiratory tract during oral breathing at ventilation rates equivalent to light exercise (ACGIH, 1985).



Source: Permission pending, $PM_{2.5}$ from Equation 1 of Peters et al. (2001) and/or 40CFR53, Subpart F, Table F-5; PM_{10} from Equation 11.19 of Hinds (1999) and/or 40CFR53.43 Table D-3; Respirable and Thoracic fractions are from Appendix C of ACGIH (2005).

Figure 4-2 Sampling conventions for U.S. EPA's $PM_{2.5}$ and PM_{10} and occupational criteria for thoracic and respirable fractions.



Source: Permission pending, Brown et al. (2013).

Figure 4-3 Thoracic fraction, i.e., particle penetration through the extrathoracic region, P(ET), as a function of breathing route in adult male during light exercise (V_T, 1,250 mL; *f*, 20 min^{-1}). F_m is the fraction of breath passing through mouth.

Brown et al. (2013) provide estimates of the thoracic and respirable fractions for healthy adult males, females, and a 10-year old child. The penetration of particles greater than 1 µm into the lower respiratory tract of humans was more affected by route of breathing than age, sex, activity level, or breathing pattern (i.e., V_T and *f*). Figure 4-3 illustrates this effect of route of breathing on the thoracic fraction. For typical activity levels and route of breathing, they estimated a 50% cut-size for the thoracic fraction at an aerodynamic diameter of around 3 µm in adults and 5 µm in children. The fraction of 10 µm particles entering the thorax was <20% for most activity levels and breathing habits. The penetration of 10 µm particles into the thorax was greatest, around 40%, for low levels of activity and purely oral breathing. Regardless of the breathing habit or activity level, the differences in the 50% cut-points for the thoracic and respirable fractions were far less than those used for occupational sampling. For oral breathing the 50% cut-point for the respirable fraction during oral breathing was within about 2 µm of the thoracic fraction cut-point, whereas it differs by 6 µm for occupational sampling criteria. For more typical breathing habits, the cut-points for the respirable and thoracic fractions were within about 0.5 µm. Two primary conclusions based on this study are: (1) PM_{10} over estimates the penetration of particles into the lower respiratory tract and (2) children are predicted to have greater particle penetration into the lower respiratory tract than adults.

Asgharian et al. (2014) recently provided estimates of the thoracic fraction in mice and rats as well as humans. The 50% cut-points for the thoracic fraction were roughly 1.1 µm in mice, 1.5 µm in rats,

and 3.7 µm in humans [see Figure 4 of Asgharian et al. (2014)]. The larger thoracic 50% cut-point for humans reported by Asgharian et al. (2014) relative to Brown et al. (2013) is, in part, due to the lower ventilation rate of 7.5 L/min used by the former versus average daily ventilation rates of 9 L/min and greater by the latter. One of the critical points that Asgharian et al. (2014) provide is that only a small fraction (2−5%) of particles greater than 3 µm reach the lower respiratory tract of the rodents. Thus, an appreciable fraction of inhaled thoracic coarse particles (i.e., $PM_{10-2.5}$) should not be expected to reach the lower respiratory tract of rodents during inhalation exposures.

Figure 4-4 illustrates the thoracic fraction in humans, rats, and mice calculated using the Multi-Path Particle Dosimetry model (MPPD; Version 3.04, ©2016).[42] For 50% cut-points are 3.4 µm (human, rest), 2.2 µm (human, light exercise), 1.6 µm (mouse, unrestrained), 1.1 µm (mouse, restrained), 1.6 µm (rat, rest). Note that although Table 4-1 shows increased breathing frequency and ventilation rates in restrained mice based on the review by Mendez et al. (2010), DeLorme and Moss (2002) consistently observed a lower breathing frequency and minute ventilation in restrained mice (f, 335 min^{-1}; minute ventilation, 70 mL/min) relative to unrestrained mice (f, 520 min^{-1}; minute ventilation, 120 mL/min). Regardless, with an increase in minute ventilation there is a decrease in the 50% cut-point for the thoracic fraction in both humans and mice.

[42]The MPPD model can be used to calculate particle deposition and clearance in multiple species. A description of the model, recent model improvements, and advancements incorporated into the MPPD model are provided by Miller et al. (2016). For additional information about the MPPD model (Version 3.04) or to obtain a copy, the reader is referred to: http://www.ara.com/products/mppd.htm.

Figure 4-4. Multispecies comparison of the thoracic fraction for nasal breathing with consideration for inhalability, i.e., particle penetration through the extrathoracic region, P(ET). Human, rest (V_T, 625 mL; *f*, 12 min^{-1}); Human, light exercise (V_T, 1,000 mL; *f*, 19 min^{-1}); Mouse, unrestrained (V_T, 0.19 mL; *f*, 145 min^{-1}); Mouse, restrained (V_T, 0.22 mL; *f*, 290 min^{-1}); Rat (V_T, 2.1 mL; *f*, 102 min^{-1}).

4.1.7 Dose and Dose Metrics

Assuming a constant exposure concentration, breathing rate, and aerosol particle size distribution, the total particle exposure or intake dose (ID) is given by:

$$ID = C \times f \times V_T \times I(d_{50\%}, \sigma_g) \times t$$

Equation 4-2

where: C is the mass concentration of the aerosol, *f* is breathing frequency, V_T is tidal volume, I(d50%, σ_g) is aerosol inhalability, and *t* is the duration of exposure. As discussed in Section 4.1.5, I(d50%, σ_g) should be considered for comparisons across species (e.g., human vs. rat), although this parameter should be negligible for particles under 1 µm. Intake doses characterized by Equation 4-2 are commonly normalized to body mass (Alexander et al., 2008). This may be particularly appropriate for soluble particles or materials expected to have systemic effects. Although C was specified as having units of particle mass per unit volume, other metrics such as particle surface area or number of particles per unit volume may be desired, especially for smaller particle sizes (e.g., <0.1 µm). Equation 4-2 is limited

in that it does not recognize that there are within-species differences as a function of particle size in total deposition (whole lung) and regional deposition (e.g., between TB and alveolar region) of particles.

The particle mass dose in a specific region (D_r) of the respiratory tract resulting from the particle inhalation may be given as:

$$D_r = ID \times DF_r$$

Equation 4-3

where: ID is the intake dose from Equation 4-2 and DF_r is the fraction of inhaled particles depositing in region *r* of the respiratory tract. The DF_r in Equation 4-3 can be calculated for a polydisperse aerosol by estimating the deposition fractions for a series of monodisperse aerosols as:

$$DF_r(d_{50\%}, \sigma_g) \approx \frac{1}{100} \sum_{P=0.01}^{0.99} DF_r(d_i)$$

Equation 4-4

where: $DF_r(d_i)$ in the summation is the deposition fraction in a region of the particle size associated with a given percentile, P, of the size distribution as calculated by Equation 4-1. Depending on health endpoints and particle size, the most appropriate dose metric choice for D_r may be mass, particle surface area, or number of particles deposited. The D_r may also be normalized to factors such as lung weight or surface area of specific regions of the respiratory tract. Because all of the variables potentially change over time, Equation 4-3 and Equation 4-4 are most appropriate for short duration exposures. Within an individual, the variability in DF_r over time is largely attributable to variations in inhaled particle size, *f*, V_T, and route of breathing (ICRP, 1994). Inter-subject and inter-species variability in DF_r is additionally affected by morphologic differences in the size and structure of the respiratory tract.

For chronic exposures, it is necessary to consider the retained dose. The particle dose retained in a region of the lung is determined by the balance between rate of input and the rate of removal. The particle burden (Br) in a region of lung may be expressed as:

$$B_r(t) = \dot{D}_r(t - \Delta t)\Delta t + B_r(t - \Delta t)[\exp(-\lambda_r \Delta t)]$$

Equation 4-5

where: $\dot{D}_r$ is the rate of deposition per unit time in region *r*, *t* is time, and λ_r is the clearance rate constant for region *r*, Δt is the time increment for the calculations (~1% [or less] of the clearance halftime [i.e., $0.693/\lambda_r$] of the region). $\dot{D}_r$ is calculated as D_r in Equation 4-3 except it is calculated for discrete Δt where parameters (namely, *f*, V_T, route of breathing, and DF_r) are relatively constant.

Under the premise that health effects from UFP are more associated with particle surface area of deposited particles than particle number or mass, some companies have started producing instruments to measure Lung Deposited Surface Area (LDSA). For a monodisperse ultrafine aerosol containing spherical

particles, the LDSA ($\mu m^2/cm^3$) is simply calculated as the particle surface area (μm^2) times particle number concentration ($\#/cm^3$) times the DF_r, where the DF_r is predicted for an adult male using the ICRP (1994) model under conditions of light exercise (V_T = 1.25 L and f = 20 min^{-1}) and nasal breathing (Asbach et al., 2009; Fissan et al., 2007). For a polydisperse aerosol, the estimated LDSA for specified particle size bins would be summed across aerosol distribution to obtain the total LDSA. Todea et al. (2015) assessed the accuracy of four types of commercially available devices available for the measurement of LDSA in the alveolar region.[43] The principle of operation is similar among the commercial devices with each imparting a unipolar charge on the incoming aerosol and subsequent measurement of electrical current from particles collected on a filter. Some conditioning of the incoming aerosol is typical, such as use of an impactor to remove large particles (roughly >1 µm) and/or an ion trap to remove small particles (generally <20 nm). The instruments do not actually measure the surface area of the particles, rather they provide an estimate of the particle surface area that is predicted to be deposited in the alveolar region of the lung. Theoretically, the measured LDSA most accurately matches predicted lung deposition for particles between 40 and 300 nm. However, measured values should be within ±30% from 20 to 400 nm. Studies characterizing LDSA in urban and microenvironments are becoming available [e.g., (Geiss et al., 2016; Kuuluvainen et al., 2016)] as are studies of health effects studies using LDSA [e.g., (Endes et al., 2017; Soppa et al., 2017)].

It should be noted that transfer into region *r* from another region may also occur. Such situations in which a region receives a portion of its burden from another region are common in the lung, for example, mucus clearance of the segmental bronchi into the lobar bronchi, which clear into the main bronchi, which in turn clear into the trachea. In addition, the clearance from one region can transfer burden into more than one other compartment, e.g., soluble particles in the airways may be cleared into the blood as well as via the mucus. Multiple pathways for clearance of insoluble particles exist. The main alveolar particle clearance pathway is macrophage mediated clearance with macrophage migration to the ciliated airways, but macrophage or particles themselves may also move from the alveoli into the lymph and remerge in the ciliated airways or blood. There are also considerable species differences in rates of clearance that should be considered for interspecies extrapolations evaluating chronic exposure scenarios.

4.2 Particle Deposition

Inhaled particles may be either exhaled or deposited in the ET, TB, or alveolar region. A particle becomes deposited when it moves from the airway lumen to the wall of an airway. The deposition of particles in the respiratory tract depends primarily on inhaled particle size, route of breathing (nasal or oronasal), tidal volume (V_T), breathing frequency (f), and respiratory tract morphology. The distinction between air passing through the nose versus the mouth is important since the nasal passages more effectively remove inhaled particles than the oral passage. Respiratory tract morphology, which affects

[43] One instrument offered the option of measuring LDSA for either the alveolar or the tracheobronchial region.

particle transport and deposition, varies between species, the size of an animal or human, and health status.

The fraction of inhaled aerosol becoming deposited in the human respiratory tract has been measured experimentally. Studies, using light scattering or particle counting techniques to quantify the amount of aerosol in inspired and expired breaths, have characterized total particle deposition for varied breathing conditions and particle sizes. The vast majority of in vivo data on the regional particle deposition has been obtained by scintigraphic methods where external monitors are used to measure gamma emissions from radiolabeled particles. These scintigraphic data have shown highly variable regional deposition with sites of highly localized deposition or "hot spots" in the obstructed lung relative to the healthy lung. Even in the healthy lung, "hot spots" occur in the region of airway bifurcations. Mathematical models aid in predicting the mixed effects of particle size, breathing conditions, and lung volume on total and regional deposition. Experimentally, however, there is considerable interindividual variability in total and regional deposition even when inhaled particle size and breathing conditions are strictly controlled. Section 4.2.4 on Biological Factors Modulating Deposition provides more detailed information on factors affecting deposition among individuals.

4.2.1 Mechanisms of Deposition

Particle deposition in the lung is predominantly governed by diffusion, impaction, and sedimentation. Most discussion herein focuses on these three dominant mechanisms of deposition. Simple interception, which is an important mechanism of fiber deposition, is not discussed in this chapter. Electrostatic and thermophoretic forces as mechanisms of deposition have not been thoroughly evaluated and receive limited discussion. Some generalizations with regard to deposition by these mechanisms follows, but should not be viewed as definitive rules. Both experimental studies and mathematical models have demonstrated that breathing patterns can dramatically alter regional and total deposition for all sized particles. The combined processes of aerodynamic and diffusive (or thermodynamic) deposition are important for particles in the range of 0.1 μm to 1 μm. Aerodynamic processes predominate above and thermodynamic processes predominate below this range. For detailed equations related to particle behavior in air and deposition in the human respiratory tract, the reader is referred to Annex D of ICRP (1994). Equations for calculation of deposition in the MPPD model are mostly summarized in Anjilvel and Asgharian (1995) and Asgharian and Price (2007) with physiological parameters summarized in Miller et al. (2016).

Diffusive deposition, by the process of Brownian diffusion, is the primary mechanism of deposition for particles having physical diameters of less than 0.1 μm. For particles having physical diameters of roughly between 0.05 and 0.1 μm, diffusive deposition occurs mainly in the small distal bronchioles and the pulmonary region of the lung. However, with further decreases in particle diameter

below ~0.05 μm, increases in particle diffusivity shift more deposition proximally to the bronchi and ET regions.

Governed by inertial or aerodynamic properties, impaction, and sedimentation increase with d_{ae}. When a particle has sufficient inertia, it is unable to follow changes in flow direction and strikes a surface thus depositing by the process of impaction. Impaction occurs predominantly at bifurcations in the proximal airways, where linear velocities are at their highest and secondary eddies form. Sedimentation, caused by the gravitational settling of a particle, is most important in the distal airways and pulmonary region of the lung. In these regions, residence time is the greatest and the distances that a particle must travel to reach the wall of an airway are minimal.

The electrical charge on some particles may result in an enhanced deposition over what would be expected based on size alone. With an estimated charge of 10−50 negative ions per particle, Scheuch et al. (1990) found deposition of 0.5 μm particles in humans (V_T = 500 mL, f = 15 min^{-1}) to increase from 13.4% (no charge) to 17.8% (charged). This increase in deposition is thought to result from image charges induced on the surface of the airway by charged particles. Yu (1985) estimated a charge threshold level above which deposition fractions would be increased of about 12, 30, and 54% for 0.3, 0.6, and 1.0 μm diameter particles, respectively. Electrostatic deposition is generally considered negligible for particles below 0.01 μm because so few of these particles carry a charge at Boltzmann equilibrium. This mechanism is also thought to be a minor contributor to overall particle deposition, but it may be important in some laboratory studies due to specific aerosol generation techniques such as nebulization. Laboratory methods such as passage of aerosols through a Kr-85 charge neutralizer prior to inhalation are commonly used to mitigate this effect.

The National Radiological Protection Board (NRPB) evaluated the potential for corona discharges from high voltage power lines to charge particles and enhance particulate doses (NRPB, 2004). They concluded that electrostatic effects would be the most important for particles in the size range from about 0.1−1 μm, where deposition may theoretically increase by a factor of three to ten. However, given that only a small fraction of ambient particles would pass through the corona to become charged, the small range of relevant particle sizes (0.1−1 μm), and the subsequent required transport of charged particles to expose individuals; the NRPB concluded that effects, if any, of electric fields on particle deposition in the human respiratory tract would likely be minimal.

When assessing particle behavior in the lower respiratory tract, it is important to consider how temperature affects their behavior. The mean free path of particles in air (i.e., the distance that particle travel in a given direction before colliding with an air molecule) and the dynamic viscosity of inhaled air are affected by the increased temperature in the lower respiratory tract relative to standard temperature and pressure. The mean free path increases from 66.4 nm at 20°C to 71.2 nm at 37°C (Briant, 1990). The dynamic viscosity of air increases from 1.82×10^{-4} poise at 20°C to 1.90×10^{-4} poise at 37°C (Briant, 1990). Due to these two parameters, the diffusivity of particles <0.1 μm is 1.08 times higher at 37 than 20°C. For micron sized particles, the time that it takes particles to change directions in response to a

change in the direction of airflow as well as the settling velocity of particles are decreased by about 4% at 37°C relative to 20°C. Thus, diffusive deposition is increased, whereas aerodynamic deposition is decreased at 37°C relative to 20°C.

There is less of an effect of body temperature on the particle behavior in the upper respiratory tract. Nasal mucosal temperatures decrease during inspiration and increase during expiration (Bailey et al., 2017; Lindemann et al., 2002). During inhalation of room temperature air (23−25°C), anterior mucosal temperatures can cycle 3−6°C between inspiration and expiration. More distally, 1°C fluctuations are observed at the nasopharynx, with average expiratory mucosal temperatures of 34°C (Lindemann et al., 2002). This indicates the temperature of inhaled air cannot achieve body temperature until it reaches the lower respiratory tract.

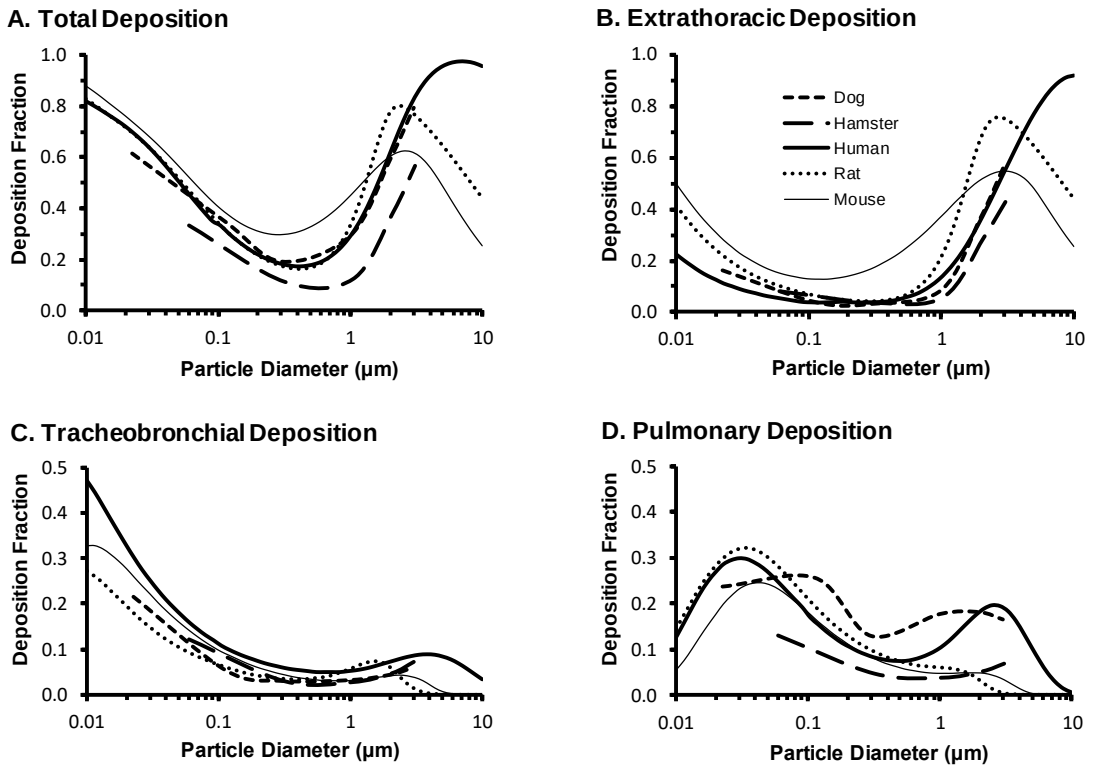
Thermophoretic forces on particles occur due to temperature differences between respired air and respiratory tract surfaces. Temperature gradients of around 20°C are thought to produce sufficient thermophoretic force to oppose diffusive and electrostatic deposition during inspiration and to perhaps augment deposition by these mechanisms during expiration (Jeffers, 2005). Thermophoresis is only relevant in the extrathoracic and large bronchi airways and reduces to zero as the temperature gradient decreases deeper in the lung. Theoretical analysis of thermophoresis has been done for smooth walled tubes and is important over distances that are several orders of magnitude smaller than the diameter of the trachea. The alteration of the flow patterns by airway surface features such as cartilaginous rings may affect particle transport and deposition over far greater distances than thermophoretic force.

4.2.2 Deposition Patterns

Knowledge of sites where particles of different sizes deposit in the respiratory tract and the amount of deposition therein is necessary for understanding and interpreting the health effects associated with exposure to particles. Particles deposited in the various respiratory tract regions are subjected to large differences in clearance mechanisms and pathways and, consequently, retention times. Deposition patterns in the human respiratory tract were described in considerable detail in dosimetry chapters of prior PM AQCD (U.S. EPA, 2004, 1996); as such, they are only briefly described here.

Predicted total and regional particle deposition in several mammalian species are illustrated in Figure 4-5. For all the species illustrated in Figure 4-5, ET deposition was based on experimental data at specific particle sizes or empirical fits to experimental data, while TB and pulmonary deposition were based on theoretical losses by diffusion, sedimentation, and impaction in species specific models of lower airways morphology. The predicted deposition for the human (male), mouse (unrestrained), and rat are for respiratory parameters in Table 4-1 using the MPPD model (Version 3.04, ©2016). Miller et al. (2016) reviews recent additions to the MPPD model that contribute to the ability to conduct cross-species extrapolations of both deposition and clearance. The effects of physiologic parameters on deposition in humans and rats free of respiratory disease are also described by de Winter-Sorkina and Cassee (2002).

The predicted deposition for the dog (V_T = 170 mL, f = 11.7 min^{-1}) and hamster (V_T = 0.72 mL, f = 59 min^{-1}) are based on Yeh (1980). The trends and magnitude of particle deposition are quite similar between the illustrated species. In the mouse and rat, due to particle inhalability, there is a gradual decrease in total and ET deposition for particles greater than about 2.5 to 3 μm. In the human, a similar decline in total deposition due to particle inhalability starts becoming apparent for particles above 7 to 8 μm.



Source: Permission pending, Adapted and updated from Brown (2015).

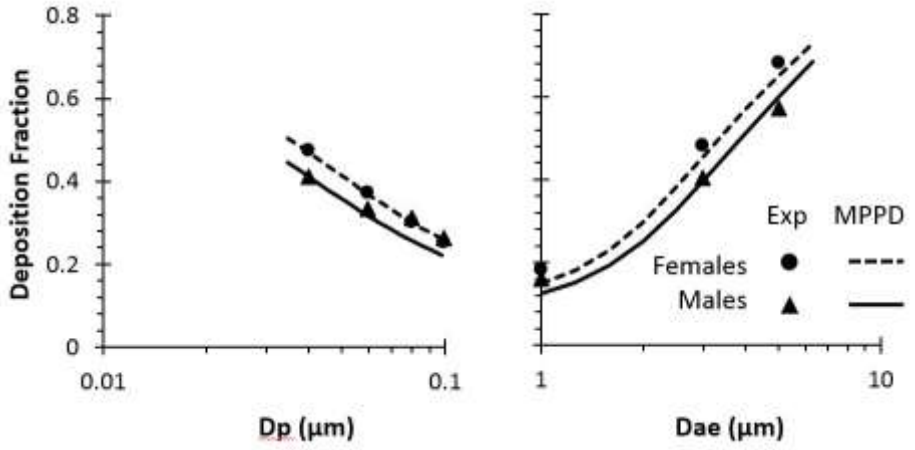
4.2.2.1 Total Respiratory Tract Deposition

Across mammalian species, the efficiency of deposition in the respiratory tract may generally be described as a "U shaped" curve on a plot of deposition efficiency versus the of log particle diameter as illustrated in Figure 4-5. Total deposition shows a minimum for particle diameters in the range of 0.1 to 1.0 μm, where particles are small enough to have minimal sedimentation or impaction and sufficiently

large so as to have minimal diffusive deposition. Total deposition does not decrease to zero for any sized particle, in part, because of mixing between particle laden tidal air and residual lung air. The particles mixed into residual air remain in the lung following a breath and are removed on subsequent breaths or gradually deposited. Total deposition approaches 100% for particles of roughly 0.01 μm due to diffusive deposition and for particles of around 10 μm due to the efficiency of sedimentation and impaction.

Total human lung deposition, as a function of particle size, is depicted in Figure 4-6. These experimental data were obtained by using monodisperse spherical test particles in healthy adults during controlled tidal breathing (V_T, 500 mL; *f*, 15 min^{-1}) on a mouthpiece. The experimental ultrafine data are for 11 males (age, 31 ± 4 years; FRC, 3,911 mL) and 11 females (age, 31 ± 4 years; FRC, 3,314 mL) from Jaques and Kim (2000). The fine and coarse data are for eight males (age, 31 ± 7 years; FRC, 3,730 mL) and seven females (age, 31 ± 6 years; FRC, 3,050 mL) from Kim and Hu (2006). The MPPD (Version 3.04) model used an upper airway volume of 40 mL and 50 mL for males and females, respectively, and the FRC from studies to predict particle deposition. Assuming isotropic expansion and contraction of the airways, scaling the airway morphology (length and diameters) to the cube root of volume, the model predictions are in good agreement with the mean experimental data.



Note: See text for more detail.

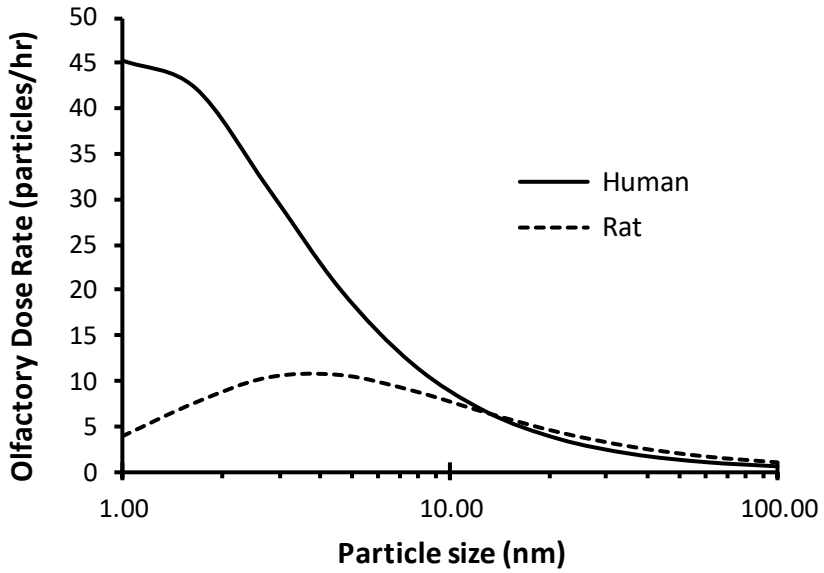
4.2.2.2 Extrathoracic Region

The first line of defense for protecting the lower respiratory tract from inhaled particles is the nose and mouth. Particle deposition in the ET region, especially the nasal passages, reduces the amount available for deposition in the TB and alveolar regions. Most of the new studies in the last PM ISA (U.S. EPA, 2009) were largely derived from computational fluid dynamics (CFD) modeling and experimental measurements in casts. Those studies generally reported that for particles >1 μm, deposition efficiency in the oral and nasal passages is a function of an impaction parameter (Stokes number) with the addition of a flow regime parameter (Reynolds number) for the oral passages. New studies are again largely derived from CFD modeling and experimental measurements in casts. Only a few new studies are discussed here, these were generally selected as those providing data for infants and children.

Several new papers from the same group describe nasal airway growth and particle deposition based on studies of nasal casts (Xi et al., 2014; Zhou et al., 2014; Zhou et al., 2013; Xi et al., 2012). The casts are for a 10-day old girl, 7-month old girl, a 5-year old boy, and a 53-year old man. The papers provide morphological data and total and regional deposition data (in vitro and CFD) for ultrafine and larger-sized particles (2−28 μm). For UFP, CFD simulations showed good agreement with other published studies of deposition in nasal casts for adults, infants, and children. Predicted ultrafine deposition was low (<10%) for particles larger than 10 nm, but rose rapidly to between 70 and 90% as particle size decreased to 1 nm (Xi et al., 2012). For particles ≤5 nm (not larger sizes), deposition also increased with decreasing flow (3 to 45 L/min), but this effect was less marked than the increase in deposition with decreasing particle size. Overall, the nasal deposition fractions of among the casts were rather similar when assessed as a function of a diffusion factor ($D^{0.5}Q^{-0.28}$; where, D is the particle diffusion coefficient and Q is flow rate). As a function of this diffusion factor, the deposition fractions were nearly identical for the 5-year old boy and 53-year old man with these two casts having greater deposition than those for the two younger girls' casts. For larger particles (monodisperse, 2−28 μm) delivered under resting breathing conditions, deposition data were well predicted and similar among all five casts as a function of a modified-impaction factor ($d_{ae}^2\Delta p^{2/3}$; where, Δp is the pressure drop across the nasal cast).

Another group has also recently published a series of experimental and CFD simulations of particle deposition in casts (Garcia et al., 2015; Schroeter et al., 2015; Garcia et al., 2009). The modified-impaction factor used by Zhou et al. (2014) was adopted from Garcia et al. (2009), who found that this factor better collapsed deposition factions among five adult nasal casts than several definitions of the Stokes number for nasal casts. More recently, Garcia et al. (2015) provided simulations of total ultrafine nasal deposition as well as that on the olfactory mucosa of humans and rats. Similar to Xi et al. (2012), these authors found that total nasal deposition in humans was low (<10%) for particles above about 10 nm, below which size deposition increased rapidly with decreasing particle size. Rats were predicted to have greater total and olfactory deposition than humans. However, due the much higher ventilation rate of humans than rats, humans were predicted to experience greater dose per olfactory

surface area for particles between 1 and 7 nm; above this size the dose per surface area was slightly greater in rats than humans. Figure 4-7 illustrates the olfactory dose rate of particles in humans and rats not normalized to olfactory surface area. Schroeter et al. (2015) provided experimental and CFD simulations for total and regional deposition of particles between 2.6 and 14.3 µm. For 5 to 14.3 µm particles inhaled during rest (Q, 16.5 L/min) about 2−5.5% deposition in the olfactory region was measured experimentally. In general, the CFD predicted pattern of deposition shifted proximally in the nose with increasing inspiratory flow and particle size. Nasal deposition was minimal for particles below 3 µm and 100% for the 14.3 µm particles.



Source: Permission pending, Based on empirical equations in Garcia et al. (2009) and Garcia et al. (2015).

Figure 4-7. Predicted nanoparticle olfactory dose rate (particles/hour) for resting ventilation (human, 7.5 L/min; rat, 0.288 L/min) and a concentration of one particle/cm^3 at any given particle size.

Some other recently published studies have used in vitro and in silico models to examine oral and nasal particle deposition in infants. Kim et al. (2014) used CFD simulations to evaluate particle inhalability (see Section 4.1.5) and penetration into the lower respiratory tract of a 7-month old. For quiet nasal breathing (Q, 5 L/min), the authors reported about 13.8% deposition of 2.5 µm particles in the nose, 0.4% in the lower-pharynx, and 11.8% in the larynx. As a point of clarification, the authors provided data separately for the nasopharynx which is the upper-pharynx and the pharynx.[44] For quiet oronasal

[44] Based on Figure 1a of Kim et al. (2014), it appears that the "pharynx" as used in the paper is the lower-pharynx or oropharynx which begins at the soft palate and extends to the openings of the larynx and esophagus.

breathing (Q, 5 L/min; 35% nasal, 65% oral), the authors reported about 3.9% deposition of 2.5 µm particles in the nose, 2.2% in the mouth, 6.9% in the lower-pharynx, and 17.2% in the larynx. Counter to studies in adults, oronasal breathing increased particle losses in the head by greatly increased deposition in the lower-pharynx and larynx. Amirav et al. (2014) also provide data suggesting greater ET removal of particles during oral than nasal breathing at typical breathing rates for 5-, 14-, and 20-month-olds. Aerosols were generated using a Respimat® soft mist inhaler which produces an aqueous aerosol with a mode in the range of 1.1−2.1 µm, although almost 50% of the aerosol mass associated with particles >3.3 µm (Zierenberg, 1999). Amirav et al. (2014) found for the 5- and 14-month-olds that the amount of aerosol penetrating the upper respiratory tract was significantly greater through the oral passages than the nose. At 20-months of age, the particle loses in the nasal and oral passages were equivalent. In contrast with adults, these studies suggest that the nasal airways of infants may have lower particle removal efficiency than the oral airway.

While these in silco (CFD) and in vitro (casts) data are informative, they are not in agreement with existing experimental data. Figure 4-8 illustrates experimental human nasal deposition data for adults and children (Bennett et al., 2008; Becquemin et al., 1991) and predictive equation fitting four children's' and an adult cast deposition data (Zhou et al., 2014). Becquemin et al. (1991) provide data for 20 children (6 M, 14 F; 5−15 years, mean 10 years) and 10 adults (5 M, 5 F; 21−54 years, mean 36 years) who inhaled 1, 2, and 3 µm particles under breathing conditions simulating rest and moderate exercise. Bennett et al. (2008) provide data for 12 children (9 M, 3 F; 6−10 years) and 11 adults (6 M, 5 F; 18−27 years) who inhaled 1 and 2 µm particles under breathing conditions simulating rest and light exercise. For Figure 4-8, mean total nasal deposition (η_{total}) data for particles were extracted from Table 2 of Becquemin et al. (1991) and Table 3 of Bennett et al. (2008). Assuming inspiratory and expiratory deposition efficiency were equivalent, inspiratory nasal deposition efficiency (η_{insp}) was calculated as:

$$\eta_{insp} = 1 - \sqrt{1 - \eta_{total}}$$

Equation 4-6

The pressure drop (Δp) across the nose was calculated as the product of nasal resistance and inspiratory flow provided in the papers. The equation fitting deposition and in five nasal casts (4 children, 1 adult) of is not predictive of mean nasal deposition either in children or adults. The mean deposition for adults tends to exceed that of children.

Figure 4-9 illustrates experimental human nasal deposition data for 2 µm particles in adults and children (Bennett et al., 2008) with the predictive equation fitting nasal cast deposition data (Zhou et al., 2014). The predictive equation fits the data for children fairly well (r = 0.67, p = 0.024). However, the fit of adults provides a negative r^2, showing that the mean is a better predictor or nasal deposition efficiency in adults than the Zhou et al. (2014) model. Bennett et al. (2008) used linear regression to examine the relationship between total nasal deposition and pressure drop and found that the intercept was significantly increased in adults relative to children. That is, as illustrated in Figure 4-9, there was overlap in $d_{ae}^2\Delta p^{2/3}$ between adults and children, but adults had greater nasal deposition than children. Similarly,

Becquemin et al. (1991) provided plots of total nasal deposition against the modified-impaction factor, $d_{ae}^2\Delta p^{2/3}$. Although there was considerable overlap in $d_{ae}^2\Delta p^{2/3}$ between children and adults, nasal deposition again tended to be greater in adults than in children.

Figure 4-9. Comparison of individual level data for 2 μm inspiratory nasal deposition efficiency in during light exercise in adults and children with nasal cast model efficiency. Individual level deposition data are for 11 children and 11 adults. See text for more details.

Theory, CFD modeling, and research measuring deposition in nasal casts show that nasal deposition efficiency increases with increasing particle size and Δp across the cast. Consistent with that evidence, the ICRP (1994) Human Respiratory Tract Model recommends the use of scaling factors to increase nasal deposition in children relative to adults. For the children (V_T, 478 mL; *f*, 28 min^{-1}; 6−10 years of age) and adults (V_T, 940 mL; *f*, 20 min^{-1}) in Figure 4-9, the ICRP model predicts a η_{insp} for 2 μm particles of 0.275−0.338 (scaling factor of 1.26 for 10 year olds and 1.58 for 6 year-olds) and η_{insp} of 0.217 (scaling factor of 1.0 for adults). The mean experimental η_{insp} were 0.136 and 0.257 in children and adults, respectively. Recognizing that experimental data showed lower nasal deposition in children than adults, Brown et al. (2013) recommended using a scaling factor of one for estimates of nasal efficiency in children. Using a scaling factor of one for children (V_T, 478 mL; *f*, 28 min^{-1}), the ICRP model predicts η_{insp} of 0.173 for 2 μm particles. The scaling factor needs to be reduced to 0.89 to match the experimental η_{insp} of 0.136 for 2 μm particles in the Bennett et al. (2008) study. Although theory and studies using casts suggest increase nasal deposition efficiency with increasing Δp across the nose, experimental data show less nasal deposition in children than adults.

4.2.2.3 Tracheobronchial and Alveolar Region

Inhaled particles passing the ET region enter and may become deposited in the lungs. For any given particle size, the pattern of particle deposition influences clearance by partitioning deposited material among lung regions. Deposition in the tracheobronchial airways and alveolar region cannot be directly measured in vivo. Much of the available deposition data for the TB and alveolar regions have been obtained from experiments with radioactively labeled, poorly soluble particles (U.S. EPA, 1996) or by use of aerosol bolus techniques (U.S. EPA, 2004). In general, the ability of these experimental data to define specific sites of particle deposition is limited to anatomically large regions of the respiratory tract such as the head, larynx, bronchi, bronchioles, and alveolar region. Mathematical modeling can provide more refined predictions of deposition sites. Highly localized sites of deposition within the bronchi are described in Section 4.2.2.4. Both experimental and modeling techniques are based on many assumptions that may be relatively good for the healthy lung but not for the diseased lung. For discussion of these issues, the reader is referred to Section 4.2.4.4 and Section 4.2.4.5.

The ICRP (1994) relied on scintigraphic and aerosol bolus techniques to estimate TB deposition. Due to concern that these methods may have led to an overestimation of deposition in the TB airways, Brown et al. (2013) used the MPPD model to determine particle penetration through the TB airways. That is, in ascertaining regional lung deposition, there are uncertainties in the ICRP (1994) assessment of TB deposition due to slow particle clearance from the TB airways and the penetration of even shallowly inhaled aerosol boluses into the alveolar region. These would lend toward an overestimation of TB particle deposition and likewise an underestimation of alveolar deposition using ICRP (1994) formulas. However, the ICRP (1994) model might be preferable since it was based on human experimental data, whereas the MPPD model is a deterministic model based on theoretical deposition in a series of tubes. Accordingly, a comparison of the models was provided by Brown et al. (2013). Most apparent for oral breathing due to low ET particle removal, the 50% cut points were between 0.5 and 1 μm smaller using the ICRP (1994) versus the MPPD model. This finding is consistent with the supposition that the ICRP (1994) model overestimates TB deposition.

4.2.2.4 Sites of Localized Deposition

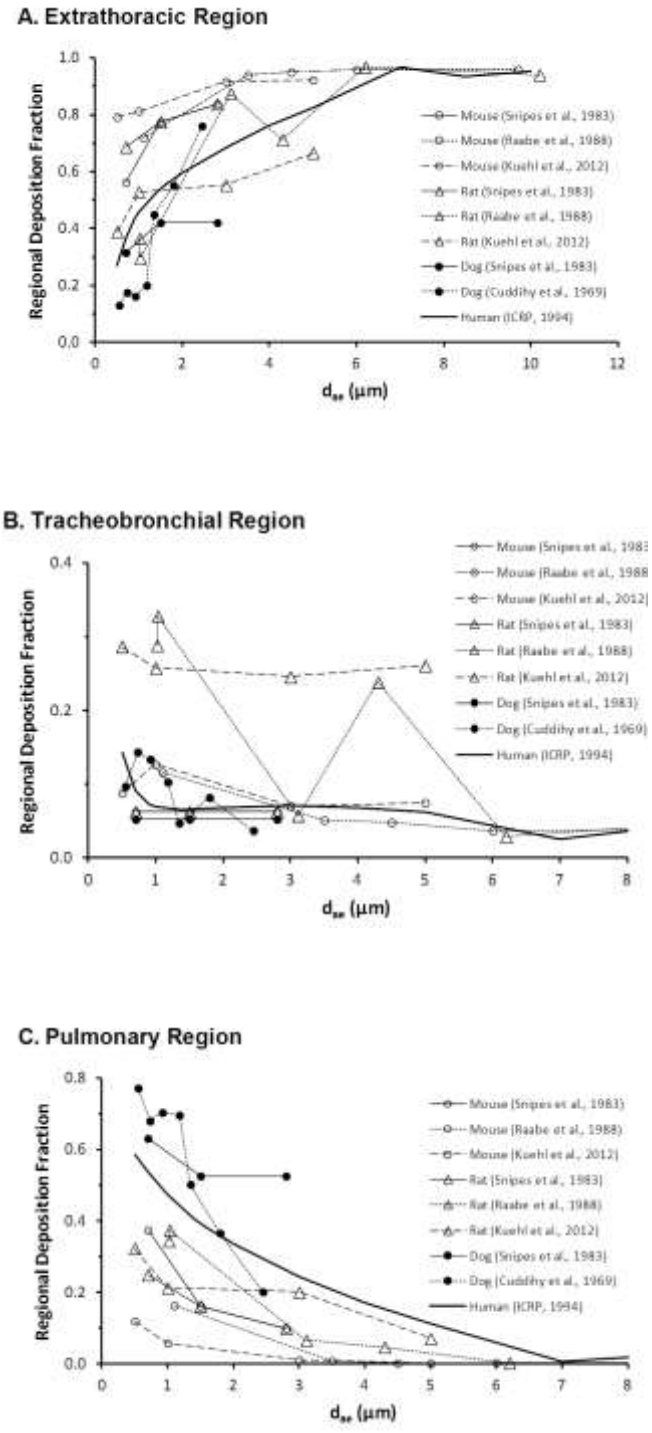
From a toxicological perspective, it is important to realize that not all epithelial cells in an airway will receive the same dose of deposited particles. Localized deposition in the vicinity of airway bifurcations has been analyzed using experimental and mathematical modeling techniques as described in prior reviews (U.S. EPA, 2009, 2004, 1996). Although there are a couple of new papers describing localized ultrafine, fine, and coarse particle deposition in the olfactory region of humans (see Section 4.3.3.1, Olfactory Delivery), there do not appear to be recent papers describing localized deposition in the tracheobronchial airways.

In the 1996 PM AQCD (U.S. EPA, 1996), experimental data were available illustrating the peak deposition of coarse particles (3, 5, and 7 μm d_{ae}) in daughter airways during inspiration and the parent airway during expiration, but always near the carinal ridge (Kim and Iglesias, 1989). In the 2004 PM AQCD (U.S. EPA, 2004), mathematical models predicted distinct "hot spots" of deposition in the vicinity of the carinal ridge for both coarse (10 μm) and ultrafine (0.01 μm) particles (Heistracher and Hofmann, 1997; Hofmann et al., 1996). In a model of lung Generations 4−5 during inspiration, hot spots occurred at the carinal ridge for 10 μm d_{ae} particles due to inertial impaction and for 0.01 μm particles due to secondary flow patterns formed at the bifurcation. During expiration, preferential sites of deposition for both particle sizes occurred (1) approaching the juncture of daughter airways on the walls forming and across the lumen from the carinal ridge; and (2) the top and bottom (visualizing the Y-shaped geometry laying horizontal) of the parent airway downstream of the bifurcation.

Studies reviewed in the 2009 ISA (U.S. EPA, 2009) further support these findings. Most of these studies quantified localized deposition in terms of an enhancement factor. Typically, the enhancement factor was the ratio of the deposition in a prespecified surface area (e.g., 100 × 100 μm which corresponds to ~10 × 10 epithelial cells) to the average deposition density for the whole airway geometry. Enhancement factors are very sensitive to the size of the surface considered (Balashazy et al., 1999). The deposition of 0.001 μm is rather uniform, however, the deposition pattern became increasingly less uniform with increasing particle size (Farkas and Balásházy, 2008; Farkas et al., 2006). For particles greater than ~0.01 μm, some cells located near the carinal ridge of bronchial bifurcations may receive hundreds to thousands of times the average dose (particles per unit surface area) of the parent and daughter airways. The inertial impaction of particles ≥1 μm d_{ae} at the carinal ridge of large bronchi also increases with increasing inspiratory flows.

4.2.3 Interspecies Patterns of Deposition

Across species comparisons of the modeling of total, extrathoracic, tracheobronchial, and alveolar deposition were provided in Figure 4-5. In general, there are consistent patterns in predicted deposition among species with the exception of rodents having lower deposition of particles larger than 2.5−3 μm due to lower inhalability of rodents relative to larger mammals. Figure 4-10 illustrates the experimental regional deposition in mice, rats, dogs, and humans. Regional deposition is the fraction of particles found in each compartment relative to total respiratory tract deposition.



Source: Permission pending, Brown (2015).

Figure 4-10. Experimental regional particle deposition (normalized to total deposition) in select mammalian species. (A) extrathoracic deposition (nasal breathing); (B) tracheobronchial deposition; and (C) pulmonary deposition.

Within a given species, considerable between study variability is apparent (see Figure 4-10). Some of the within species variability may be attributable to breathing pattern. Kuehl et al. (2012) reported breathing patterns for mice (V_T = 0.20 mL, f = 275 min^{-1}) and rats (V_T = 1.71 mL, f = 181 min^{-1}). The f reported by Kuehl et al. (2012) for mice are similar to those of restrained mice in Table 4-1. Neither Raabe et al. (1988) nor Snipes et al. (1983) reported breathing patterns. On average, Cuddihy et al. (1969) reported a V_T of 164 mL and f of 12 min^{-1} in dogs. However, there was considerable within dog variability among the aerosol exposures in the Cuddihy et al. (1969) study, with V_T ranging from 130 to 200 mL and f ranging from 8 to 20 min^{-1}. The human data are for a male with resting breathing pattern (V_T = 625 mL, f = 12 min^{-1}) as predicted by the ICRP (1994) Human Respiratory Tract Model. There are some limited scintigraphic regional deposition data for three baboons (10−14 kg; 6.3 ± 0.5 years of age) from Albuquerque-Silva et al. (2014). Similar to data in Figure 4-10, the baboon data showed increasing extrathoracic deposition with increasing particle size from 0.23 to 2.8 µm (activity median aerodynamic diameter).

Despite the within and between species differences, some trends become apparent from this figure. First, the ET fraction generally increases with decreasing species size and increasing particle size. Second, the pulmonary fraction generally decreases with decreasing species size and increasing particle size. Third, the TB fraction is a small component of the overall deposition. With respect to this third observation, however, it should be noted that due to relatively small surface area of the TB region, delivered surface doses can be quite high.

4.2.4 Factors Modulating Deposition

4.2.4.1 Physical Activity

The activity level of an individual is well recognized to affect their minute ventilation and route of breathing. Changes in minute ventilation during exercise are accomplished by increasing both V_T and f (Table 4-2). As discussed in Section 4.1.3, route of breathing generally changes from the nose when at rest to increasingly through the mouth with increasing activity level. There is considerable variability in both the route by which people breathe and is affected by sex, age, nasal resistance, and upper airway infection and inflammation.

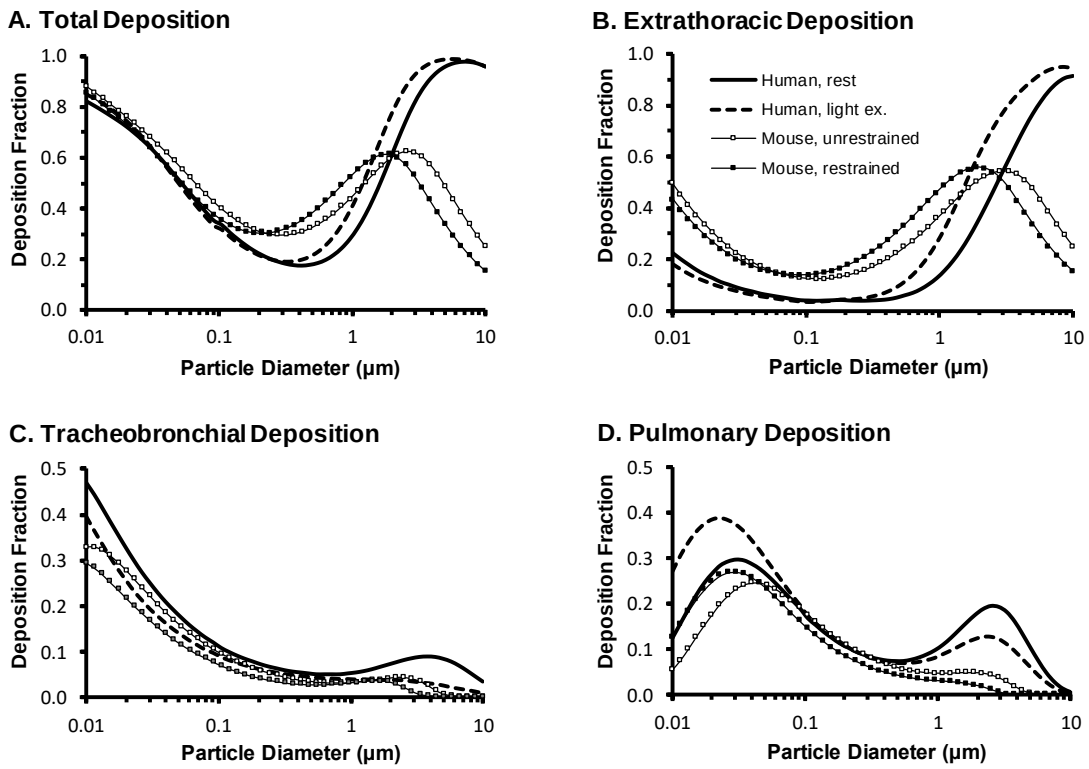
Table 4-2. Breathing patterns with activity level in adult human male.

Activity	Awake Rest[a]	Slow Walk[a]	Light Exertion[a]	Moderate Exertion[a]	Heavy Exertion[b]
Breaths/min	12	16	19	28	26
Tidal volume, mL	625	813	1,000	1,429	1,923
Minute ventilation, L/min	7.5	13	19	40	50

[a]de Winter-Sorkina and Cassee (2002).
[b]ICRP (1994).

When individuals increase their ventilation with activity the total number of particles inhaled per unit time (i.e., exposure rate) increases, but the fractional deposition of particles in each breath also changes with breathing pattern. Figure 4-11 illustrates the particle deposition at two breathing patterns in both a human and mouse. During exercise, both V_T and *f* increase. Fractional deposition for all particles increases with increased V_T. Increasing the *f*, however, decreases the fractional deposition of $PM_{2.5}$ and UFPs due to decreased time for gravitational and diffusive deposition. For particles of larger than a d^{ae} of roughly 3 μm, increasing *f* can increase the deposition fraction due to increased impaction in the extrathoracic and TB airways. Thus, it should be expected that the change in deposition fraction with activity will vary among individuals depending on the relative influences of these two variables (i.e., V_T and *f*) in a given subject and the particle size to which they are exposed.

Experimentally, the lung deposition fractions of fine particles during moderate exercise and mouth breathing are unchanged between rest and exercise (Bennett et al., 1985; Morgan et al., 1984). Löndahl et al. (2007) also found no difference in deposition fractions of particles (hygroscopic and hydrophobic; 0.013−0.290 μm mobility diameter of dry particles) between rest (V_T = 0.72 ± 0.15 L; *f* = 12 ± 2 min^{-1}) and exercise (V_T = 2.1 ± 0.5 L; *f* = 17 ± 4 min^{-1}). Kim (2000) evaluated differences in deposition of 1, 3, and 5 μm particles under varying breathing patterns (simulating breathing conditions of sleep, resting, and mild exercise). Total lung deposition increased with increasing V_T at a given flow rate and with increasing flow rate at a given breathing period. These experimental studies suggest that the total deposited dose rate (i.e., deposition per unit time) of particles will generally increase in direct proportion to the increase in minute ventilation associated with exercise.



Source: Permission pending, Deposition fractions estimated using MPPD (Version 3.04) model.

Figure 4-11. Effect of increasing minute ventilation on total and regional deposition. Human, rest (V_T, 625 mL; *f*, 12 min^{-1}); Human, light exercise (V_T, 1,000 mL; *f*, 19 min^{-1}); Mouse, unrestrained (V_T, 0.19 mL; *f*, 145 min^{-1}); Mouse, restrained (V_T, 0.22 mL; *f*, 290 min^{-1}).

The changes in ventilation, i.e., breathing pattern and flow rate, may also alter the regional deposition of particles. Coarse particle deposition increases in the TB and ET regions during exercise due to the increased flow rates and associated impaction. A rapid-shallow breathing pattern during exercise may result in more bronchial airway versus alveolar deposition, while a slow-deep pattern will shift deposition to deeper lung regions (Valberg et al., 1982). Bennett et al. (1985) showed for 2.6 µm particles that moderate exercise shifted deposition from the lung periphery towards ET and larger, bronchial airways. Similarly, Morgan et al. (1984) showed that even for fine particles (0.7 µm) TB deposition was enhanced with exercise. This shift in deposition toward the bronchial airways results in a much greater dose per unit surface area of tissue in those regions. Morgan et al. (1984) also found that the apical-to-basal distribution of fine particles increased with exercise, i.e., a shift towards increased deposition in the lung apices. This shift may be less likely for larger particles, however, whose deposition

in large airway bifurcations may preclude their transport to these more apical regions (Bennett et al., 1985).

4.2.4.2 Age

Airway structure and respiratory conditions vary with age, and these variations may alter the amount and site of particle deposition in the respiratory tract. It was concluded in the 2004 PM AQCD (U.S. EPA, 2004) that significant differences between adults and children had been predicted by mathematical models and observed in experimental studies. Modeling studies generally indicated that ET and TB deposition was greater in children and that children received greater doses of particles per lung surface area than adults. Experimental studies show lower nasal particle deposition in children than adults (see Figure 4-9). Relative to adults, children also tend to breathe more through their mouth (see Section 4.1.3 Route of Breathing) which is less efficient for removing inhaled particles than the nose (see Section 4.1.6 Thoracic and Respirable Particles). For typical activity levels and route of breathing, the 50% cut-size for the thoracic fraction is at an aerodynamic diameter of around 3 μm in adults and 5 μm in children. These findings suggest that the lower respiratory tract of children may receive a higher intake dose of ambient PM compared to adults. Recent experimental studies suggest increased lower respiratory tract deposition fraction of particles in children relative to adults, but this may be an artifact of the methodology.

As discussed in the last PM ISA (U.S. EPA, 2009), during oral breathing on a mouthpiece, Bennett and Zeman (1998) measured the deposition fraction of inhaled, fine particles (2 μm d_{ae}) in children (age 7−14 years, n = 16), adolescents (age 14−18 years, n = 11), and adults (age 19−35 years, n = 12) as they breathed the aerosol with their natural, resting breathing pattern. The deposition fraction of particles was not significantly different among age groups. Among the children, variation in deposition fractions was highly dependent on inter-subject variation in V_T, but not height which is a predictor of lung volume. However, there was no difference in deposition fractions between children and adults for these fine particles. This finding and the modeling predictions (Hofmann et al., 1989) are explained, in part, by the smaller V_T and faster breathing rate of children relative to adults for natural breathing conditions. Bennett et al. (2008) also reported measures of fine particle (1 and 2 μm) deposition at ventilation rates typical of rest and light exercise in children (age 6−10 years, n = 12) and adults (age 18−27 years, n = 11). This study also found that the deposition of 2 μm d_{ae} particles during oral breathing and under conditions of rest and light exercise did not differ significantly between children and adults. However, the DF of 1 μm d_{ae} particles during oral breathing was significantly increased in adults relative to children for both breathing rates. The authors attributed increased DF in adults to mixing of inhaled aerosol with reserve air. Deposition during nasal inhalations, were significantly increased in adults relative to children for the 2 μm particles at both breathing patterns (rest and light exercise) and for the 1 μm particles during light exercise. Across all children and adults, the deposition of both 1 and 2 μm particles was generally a function of residences time within the lungs and depth of breathing. Because children breathe at higher

minute ventilations relative to their lung volumes, the rate of deposition of fine particles normalized to lung surface area may be greater in children versus adults (Bennett and Zeman, 1998).

Rissler et al. (2017a) also measured deposition in children and adults, but who were spontaneous breathing on a mouthpiece. On average, across all particle sizes (15 nm to 5 µm), the deposition fraction tended to be greater by 11% ($1\text{-}DF_{child}/DF_{adult}$) in children (n = 7; 7−12 years; V_T, 0.51 ± 0.13 L; *f*, 16 ± 3 min^{-1}) than adults (n = 60; 20−67 years; V_T, 0.73 ± 0.22 L; *f*, 11 ± 3 min^{-1}). Absolute difference in the deposition fractions between children and adults were 5% for 15 nm to 50 nm particles; 3−4% for 50 nm to 1.9 µm particles; 6−10% for 1.9 µm to 5 µm particles. Generally consistent with Bennett and Zeman (1998) and Bennett et al. (2008), stepwise regression showed the best predictors of deposition for prespecified size ranges (e.g., 15−30 nm and 1.3−1.9 µm) to be V_T, time of breathing cycle, anatomic dead space, and a measure of airway resistance. For most particle sizes, deposition decreased increasing anatomic dead space; deposition increased with increasing V_T, time of breathing cycle, and airway resistance.

Olvera et al. (2012) measured hygroscopic particle deposition during spontaneous breathing on a mouthpiece in healthy men (n = 5; age, 26 ± 7 years; V_T, 0.66 ± 0.34 L; *f*, 13 ± 2 min^{-1}), healthy boys (n = 8; age, 13 ± 2 years; V_T, 0.37 ± 0.20 L; *f*, 18 ± 10 min^{-1}), and boys with asthma (n = 9; age, 12 ± 3 years; V_T, 0.38 ± 0.20 L; *f*, 16 ± 5 min^{-1}). The authors estimated a total deposition fraction for a polydisperse UFPs (median, 40 nm; GSD, 1.9) of 0.48 for the healthy children and 0.54 for the asthmatic children, the latter of which was significantly ($p = 0.002$) greater than 0.36 for the adults.

The tendencies for increased deposition in healthy children versus healthy adults in the Rissler et al. (2017a) and Olvera et al. (2012) studies could, in large part, be due to spontaneous breathing on a mouthpiece. Spontaneous breathing on a mouthpiece generally results in increases in V_T and decreases in *f* (long breathing period) relative to natural unencumbered breathing (Bennett et al., 1996). Both of these changes in breathing pattern (i.e., the increase in V_T and decrease in *f*) cause increases in deposition by diffusion and sedimentation. If these changes were equivalently affecting both children and adults, then a comparison of the relative deposition fractions may be unaffected. For natural breathing, Bennett et al. (2008) found that V_T as a fraction of resting lung volume (i.e., $V_T/(FRC + V_T)$ was not different between adults and children (0.14 ± 0.03 vs. 0.16 ± 0.04, respectively); whereas, for spontaneous breathing on a mouthpiece in the Rissler et al. (2017a) study, the different between adults and children (0.21 ± 0.16 vs. 0.25 ± 0.05, respectively) is statistically significant by a two-tailed *t*-test ($p = 0.011$) based on data in supplemental materials (Rissler et al., 2017b). Spontaneous breathing on a mouthpiece resulted in an increase in V_T relative to lung volume that was larger for children than adults which in and of itself may have led to the tendency for greater deposition in children versus adults.

In 62 healthy adults with normal lung function aged 18−80 years, Bennett et al. (1996) showed there was no effect of age on the whole lung deposition fractions of 2-µm particles under natural breathing conditions. Across all subjects, the deposition fractions were found to be independent of age, depending on breathing period ($r = 0.58$, $p < 0.001$) and airway resistance ($r = 0.46$, $p < 0.001$). In the

same adults breathing with a fixed pattern (360 mL V_T, 3.4 s breathing period), there was a mild decrease in deposition with increasing age, which could be attributed to increased peripheral airspace dimensions in the elderly.

4.2.4.3 Sex

Males and females differ in body size, conductive airway size, and ventilatory parameters; therefore, sex differences in deposition might be expected. In some of the controlled studies, however, the men and women were constrained to breathe at the same V_T and *f*. Since women are generally smaller than men, the increased minute ventilation of women compared to their normal ventilation could affect deposition patterns. This may help explain why sex related effects on deposition have been observed in some studies. As discussed in Section 4.1.3, females have a greater nasal breathing contribution than males across all ages. This reduces exposure and deposition of particles in the lower respiratory tract of females relative to males under normal breathing conditions.

(Kim and Hu, 1998) assessed the regional deposition patterns of 1-, 3-, and 5-μm particles in healthy adult males and females using controlled breathing on a mouthpiece. The total fractional deposition in the lungs was similar for both sexes with the 1-μm particle size, but was greater in women for the 3- and 5-μm particles. Deposition also appeared to be more localized in the lungs of females compared to those of males. Kim and Jaques (2000) measured deposition in healthy adults using sizes in the ultrafine mode (0.04−0.1 μm). Total fractional lung deposition was greater in females than in males for 0.04- and 0.06-μm particles. The region of peak fractional deposition was shifted closer to the mouth and peak height was slightly greater for women than for men for all exposure conditions. The total lung deposition data for these ultrafine aerosols in men and women are illustrated in Figure 4-6 in Section 4.2.2.1, data for the coarse particles are form a different study (Kim and Hu, 2006) than discussed above. As illustrated in Figure 4-6, difference between males and females were relatively well predicted by the MPPD model. These differences can generally be attributed to the smaller size of the upper airways, particularly of the laryngeal structure, and smaller airways in the lungs of females than males.

In another study by Bennett et al. (1996), the total respiratory tract deposition of 2-μm particles was examined in adult males and females aged 18−80 years who breathed with a normal resting pattern. There was a tendency for a greater deposition fractions in females compared to males. However, since males had greater minute ventilation, the deposition rate (i.e., deposition per unit time) was greater in males than in females. Bennett and Zeman (2004) found no difference in the deposition of 2-μm particles in boys versus girls aged 6−13 years (n = 36).

4.2.4.4 Body Mass Index

Bennett and Zeman (2004) expanded their measures of fine particle deposition during resting breathing to a larger group of healthy children (6−13 years; 20 boys, 16 girls) and found again that the variation in total deposition, was best predicted by V_T ($r = 0.79$, $p < 0.001$). But both V_T and resting minute ventilation increased with both height and body mass index (BMI) of the children. Interestingly, these data suggest that for a given height and age, children with higher BMI have larger minute ventilations and V_T at rest than those with lower BMI. These differences in breathing patterns as a function of BMI translated into increased deposition of fine particles in the heaviest children. The rate of deposition (i.e., particles depositing per unit time) in the overweight children was 2.8 times that of the leanest children ($p < 0.02$). Among all children, the rate of deposition was significantly correlated with BMI ($r = 0.46$, $p < 0.004$). Some of the increase in deposition fractions of heavier children may be due to their elevated V_T, which was well correlated with BMI ($r = 0.72$, $p < 0.001$).

Consistent with the findings of Bennett and Zeman (2004), ventilation rates are increased in overweight individuals compared to those of normal weight (Brochu et al., 2014). For example, median daily ventilation rates (m^3/d) are about 1.2 times greater in overweight (>85th percentile body mass index [BMI]) than normal weight children (5−10 years of age). In 35−45-year-old adult males and females, ventilation rates are 1.4 times greater in overweight (BMI ≥ 25 kg/m^2) than normal weight (18.5 to <25 kg/m^2 BMI) individuals. Across all ages, overweight/obese individuals respire greater amounts of air and associated pollutants than age matched normal weight individuals. As discussed in Section 4.1.3 (Route of Breathing), some studies suggest that obese children may breathe a higher fraction through the mouth than normal weight children. Increased minute ventilation, a potentially lower nasal breathing fraction, and increased DF with increasing BMI would all lead to greater rates of deposition in the lung as well.

4.2.4.5 Anatomical Variability

Anatomical variability, even in the absence of respiratory disease, can affect deposition throughout the respiratory tract. The ET region is the first exposed to inhaled particles and, therefore, deposition within this region would reduce the amount of particles available for deposition in the lungs. Variations in relative deposition within the ET region will, therefore, propagate through the rest of the respiratory tract, creating differences in calculated doses among individuals.

The influence of variations in nasal airway geometry on particle deposition has been investigated. Cheng et al. (1996) examined nasal airway deposition in healthy adults using particles ranging in size from 0.004 to 0.15 μm and at two constant inspiratory flow rates, 167 and 333 mL/s. Interindividual variability in deposition was correlated with the wide variation of nasal dimensions; in that, greater surface area, smaller cross-sectional area, and increasing complexity of airway shape were all associated

with enhanced deposition. Bennett and Zeman (2005) have also shown that nasal anatomy influences the efficiency of particle uptake in the noses of adults. For light exercise breathing conditions in adults, their study demonstrated that nasal deposition efficiencies for both 1 and 2 μm monodisperse particles were significantly less in African Americans versus Caucasians. The lesser nasal efficiencies in African-Americans were associated with both lower nasal resistance and less elliptical nostrils compared to Caucasians.

Within the lungs, the branching structure of the airways may also differ between individuals. Zhao et al. (2009) examined the bronchial anatomy of the left lung in patients (132 M, 84 W; mean age 47 years) who underwent conventional thoracic computed tomography scans for various reasons. At the level of the segmental bronchus in the upper and lower lobes, a bifurcation occurred in the majority of patients. A trifurcation, however, was observed in 23% of the upper and 18% of the lower lobes. Other more unusual findings were also reported such as four bronchi arising from the left upper lobe bronchus.

Anatomic variability is also seen in other species. Miller et al. (2014) provide noticeably differing TB morphologies between two Sprague-Dawley rats of quite similar weight and lung volume. Although the patterns of depositing between lung regions were nearly identical, the morphometric differences in the TB airways caused slightly increased deposition (1−4% absolute difference) of 1 to 3 μm in this region of one rat relative to the other. However, across rat strains, Miller et al. (2014) found large differences in deposition patterns across all particle sizes (0.01−10 μm) with Sprague-Dawley having increased TB and decreased PU particle deposition relative to a Long-Evans rat. For example, with endotracheal exposure the deposition fractions in the TB region for 0.03 and 3 μm particles were 30 and 80% (respectively) in the Sprague-Dawley, whereas they were only 10 and 30% (for 0.03 and 3 μm, respectively) in the Long-Evans rat. However, the PU deposition was much greater for particles <0.1 and >1 μm in the Long-Evans than the Sprague-Dawley rat. More interesting, for the case of an endotracheal exposure, particles >3 μm were able to penetrate through the TB airways to deposit in the PU region of the Long-Evans rat, whereas the PU deposition was effectively zero by 4 μm in the Sprague-Dawley.

As described in Section 4.2.2.4, deposition can be highly localized near the carinal ridge of bifurcations. The effect of a bifurcation versus other branching patterns on airflow patterns and particle deposition has not been described in the literature. Martonen et al. (1994) showed that a wide blunt carinal ridge shape dramatically affected the flow stream lines relative to a narrower and more rounded ridge shape. Specifically, there were high flow velocities across the entire area of the blunt carinal ridge versus a smoother division of the airstream in the case of the narrow-rounded ridge shape. The implication may be that localized particle deposition on the carinal ridge would increase with ridge width. A similar situation might be expected for a trifurcation versus a bifurcation. These differences in branching patterns provide a clear example of anatomical variability among individuals that might affect both air flow patterns and sites of particle deposition.

4.2.4.6 Ventilation Distribution

Regional deposition in excess of regional ventilation to poorly ventilated areas has been reported for aerosols in the 0.5 to 1.0 μm size range and attributed to increased residence time in obstructed areas (Susskind et al., 1986; Trajan et al., 1984). However, others show increasing deposition with increasing ventilation. For instance, a significant association of increased aerosol (1.2 μm) deposition in better ventilated regions has been observed in lung transplant patients with bronchiolitis obliterans (O'Riordan et al., 1995). The trend for increased aerosol (0.78 μm) deposition with increasing ventilation has also been reported in normal individuals and asymptomatic smokers (Chamberlain et al., 1983). Other studies using similar sized aerosols, have found no association between ventilation distribution and particle deposition (O'Riordan and Smaldone, 1994; Smaldone et al., 1991). All of these studies compared regional ventilation to the regional particle deposition using scintigraphic methods. The mixed results in these studies may be due to deposition not having a simple monotonic relationship with ventilation.

Brown et al. (2001) examined the relationship of 5 μm particles in healthy adults (n = 11) and patients with cystic fibrosis (n = 12) using scintigraphic techniques. Deposition of particles in the TB airways followed the pattern of ventilation in the healthy individuals, whereas it was inversely related to ventilation in the patients. This is consistent with Kim et al. (1983) who found the pattern of particle deposition (3.0 μm) followed ventilation distribution in a three generation model, but was enhanced in the vicinity of obstructions. Consistent with Brown et al. (2001) data in healthy individuals, Verbanck et al. (2016) recently found experimentally and using CFD modeling that the regional deposition of coarse particles (6 μm) followed regional ventilation in a human airway cast which extended out to the fifth airway generation at inspiratory flows mimicking light and heavy exercise.

In the alveolar region, Brown et al. (2001) found deposition very strongly associated with ventilation distribution in the patients, i.e., the well-ventilated regions received increased alveolar deposition of particles relative to poorly ventilated regions. A similar trend was observed in the healthy individuals, but a more uniform pattern of ventilation lead to smaller differences in ventilation and deposition between lung regions. The recent experimental study of healthy adults (n = 7) by Sá et al. (2017) supports that alveolar deposition of coarse particles (5 μm) is directory proportional ventilation. As extreme example of no regional ventilation in patients with mild-to-moderate asthma, (King et al., 1998) reported large wedge-shaped regions of the lung which were absent the deposition of 0.12 μm particles.

With regard to interpreting the above discussion of coarse particle (5−6 μm) deposition in the lungs, it should be stress that the experimental and modeling work done with oral breathing on a mouthpiece. Referring back to Section 4.1.6 and Figure 4-3, these coarse particles would not be expected to reach the lower respiratory tract during nasal breathing.

4.2.4.7 Respiratory Tract Disease

The presence of respiratory tract disease can affect airway structure and ventilatory parameters, thus altering deposition compared to that occurring in healthy individuals. The effect of airway diseases on deposition has been studied extensively, as described in the 1996 and 2004 PM AQCD (U.S. EPA, 2004, 1996) and the 2009 PM ISA (U.S. EPA, 2009). Studies described therein showed that people with chronic obstructive pulmonary disease (COPD) had very heterogeneous deposition patterns and differences in regional deposition compared to healthy individuals. People with obstructive pulmonary diseases tended to have greater deposition in the TB region than did healthy people. Furthermore, there tended to be an inverse relationship between bronchoconstriction and the extent of deposition in the alveolar region, whereas total respiratory tract deposition generally increased with increasing degrees of airway obstruction. There are some limited new data available for children with asthma.

Olvera et al. (2012) measured hygroscopic particle deposition during spontaneous breathing on a mouthpiece in healthy men (n = 5; age, 26 ± 7 years; V_T, 0.66 ± 0.34 L; *f*, 13 ± 2 min^{-1}), healthy boys (n = 8; age, 13 ± 2 years; V_T, 0.37 ± 0.20 L; *f*, 18 ± 10 min^{-1}), and boys with asthma (n = 9; age, 12 ± 3 years; V_T, 0.38 ± 0.20 L; *f*, 16 ± 5 min^{-1}). The children with asthma had about 2−4% (absolute difference) greater deposition than healthy children for particles between 10−90 nm, and above this size the data converged. Across all particles sizes, the children with asthma had 8% (absolute difference) greater deposition than adults, this difference ranged from 3% for 11 nm particles to 10% for 200 nm particles. The authors estimated a total deposition fraction for a polydisperse UFPs (median, 40 nm; GSD, 1.9) of 0.48 for the healthy children and 0.54 for the asthmatic children, the latter of which was significantly (p = 0.002) greater than 0.36 for the adults. As discussed in Section 4.2.4.2, spontaneous breathing on a mouthpiece may have resulted in an increase in V_T relative to lung volume that was larger for children than adults which may have led to the tendency for greater deposition in children versus adults. It is not clear if asthma additionally affected breathing patterns. A prior study of adults using a fixed breathing pattering showed a greater deposition fraction of 1 µm particles in individuals with asthma relative to healthy adults (22 vs. 14%, respectively) (Kim and Kang, 1997).

The vast majority of deposition studies in individuals with respiratory disease have been performed during controlled breathing, i.e., all subjects breathed with the same V_T and *f*. However, although resting V_T is similar or elevated in people with COPD compared to healthy individuals, the former tend to breathe at a faster rate, resulting in higher than normal tidal peak flow and resting minute ventilation. Thus, given that breathing patterns differ between healthy and obstructed individuals, particle deposition data for controlled breathing may not be appropriate for estimating respiratory doses or dose rates from ambient PM exposures.

Bennett et al. (1997) measured the fractional deposition of insoluble 2 µm particles in moderate-to-severe COPD patients (n = 13; mean age 62 years) and healthy older adults (n = 11; mean age 67 years) during natural resting breathing. COPD patients had about a 1.6-times greater deposition fraction and a 1.5-times greater resting minute ventilation relative to the healthy adults. As a result, the

patients had an average deposition rate of about 2.4-times that of healthy adults. Similar to previously reviewed studies (U.S. EPA, 2004, 1996), these investigators observed an increase in deposition with an increase in airway resistance, suggesting that deposition increased with the severity of airway disease. Across a broad range of obstructive disease severity using a fixed breathing pattern, Kim and Kang (1997) previously reported the deposition of 1 μm particles to be well associated with several measures of lung function.

Brown et al. (2002) measured the deposition of UFPs (CMD = 0.033 μm) during natural resting breathing in 10 patients with moderate-to-severe COPD (mean age 61 years) and nine healthy adults (mean age 53 years). The COPD group consisted of seven patients with chronic bronchitis and three patients with emphysema. The total deposition fraction in the bronchitic patients (DF, 0.67) was significantly ($p < 0.02$) greater than in either the patients with emphysema (DF, 0.48) or the healthy subjects (DF, 0.54). Minute ventilation increased with disease severity (healthy, 5.8 L/min; chronic bronchitic, 6.9 L/min; emphysema, 11 L/min). Relative to the healthy subjects, the average dose rate was significantly ($p < 0.05$) increased by 1.5 times in the COPD patients, whereas the average deposition fraction only tended to be increased by 1.1 times. These data further demonstrate the need to consider dose rates (which depend on minute ventilation) rather than just deposition fractions when evaluating the effect of respiratory disease on particle deposition and dose.

Most of the available literature on particle deposition in the diseased lung have considered obstructive lung disease. There are some limited data showing ultrafine and fine particle (0.02−0.25 μm) deposition fractions are similar between healthy adults and those with restrictive lung disease (Anderson et al., 1990). However, individuals with restrictive lung disease have an increased minute ventilation relative to individuals with normal lungs (Tobin et al., 1983b). Thus, as described above for individuals with obstructive disease, it should be expected that dose rate for particulate matter would be increased in individuals with restrictive lung disease due to their increased ventilation rates comparted to individuals free of lung disease.

4.2.4.8 Particle Hygroscopicity

In an individual during controlled breathing (V_T = 0.75−1.0 L; f = 15 min^{-1}), Tu and Knutson (1984) found minimal deposition in the range of 0.06 to 0.09 μm for hygroscopic particles, whereas it was in the range 0.3 to 0.6 μm for hydrophobic particles. The deposition curves for hygroscopic and hydrophobic particles intersected at approximately 0.15 μm in the Tu and Knutson (1984) study. This implies that hygroscopic growth reduced diffusive deposition below 0.15 μm and increased aerodynamic deposition above this particle size. Nonhygroscopic particles around 0.3 μm have minimal intrinsic mobility and low total deposition in the lungs. Hygroscopic 0.3 μm (dry diameter) salt particles will grow to nearly 2 μm in the respiratory tract and deposit to a far greater extent than hydrophobic 0.3 μm particles (Anselm et al., 1990).

Löndahl et al. (2007) measured particle deposition in 29 individuals (20 M, 9 F; median age, 25 years) who inhaled hygroscopic and hydrophobic particles between 0.013 and 0.290 μm (mobility diameter of dry particles) by mouth during spontaneous breathing (not their natural breathing pattern measured prior to being on a mouthpiece) while engaged in rest (V_T = 0.72 ± 0.15 L; f = 12 ± 2 min^{-1}) or exercise (V_T = 2.1 ± 0.5 L; f = 17 ± 4 min^{-1}). Deposition fractions for each particle type were minimally affected by sex or activity. The prior study by Tu and Knutson (1984) found the deposition curves for hygroscopic and hydrophobic particles were also generally unaffected by route of breathing. Figure 4-12 illustrates deposition curves for hygroscopic and hydrophobic particles inhaled during rest in the Löndahl et al. (2007) study. From this figure, it is seen that the growth of 0.02 to 0.03 μm hygroscopic particles lowers their diffusive deposition to that of 0.07 μm hydrophobic particles. Deposition of the hygroscopic particles reached a minimum in the range of 0.1 to 0.14 μm. Hygroscopic growth reduced diffusive deposition below 0.2 μm and increased aerodynamic deposition above this particle size.

Olvera et al. (2012) also measured hygroscopic particle deposition during spontaneous breathing on a mouthpiece in five healthy men (age, 26 ± 7 years; V_T, 0.66 ± 0.34 L; f, 13 ± 2 min^{-1}), eight healthy boys (age, 13 ± 2 years; V_T, 0.37 ± 0.20 L; f, 18 ± 10 min^{-1}), and nine boys with asthma (age, 12 ± 3 years; V_T, 0.38 ± 0.20 L; f, 16 ± 5 min^{-1}). The data for the adult males appear in Figure 4-12 for comparison with the data by Löndahl et al. (2007).

Ferron et al. (2013) provide a model for hygroscopic particle deposition in the rat lung and compare with the predicted deposition in humans (adult male only). The paper illustrates the effect of particle size on the time required to its equilibrium size in the respiratory tract. As particle size is increased from 0.05 to 0.5 and to 2.0 μm, the time to reach equilibrium increased from 0.01 s to 1 s and to 10 s, respectively. The effect of varied hygroscopicity on particle equilibrium size and deposition were also provided. For example, given the same inhaled particle size, sodium chloride grows to about twice as large as zinc sulfate. Relative to hydrophobic particles, total deposition decreased for sodium chloride particles <0.3 μm and decreased for zinc sulfate particles <0.4 μm due to the reduction in diffusivity with increasing size due to particle growth. Above these sizes (i.e., 0.3 to 0.4 μm), total deposition increased due to the increase in inertial properties relative to hydrophobic particles. The reduction in diffusive deposition and increase in inertial deposition were more pronounced for sodium chloride than zinc sulfate relative to hydrophobic particles. For relaxed, resting breathing, Ferron et al. (2013) predicted that hygroscopic growth would affect deposition mainly for particles between 0.02 and 5 μm in the rat and between 0.02 and 6 μm in adult human males.

4.2.5 Summary

Particle deposition in the respiratory tract occurs predominantly by diffusion, impaction, and sedimentation. Deposition is minimal for particle diameters in the range of 0.1 to 1.0 μm, where particles are small enough to have minimal sedimentation or impaction and sufficiently large so as to have minimal diffusive deposition. In humans, total respiratory tract deposition approaches 100% for particles of roughly 0.01 μm due to diffusive deposition and for particles of around 10 μm due to the efficiency of sedimentation and impaction.

The first line of defense for protecting the lower respiratory tract from inhaled particles is the nose and mouth. Nasal deposition approaches 100% in the average human for 10 μm particles. Experimental studies show lower nasal particle deposition in children than adults. Relative to adults, children also tend to breathe more through their mouth which is less efficient for removing inhaled particles than the nose. These findings suggest that the lower respiratory tract of children may receive a higher dose of ambient PM compared to adults. Since children breathe at higher minute ventilations

relative to their lung volumes, the rate of particle deposition normalized to lung surface area may be further increased relative to adults.

People with COPD generally have greater total deposition and more heterogeneous deposition patterns compared to healthy individuals. The observed increase in deposition correlates with increases in airway resistance, suggesting that deposition increases with the severity of airway obstruction. Destruction of peripheral airspaces, such as with emphysema, can decrease particle deposition on a breath by breath basis. However, COPD patients also have an increased resting minute ventilation relative to the healthy adults. This demonstrates the need to consider dose rates (which depend on minute ventilation) rather than just deposition fractions when evaluating the effect of respiratory disease on particle deposition and dose.

Modeling studies indicate that, for particles greater than ~0.01 μm, some cells located near the carinal ridge of bronchial bifurcations may receive hundreds to thousands of times the average dose (particles per unit surface area) of the parent and daughter airways. The inertial impaction of particles ≥1 μm at the carinal ridge of large bronchi increases with increasing inspiratory flows. Airway constriction can further augment the overall deposition efficiency of coarse particles at downstream bifurcations. These findings suggest that substantial doses of particles may be justified for in vitro studies using tracheobronchial epithelial cell cultures.

Our ability to extrapolate between species has improved since the 2009 ISA (U.S. EPA, 2009). However, some considerations related to coarse particles warrant comment. The inhalability of particles having of 2.5, 5, and 10 μm is 80, 65, and 44% in rats, respectively, whereas it remains near 100% for 10 μm particles in humans. In most laboratory animal species (rat, mouse, hamster, guinea pig, and dogs), deposition in the extrathoracic region is near 100% for particles greater than 5 μm. By contrast, in humans, nasal deposition approaches 100% for 10 μm particles. Oronasal breathing versus obligate nasal breathing further contributes to greater penetration of coarse particles into the lower respiratory tract of humans than rodents.

4.3 Particle Clearance

This section discusses the clearance and translocation of poorly soluble particles that have deposited in the respiratory tract. The term “clearance” is used here to refer to the processes by which deposited particles are removed by mucociliary action or phagocytosis from the respiratory tract. “Translocation” is used here mainly to refer to the movement of free particles across cell membranes and to extrapulmonary sites. In the literature, translocation may also refer to the extra and intracellular dissolution of particles and the subsequent transfer of dissociated material to the blood through extra and intracellular fluids and across the various cell membranes and lung tissues.

A basic overview of biological mechanisms and clearance pathways from various regions of the respiratory tract are presented in the following sections. Then regional kinetics of particle clearance are addressed. Subsequently, an update on interspecies patterns and rates of particle clearance is provided. The translocation of UFPs is also discussed. Finally, information on biological factors that may modulate clearance is presented.

4.3.1 Clearance Mechanisms

For any given particle size, the deposition pattern of poorly soluble particles influences clearance by partitioning deposited material between lung regions. Tracheobronchial clearance of poorly soluble particles in humans, with some exceptions, is thought (in general) to be complete within 24−48 hours through the action of the mucociliary escalator. Clearance of poorly soluble particles from the alveolar region is a much slower process which may continue from months to years.

4.3.1.1 Extrathoracic Region

Particles deposited in either the nasal or oral passages are cleared by several mechanisms. Particles depositing in the mouth may generally be assumed to be swallowed or removed by expectoration. Particles deposited in the posterior portions of the nasal passages are moved via mucociliary transport towards the nasopharynx and swallowed. Mucus flow in the most anterior portion of the nasal passages is forward, toward the vestibular region where removal occurs by sneezing, wiping, or nose blowing.

Smith et al. (2014) updates the extrathoracic clearance portion of the ICRP (1994) human respiratory tract model. Deposition in the extrathoracic regions is considered as divided among the anterior and posterior nasal passage, oropharynx, and, depending on route of breathing, the mouth. Regardless of inhaled particle size, deposition in the nasal passages is portioned to have 65% in the anterior and 35% in the posterior nose. Of the deposition in the anterior nose, 29% is cleared by nose blowing, 71% is cleared to the posterior nose from which nearly all is cleared to the gastro-intestinal (GI) tract with only 0.05% sequestered in the nose. This new model was based on a study of nasal clearance in healthy adults (8 M, 1 F; 43 ± 10 years) who inhaled ^{111}In-labeled particles of 1.5, 3, or 6 µm under conditions of rest and light exercise (Smith et al., 2011).

4.3.1.2 Tracheobronchial Region

Mucociliary clearance in the TB region has generally been considered to be a rapid process that is relatively complete by 24−48 hours post-inhalation in humans. Mucociliary clearance is frequently

modeled as a series of "escalators" moving material proximally from one generation to the next. As such, the removal rate of particles from an airway generation increases with increasing tracheal mucus velocity. Assuming continuity in the amount of mucus between airway generations, mucus velocities decrease and transit times within an airway generation increase with distal progression. Although clearance from the TB region is generally rapid, experimental evidence discussed in the 1996 and 2004 PM AQCD (U.S. EPA, 2004, 1996), showed that a fraction of material deposited in the TB region is retained much longer.

The slow-cleared TB fraction (i.e., the fraction of particles deposited in the TB region that are subject to slow clearance) was thought to increase with decreasing particle size. For instance, Roth et al. (1993) showed approximately 93% retention of UFPs (30 nm median diameter) thought to be deposited in the TB region at 24 hours post-inhalation. The slow phase clearance of these UFPs continued with an estimated half-time ($t_{1/2}$) of around 40 days. Using a technique to target inhaled particles (monodisperse 4.2 µm MMAD) to the conducting airways, Möller et al. (2004) observed that 49 ± 9% of particles cleared rapidly ($t_{1/2}$ of 3.0 ± 1.6 hours), whereas the remaining fraction cleared considerably slower ($t_{1/2}$ of 109 ± 78 days). The ICRP (1994) human respiratory tract model assumes particles ≤2.5 µm (physical diameter) to have a slow-cleared TB fraction of 50%. The slow-cleared fraction assumed by the ICRP (1994) decreases with increasing particle size to <1% for 9 µm particles. Considering the UFP data of Roth et al. (1993) in addition to data considered by the ICRP (1994), Bailey et al. (1995) estimated a slow-cleared TB fraction of 75% for UFPs. At that time, they (Bailey et al., 1995) also estimated the slow-cleared fraction to decrease with increasing particle size to 0% for particles ≥6 µm. Experimental evidence from the same group (Smith et al., 2008) showed no difference in TB clearance among humans for particles with geometric sizes of 1.2 µm versus 5 µm, but the same d_{ae} (5 µm) so as to deposit similarly in the TB airways. For at least micron-sized particles, these findings do not support the particle size dependence of a slow-cleared TB fraction. As discussed further below, much of the apparent slow-cleared TB fraction may be accounted for by differences in deposition patterns, i.e., greater deposition in the alveolar region than expected based on symmetric, bulk flow into the lungs without longitudinal mixing.

A portion of the slow cleared fraction from the TB region appears to be associated with the smaller, more distal bronchioles. For large particles (d_{ae} = 6.2 µm) inhaled at a very slow rate to theoretically deposit mainly in small ciliated airways, 50% had cleared by 24 hours post-inhalation. Of the remaining particles, 20% cleared with a $t_{1/2}$ of 2.0 days and 80% with a $t_{1/2}$ of 50 days (Falk et al., 1997). Using the same techniques, Svartengren et al. (2005) also reported the existence of long-term clearance in humans from the small airways. It should be noted that the clearance rates for the slow-cleared TB fraction still exceeds the clearance rate of the alveolar region in humans. Kreyling et al. (1999) targeted inhaled particle (2.5 µm) deposition to the TB airways of adult beagle dogs and subsequently quantified particle retention using scintigraphic and morphometric analyses. Despite the use of shallow aerosol bolus inhalation to a volumetric lung depth of less than the anatomic dead space, 25% of inhaled particles deposited in alveoli. At 24 and 96 hours post-inhalation, more than 50% of the retained particles were in alveoli. However, 40% of particles present at 24 and 96 hours were localized to

small bronchioles of between 0.3 and 1 mm in diameter. Collectively, these studies suggest that although mucociliary clearance is fast and effective in healthy bronchi and larger bronchioles, it is less effective and sites of longer retention exist in smaller bronchioles.

The underlying sites and mechanisms of long-term retention in the bronchioles remain largely unknown. Several factors may contribute to the existence or experimental artifact of slow clearance from the smaller TB airways. Even when inhaled to very shallow lung volumes, some particles reach the alveolar region (Kreyling et al., 1999). Therefore, experiments utilizing bolus techniques to target inhaled particle deposition to the TB airways may have had some deposition in the alveolar region. This may occur due to variability in path length and the number of generations to the alveoli (Asgharian et al., 2001) and/or differences in regional ventilation (Brown and Bennett, 2004). Nonetheless, the experimentally measured clearance rates measured for the slow cleared TB fraction are faster than that of the alveolar region in both humans and canines. Thus, although experimental artifacts likely occur, they do not discount the existence of a slow cleared TB fraction. To some extent, it is possible that the slow cleared TB fraction may be due to distal bronchioles that do not have a continuous ciliated epithelium as in the larger bronchi and more proximal bronchioles. Neither path length, ventilation distribution, nor a discontinuous ciliated epithelium explains an apparently slow cleared TB fraction with decreasing particle size below 0.1 μm. As discussed in Section 4.3.3 on Particle Translocation, UFPs cross cell membranes by mechanisms different from larger (~1 μm) particles. Based on that body of literature, particles smaller than a micron may enter epithelial cells resulting in their prolonged retention, particularly in the bronchioles where the residence time is longer and distances necessary to reach the epithelium are shorter compared to that in the bronchi.

4.3.1.3 Alveolar Region

The primary alveolar clearance mechanism is macrophage phagocytosis and migration to terminal bronchioles where the cells are cleared by the mucociliary escalator. Alveolar macrophages originate from bone marrow, circulate briefly as monocytes in the blood, and then become pulmonary interstitial macrophages before migrating to the luminal surfaces. Under normal conditions, a small fraction of ingested particles may also be cleared through the lymphatic system. This may occur by transepithelial migration of alveolar macrophage following particle ingestion or free particle translocation with subsequent uptake by interstitial macrophages. Snipes et al. (1997) have also demonstrated the importance of neutrophil phagocytosis in clearance of particles from the alveolar region. Rates of alveolar clearance of poorly soluble particles vary between species and are briefly discussed in Section 4.3.2. The translocation of particles from their site of deposition is discussed in Section 4.3.3. The effect particle dissolution on retention in the alveolar region was recently reviewed by Oberdörster and Kuhlbusch (2018).

The efficiency of macrophage phagocytosis is thought to be greatest for particles between 1.5 and 3 μm (Oberdörster, 1988). The decreased efficiency of alveolar macrophage for engulfing UFPs increases the time available for these particles to be taken up by epithelial cells and moved into the inter-stitium (Ferin et al., 1992). Consistent with this supposition (i.e., translocation increases with time), an increase in titanium dioxide (TiO_2) particle transport to lymph nodes has been reported following inhalation of a cytotoxin to macrophages (Greenspan et al., 1988). Interestingly, the long-term clearance kinetics of the poorly soluble ultrafine (15−20 nm CMD) iridium (Ir) particles were found to be similar to the kinetics reported in the literature for micrometer-sized particles (Semmler-Behnke et al., 2007; Semmler et al., 2004). For rats, Semmler-Behnke et al. (2007) concluded that ultrafine Ir particles are less phagocytized by alveolar macrophage than larger particles, but are effectively removed from the airway surface into the inter-stitium. Particles are then engulfed by interstitial macrophages which then migrate to the airway lumen and are removed by mucociliary clearance to the larynx. The major role of macrophage-mediated clearance was supported by lavage of relatively few free particles versus predominantly phagocytized particles at time-points of up to 6 months. It is also possible that some free UFP as well as particle-laden macrophage were carried from interstitial sites via the lymph flow to bronchial and bronchiolar sites, including bronchial-associated lymphatic tissue, where they were excreted again into the airway lumen (Semmler-Behnke et al., 2007; Brundelet, 1965). In addition to macrophage phagocytosis and migration to the ciliated airways, these studies suggest that alveolar particle clearance via interstitial translocation and uptake into the lymphatics may be an important clearance pathway for UFP.

There is evidence that particle aggregates may disassociate once deposited in the lungs. This disassociation makes inhaled aggregate size the determinant of deposition amount and site, but primary particle size the determinant of subsequent clearance (Bermudez et al., 2002; Ferin et al., 1992; Takenaka et al., 1986). Following disaggregation, the ultrafine TiO_2 particles are cleared more slowly and cause a greater inflammatory response (neutrophil influx) than fine TiO_2 particles (Bermudez et al., 2002; Oberdorster et al., 2000; Oberdörster et al., 1994a; Oberdörster et al., 1994b; Ferin et al., 1992). (Balasubramanian et al., 2013) also suggested that disaggregation of following inhalation lead to differential organ concentration of 7 nm versus 20 nm gold particles. The differences in inflammatory effects and possibly lymph burdens between fine and ultrafine TiO_2 in many studies appear related to lung burden in terms of particle surface area and not particle mass or number (Oberdorster et al., 2000; Tran et al., 2000; Oberdorster, 1996; Oberdörster et al., 1992). There is some uncertainty related to these conclusions since the crystal form of TiO_2, anatase versus rutile, may have affected some results. Others have noted that particle surface area is not an appropriate metric across all particle types (Warheit et al., 2006). Surface characteristics such as roughness can also affect protein binding and potentially clearance kinetics, with smoother TiO_2 surfaces being more hydrophobic (Sousa et al., 2004).

4.3.2 Interspecies Clearance and Retention

There are differences between species in both the rates of particle clearance from the lung and manner in which particles are retained in the lung. For instance, based on models of mucociliary clearance from undiseased airways, >95% of particles deposited in the tracheobronchial airways of rats are predicted to be cleared by 5 hours post deposition, whereas it takes nearly 40 hours for comparable clearance in humans (Hofmann and Asgharian, 2003). As noted in Section 4.3.1.2, however, there is some evidence that a sizeable fraction of particles deposited at the bronchiolar level of the ciliated airways in humans (as well as canines) are cleared at a far slower rate. Some evidence suggests that the slow cleared TB fraction increases with decreasing particle size.

From interspecies comparisons of alveolar clearance, the path length from alveoli to ciliated terminal bronchioles may affect the particle transport rate (Kreyling and Scheuch, 2000). The average path length from alveoli to ciliated terminal bronchioles is longer in humans, monkeys, and dogs, than in sheep, rats, hamsters, and mice. Transport time and hence retention times may increase with path length. This hypothesis fits with all species in this comparison, except guinea pigs, which have a short path length yet particle retention that is nearly as long as in humans, monkeys, and dogs. However, sheep have a short path length and particle transport as fast as rodents. In general, alveolar clearance rates appear to increase with increasing path length from the alveoli to ciliated airways. This supports the important role of particle laden macrophage migration from the alveolar region to the ciliated airways with subsequent clearance from the lungs.

There are also distinct differences in the normal sites of particle retention that affect clearance pathways between species. Large mammals retain particles in interstitial tissues under normal conditions, whereas rats retain particles on epithelial surfaces and in alveolar macrophages (Snipes, 1996). The influence of exposure concentration on the pattern of particle retention in rats (exposed to diesel soot) and humans (exposed to coal dust) was examined by Nikula et al. (2001). In rats, the diesel particles were found to be primarily in the lumens of the alveolar duct and alveoli; whereas in humans, retained dust was found primarily in the interstitial tissue within the respiratory acini. With chronic high doses, there is a shift in rat's pattern of dust accumulation and response from that observed at lower doses in the lungs (Snipes, 1996; Vincent and Donaldson, 1990). Rats chronically exposed to high concentrations of insoluble particles experience a reduction in their alveolar clearance rates and an accumulation of interstitial particle burden (Bermudez et al., 2004; Bermudez et al., 2002; Warheit et al., 1997; Oberdörster et al., 1994a; Oberdörster et al., 1994b; Ferin et al., 1992). Even at lower acute doses of particles, the temporary impairment of alveolar clearance results in increased movement of particles into the interstitial tissues of rats (Snipes et al., 1997). However, the results of Semmler-Behnke et al. (2007) and other older studies (Brundelet, 1965; Gross and Westrick, 1954) suggest that alveolar particle clearance via interstitial translocation and uptake into the lymphatics may be an important clearance pathway for UFP.

Following transport of particles from the alveolar epithelium via macrophages or as free particles into interstitial tissues, fluid flow can draw particles into pulmonary lymphatics. Whether it is free particles that enter the inter-stitium and lymphatics or whether macrophage emigrate from pulmonary capillaries into the alveoli and then immigrate back into the inter-stitium after phagocyting particles has been debated since the 1870s (Gross and Westrick, 1954). Gross and Westrick (1954) demonstrated that free particles themselves can enter interstitial tissues and migrate to peribronchial (possibly via the lymphatics) and perivascular positions. Pulmonary particle clearance of via lymphatics has generally been considered minimal and its importance debated (Oberdörster, 1988). Particle transport in the pulmonary lymphatics is typically considered to terminate in lymph nodes (Stober and McClellan, 1997). Semmler-Behnke et al. (2007) concluded that, in rats, ultrafine Ir particles are less phagocytized by alveolar macrophage than larger particles, but are effectively removed from the airway surface into the inter-stitium. They further suggested that some free particles as well as particle-laden macrophage are carried from interstitial sites via the lymph flow to bronchial and bronchiolar sites, including bronchial-associated lymphatic tissue, where they are excreted again into the airway lumen.

4.3.3 Particle Translocation

Mucociliary and macrophage mediated clearance of poorly soluble particles from the respiratory tract was discussed in Section 4.3.1. There is growing evidence that a small fraction of particles may cross cell membranes and move from their site of deposition by other mechanisms. The following subsections discuss the movement of particles from the olfactory mucosa to the brain and from the luminal surfaces of the alveolar region into lung tissues and other organs. The clearance and distribution of soluble particles and soluble components of particles are also considered. There are pathways that particles could reach extrapulmonary organs by means other than direct translocation from the alveoli into the blood. For example, mucociliary clearance moves particles proximally until they are eventually swallowed. Recognizing this, the organ distribution of particles following gastrointestinal and intravenous delivery are also discussed. Finally, there are a few recent studies examining particle translocation to the fetus that are discussed.

In the last PM ISA (U.S. EPA, 2009) it was concluded that olfactory transport to the brain was likely unimportant in humans, it was not clear what portion of inhaled nanoparticles reached extrapulmonary sites via the lung's air-blood barrier versus clearance to the gastrointestinal tract with subsequent absorption and distribution to the organs, and there were data supporting translocation of poorly soluble particles from the human lung. It is now concluded that olfactory transport may be important in humans as well as rodents. A comparison of particle translocation following instillation versus ingestion also shows translocation of particles from the lungs occurs in a size dependent manner and that GI absorption of particles cleared from the respiratory tract is relatively minor route into circulation. A new human study shows that following inhalation, a small fraction of gold nanoparticles enters circulation.

4.3.3.1 Olfactory Delivery

Studies reviewed in the last PM ISA (U.S. EPA, 2009) demonstrated the translocation of soluble solutions (manganese chloride and sulfate, zinc) and poorly soluble particles (hureaulite, manganese oxide and tetroxide, silver, titanium dioxide, iridium) from the olfactory mucosa via axons to the olfactory bulb of the brain. Translocation via the axon to the olfactory bulb was observed for numerous compounds of varying composition, particle size, and solubility. Studies showed that the rate of translocation was rapid, less than an hour. The vast majority of these studies were conducted by instillation in rodents. However, DeLorenzo (1970) also observed the rapid (within 30−60 min) movement of 50 nm silver-coated colloidal gold particles instilled on the olfactory mucosa to the olfactory bulb of squirrel monkeys. Information on transport from the olfactory bulb to the olfactory tubercle, stratum, or other brain regions is limited.

Based on the diameter of the axon, the transport of insoluble particles from the olfactory mucosa via axons to the olfactory bulb should be limited to particles of less than about 200 nm (Griff et al., 2000; Plattig, 1989; De Lorenzo, 1957). These thin olfactory axons bundle into thicker filaments (aka fila olfactoria or olfactory nerves) and pass directly into the olfactory bulb through numerous foramina in the cribriform plate of the ethmoid bone (Plattig, 1989; De Lorenzo, 1957). Analysis of 40 skulls of known age and sex by Kalmey et al. (1998) showed a reduction in the area of the foramina in the cribriform plate with increasing age that did not differ significantly between the sexes. The reduction of the foramina area with aging has been postulated as a cause of a reduced sense of smell with aging and would suggest that olfactory translocation may also decrease with age.

A number of inhalation studies have investigated the transport of soluble and poorly soluble manganese compounds to the brain of rats. While most of this discussion and the available literature focuses on transport from the olfactory mucosa, it should be noted that Lewis et al. (2005) reported an accumulation of manganese in the trigeminal ganglia in rats following a 10-day inhalation exposure to soluble manganese chloride particles. Following a 13-week inhalation exposure to 0.1 mg Mn/m^3, relative to air controls, more soluble manganese sulfate reached the olfactory bulb of rats than was observed for the less soluble manganese phosphate in the form of hureaulite (Dorman et al., 2004). Manganese concentration in the olfactory bulb increased 2.3-times with exposure to Mn sulfate and only 1.5-times with exposure to hureaulite (Dorman et al., 2004). As part of this same study, exposures to 0.01 and 0.5 mg Mn/m^3 of Mn sulfate resulted in olfactory bulb concentrations of 1.3-times and 3.5-times relative to air control, respectively. Since the inhaled hureaulite particles were 1.0−1.1 µm (physical diameter) and so not likely due to their size to move along axons, these data suggest that around 20−30% of the hureaulite was solubilized to reach the olfactory bulb. However, insufficient hureaulite was solubilized find increased Mn in the striatum as occurred following the Mn sulfate exposures of 0.1 and 0.5 mg Mn/m^3.

Using smaller sized particles, a 2-day inhalation exposure to poorly soluble manganese oxide (~30 nm) with the right nostril blocked showed an accumulation of the Mn oxide in the left olfactory bulb

(Elder et al., 2006). This study demonstrates neuronal uptake and translocation of UFPs following inhalation without particle dissolution and in the absence of mucosal injury that may occur with instillation. For a longer 12-day inhalation exposure to poorly soluble manganese oxide (~30 nm) with both nostrils patent, Elder et al. (2006) also found Mn concentration was significantly increased in several brain regions (striatum, 1.6×; frontal cortex, 1.4×; cortex, 1.2× cerebellum, 1.2×), but most notably increased in the olfactory bulb (3.4×). Additionally, following nasal instillation of particles, similar amounts of Mn were found in the left olfactory bulb of rats instilled with soluble manganese chloride (8.2 ± 3.6% of instilled) and small poorly soluble particles (30 nm; 1.5% dissolution per day) of manganese oxide (8.2 ± 0.7% of instilled) at 24 hours post instillation. This finding supports the conclusion that poorly soluble manganese particles, if of a sufficiently small size, do not need to be solubilized to reach the olfactory bulb. The slow solubilization process would have resulted lesser amounts of the manganese oxide than manganese chloride in the brain by 24 hours similar to the finding by Dorman et al. (2004) following 13 week inhalation exposures to manganese sulfate versus less soluble hureaulite described in the preceding paragraph.

Leavens et al. (2007) modeled the transport of Mn from soluble and poorly soluble particles to the olfactory bulb and stratum based on the experimental studies by Brenneman et al. (2000) and Dorman et al. (2002), respectively. In both of these experimental studies rats were exposed to Mn-aerosol for a single 90 minute period. Leavens et al. (2007) estimated that 92−93% Mn from soluble particles reached the striatum via the blood with the additional 6−8% arriving via the olfactory transport. However, only small amount of Mn reaching the olfactory bulb from the inhaled soluble Mn chloride (0.1%) and poorly soluble Mn phosphate (3.3%) particles was estimated to reach the striatum. That is, Mn reached the olfactory bulb, but generally did not proceed to the adjacent stratum. The transport of Mn to the stratum from the olfactory bulb was estimated based on data from animals where one nostril was plugged while the other was left patent. Thus, the olfactory transport of Mn to the stratum only occurs on the side of the animal with a patent nostril. Mn in that stratum on the plugged side of the animal is presumably derived from the blood. At least two issues affect the interpretation of these data. First, rats having a plugged nostril reduce their minute ventilation by about 50% (Brenneman et al., 2000), this lowers the signal to noise ratio in these studies versus animals with fully patent nostrils. Second, rather large sized particles were delivered to the rats in these studies, 2.51 µm MMAD (GSD 1.17) by Brenneman et al. (2000) and 1.68 µm MMAD (GSD 1.42) (Dorman et al., 2002). Referring back to Figure 4-4 and Figure 4-5, only a small fraction of these sized particles are expected to penetrate through the head to reach the lower respiratory tract. The majority of deposition occurs in the extrathoracic airways, in this case, the nasal passages of the rat. Although Leavens et al. (2007) attributed all Mn in the blood as derived from the lungs, Mn reaching circulation through areas such as the turbinates following nasal particle deposition should not be ignored.

More recently, Kreyling (2016) determined the fraction of iridium-192 (^{192}Ir) nanoparticles reaching the brain via transport from the upper versus the lower respiratory tract. Female Wistar-Kyoto rats (8−10 weeks old, 270-300 g body weight) were exposed to aerosols (20 nm; GSD, 1.6) via nose-only

inhalation or intratracheal inhalation. Estimates of particle translocation at 24 hours post inhalation excluded activity of particles on the skin or rapidly cleared to the gut and feces. Of the delivered particles (excluding skin and rapidly cleared), at 24 hours post inhalation, 0.012% of what deposited in the upper respiratory tract and 0.0014% of what deposited in the lower respiratory tract reached the brain. That is, there was 9-times more in the brain derived from the upper than the lower respiratory tract. The predicted deposition was 3-times higher in the alveolar region than in the upper respiratory tract for the nose-only exposure. These results suggest that olfactory transport to the brain was 27-times (i.e., 9×3) greater than translocation from the alveolar region. This work, however, does not indicate what brain regions contained particles or how those brain regions differed between the exposures.

Antonini et al. (2009) exposed rats to welding fumes (0.31 µm MMAD) via inhalation or filtered air for 10 days. The poorly soluble particles (soluble/insoluble ratio, 0.0139 in water) were composed primarily of iron (80.6%), manganese (14.7%), silicon (2.75%), and copper (1.79%). The welding fume was reported to be highly insoluble in water (pH, 7.4; 37°C) with dissolution of 1.4% in 24 hours. The most marked increases in iron, manganese, and copper relative to control were found in the lungs. There was no evidence of pulmonary inflammation or injury despite exposure to 40 mg/m^3 of welding fume. Consistent with studies described in Section 4.3.3.2 on translocation from the lungs, there was a slight increase in iron and manganese concentrations in the liver, heart, kidney, and spleen at 1-day post-exposure relative to controls. Metal content was also assessed in seven brain regions: hippocampus, cerebellum, striatum, thalamus, cortex, olfactory bulb, and midbrain. Manganese concentrations, but not iron or copper, were significantly increased relative to controls in the cortex (1.3×) and cerebellum (1.2×), and especially the olfactory bulb (2.2×). Of the brain regions examined, only the thalamus showed a slight insignificant reduction in manganese relative to controls. Interestingly, although there was only a tendency for a small increase in Mn concentrations within the striatum (1.1×), proinflammatory chemokines and cytokines were significantly increased by about 1.5 times in the striatum. The lower relative increase in the olfactory bulb in this study as compared to the Elder et al. (2006) study (2.2× vs. 3.4×, respectively) may, in part, be due to the larger inhaled particle size with only around 30−40% (assuming log-normal particle size distribution with a GSD of 2−4) of the welding fume being less than 200 nm, the particle size necessary for olfactory translocation, whereas all the particles in the Elder et al. (2006) study were well under 200 nm. Less than 5% of the welding fume would be smaller than the 30 nm particles used by Elder et al. (2006). Given the distribution of manganese among brain regions, the Antonini et al. (2009) study supports the transport of manganese from welding fume particles depositing on the olfactory mucosa to the olfactory bulb. However, finding increased Mn concentrations but not other metals in the brain, suggests the differential solubilization and mobilization of the Mn rather than the movement of particles themselves along axons to the brain.

New modeling studies contradict the conclusion in the 2009 PM ISA that between species differences may predispose rats, more so than humans, to deposition of particles in the olfactory region with subsequent particle translocation to the olfactory bulb. The 2009 conclusion was based on two main differences between rodents and primates. First, the olfactory mucosa covers approximately 50% of the

nasal epithelium in rodents versus only about 5% in primates (Aschner et al., 2005). Second, a greater portion of inhaled air passes through the olfactory region of rats relative to primates (Kimbell, 2006). More recently, Garcia et al. (2015) provided CFD simulations of total ultrafine nasal deposition as well as that in the olfactory region of humans and compared to prior simulations (Garcia and Kimbell, 2009) for rats. Rats were predicted to have greater total and olfactory deposition than humans. However, due the much higher ventilation rate of humans than rats, humans were predicted to experience greater dose rate to the olfactory mucosa for particles between 1 and 13 nm, above this size the dose rate was slightly greater in rats than humans (Section 4.2.2.2 and Figure 4-7). Schroeter et al. (2015) provided experimental replica cast data and CFD simulations for total and regional deposition of particles between 2.6 and 14.3 µm. The olfactory region was assumed to be 14% of the nasal surface area. For 5 µm to 11 µm particles inhaled during light activity (flow = 30 L/min), greater than 1% deposition in the olfactory region was predicted with a maximum of 6% predicted for 8 µm particles. During a resting inhalation (flow = 15 L/min), the predicted olfactory deposition exceeded 1% for particles between 9 and 19 µm, with a maximum of 8% for 13 µm particles. Although the larger particles would not themselves be expected to move along to axon from the olfactory region of the nose to the olfactory bulb, soluble materials associated with large particles could be solubilized and pass along the axon to the olfactory bulb. Greater particle deposition was predicted to occur in the turbinates than the olfactory region by Schroeter et al. (2015), soluble materials could also move into the blood from this well perfused area and reach the brain. These newer modeling studies suggest that ultrafine particle translocation as well as soluble components associated with all sized particles could reach the olfactory bulb of humans as well as rodents in a measurable amount depending on the exposure concentration.

Human autopsy data are becoming available that also suggest the importance of translocation of material from the olfactory mucosa to the olfactory bulb. Although their source is unknown, the presence of UFP in the olfactory bulb was reported in 2 of 35 Mexico City residents (Calderon-Garciduenas et al., 2010). Presumably metal components of urban PM, statistically significant increases in manganese, nickel, and chromium have been reported in the frontal lobe of Mexico City residents relative to lower air pollution areas (Calderón-Garcidueñas et al., 2013). More recently, Maher et al. (2016) examined magnetite particles in the frontal lobes from subjects that lived in Mexico City and Manchester, U.K. The magnetite (Fe_3O_4) particles were found in two forms: smooth spherical particles and, more rarely, as angular cuboctahedrons. The authors attributed the presence of the smooth spherical particles to inhaled ambient combustion-related particles, whereas the angular cuboctahedral particles were attributed to endogenous formation. The spherical particles showed a median diameter around 14−18 nm with a maximum size of about 150 nm, sizes that can be transported to the olfactory bulb from the olfactory mucosa. As discussed in Section 4.3.3.2, some of these particles may have also reached the brain via the circulation following deposition in the alveolar region of the lung. The combined literature for animal toxicological studies, CFD modeling studies, and human autopsy data support the existence of olfactory translocation in animals and suggest its relevance in humans. Although olfactory translocation is rapid with particles appearing in the olfactory bulb within an hour following instillation on the olfactory mucosa, the relative amount of particles translocated is relatively small. For example, based on Garcia et

al. (2015) only 0.001% of 20 nm particles would potentially deposit on the olfactory mucosa in humans at rest or 0.03% in rats. Based on Elder et al. (2006), around 10% of the particles on the olfactory mucosa would translocate to the olfactory bulb. Thus, only a small fraction of poorly soluble particles inhaled through the nose might be expected to reach the olfactory bulb via the axons in humans or rats. However, absolute number of particles potentially reaching the olfactory bulb over time can be considerable (see Figure 4-7).

4.3.3.2 Pulmonary Delivery

4.3.3.2.1 Membrane Translocation

It was first demonstrated by Gross and Westrick (1954) that free particles can enter interstitial tissues and migrate to peribronchial (possibly via the lymphatics) and perivascular positions. Both in vitro and in vivo studies support the rapid (≤1 hour) translocation of free ultrafine TiO_2 particles across cell membranes (Geiser et al., 2005; Churg et al., 1998; Ferin et al., 1992). Geiser et al. (2005) conducted a detailed examination of the disposition of inhaled ultrafine TiO_2 in 20 healthy adult rats. They found that distributions of particles among lung tissue compartments appeared to follow the volume fraction of the tissues and did not significantly differ between 1 and 24 hours post-inhalation. Averaging 1 and 24-hour data, 79.3 ± 7.6% of particles were on the luminal side of the airway surfaces, 4.6 ± 2.6% were in epithelial or endothelial cells, 4.8 ± 4.5% were in connective tissues, and 11.3 ± 3.9% were within capillaries. Particles within cells were not membrane bound. It is not clear why the fraction of particles identified in compartments such as the capillaries did not differ between 1 and 24 hours post-inhalation. These findings were consistent with the smaller study of five rats by Kapp et al. (2004) who reported identifying TiO_2 aggregates in a Type II pneumocyte; a capillary close to the endothelial cells; and within the surface-lining layer close to the alveolar epithelium immediately following a 1 hour exposure. These studies effectively demonstrate that some inhaled ultrafine TiO_2 particles, once deposited on the pulmonary surfaces, can rapidly (≤1 hour) translocate beyond the epithelium and potentially into the vasculature.

A few studies have characterized differences in the behavior of fine and UFPs in vitro. Geiser et al. (2005) found that both ultrafine and fine (0.025 µm gold, 0.078 µm TiO_2, and 0.2 µm TiO_2) particles cross cellular membranes by nonendocytic (i.e., not involving vesicle formation) mechanisms such as adhesive interactions and diffusion, whereas the phagocytosis of larger 1 µm TiO_2 particles is ligand-receptor mediated. Gross and Westrick (1954) surmised that free particle translocation from the alveolar surface to interstitial tissues may be limited to smaller fine particles (<0.5 µm). Edetsberger et al. (2005) found that UFPs (0.020 µm polystyrene) translocated into cells by first measurement (~1 min after particle application). Intracellular agglomerates of 88−117 nm were seen by 15−20 min and of 253−675 nm by 50−60 min after particle application. These intracellular aggregates were thought to result

from particle incorporation into endosomes or similar structures since Genistein or Cytochalasin treatment generally blocked aggregate formation. Interestingly, particles did not translocate into dead cells, rather they attached to the outside of the cell membrane. Amine- or carboxyl-modified surfaces (46 nm polystyrene) did not affect translocation across cultures of human bronchial epithelial cells with about 6% regardless of the surface characteristics (Geys et al., 2006).

4.3.3.2.2 Extrapulmonary Distribution

Soluble material can move rapidly from the alveolar surface into the blood, but poorly soluble particles generally remain in the lung for an extended period of time. A number of human studies are available confirming that the majority of poorly soluble UFP deposited in the alveolar region undergo slow clearance and do not rapidly enter circulation. However, animal studies (primarily of rats) show that UFPs cross cell membranes by mechanisms different from larger (~1 μm) particles and that a small fraction of these particles enter capillaries and distribute systemically. Some evidence suggests that a small degree of pulmonary inflammation increases interstitial hydraulic pressure sufficiently to exceed pulmonary capillary pressure, resulting in a flux of fluid and any associated particles or fibers into pulmonary capillaries (Miserocchi et al., 2008). This is consistent with the presence of airway inflammation in a variety of airway diseases (e.g., asthma, fibrosis, ARDS, pulmonary edema, inflammation from smoking) and altered epithelial integrity, allowing more rapid movement of solutes into the bloodstream [see Section 4.4.2 of U.S. EPA (2009)]. In general, increased alveolar permeability to ^{99m}Tc-DTPA is associated with any lung syndrome characterized by pulmonary edema. Fluid flow and particle migration would be from the alveolar surface into the inter-stitium as inflammation and edema resolve.

Several human studies have investigated the pulmonary retention of radiolabeled UFPs (Wiebert et al., 2006a; Brown et al., 2002; Roth et al., 1994) or fine aggregates of UFPs (Möller et al., 2008; Mills et al., 2006; Wiebert et al., 2006b; Roth et al., 1997; Burch et al., 1986). All of these studies used technician-99m (^{99m}Tc; $t_{1/2}$ = 0.25 days; pure gamma emitter) labeled carbon, except for Roth et al. (1994) who used indium-111 (^{111}In; $t_{1/2}$ = 2.8 days; pure gamma emitter) oxide. All of these studies reported ≥80% pulmonary retention of particles at 24 hours post-inhalation. However, of the fraction cleared from the lungs in the studies using ^{99m}Tc-labeled particles, it is not entirely clear how much was deposited in the ciliated airways and cleared versus how much of the radiolabel leached from the particles and was cleared in its soluble pertechnetate form. Highly soluble in normal saline, pertechnetate clears rapidly from the lung with a $t_{1/2}$ of ~10 min and accumulates most notably in the bladder, stomach, thyroid, and salivary glands (Isawa et al., 1995; Monaghan et al., 1991). Wiebert et al. (2006a) were able to reduce leaching of the ^{99m}Tc-labeled carbon (35 nm CMD inhaled) and found effectively 100% retention at 24 hours post-inhalation. Similarly, Wiebert et al. (2006b) minimized leaching of ^{99m}Tc-labeled carbon (87 nm CMD inhaled) and found negligible particle clearance from the lungs by 70 hours post-inhalation. Using the longer half-life ^{111}In-oxide aerosol (18 nm CMD), Roth et al. (1994) found 93% retention in the

human lung at 24 hours and 80% retention at 9 days post inhalation. ^{111}In-oxide is poorly soluble and as such was not expected to move into circulation as pertechnetate does. The 7% clearance of the 18 nm ^{111}In-oxide versus near 0% clearance of the 35 nm ^{99m}Tc-labeled carbon may be, in part, caused by a more proximal deposition pattern of the smaller particles (see Figure 4-5C). These human data show that the majority of poorly soluble UFP remain in the lung.

Miller et al. (2017) investigated the translocation of gold nanoparticles having primary particle sizes of approximately 4−5 nm and 34 nm in a series of two separate inhalation experiments involving young healthy adults. In experiment one, 14 young healthy adult males inhaled (3.8 nm primary particle size) 18.7 nm agglomerates (1.5 GSD) via a face mask for 2 hours with intermittent exercise (exercise target of 25 L/min/m^2 body surface area, BSA). By 15 minutes post-exposure, gold was identified in the blood of three subjects. Gold was found in the blood of 12 subjects at 6 hours, 11 subjects at 24 hours, and 7 subjects at 3 months post-exposure.[45] Gold was also identified in the urine in an unspecified number of subjects at 24 hours and 3 months post-exposure. In experiment two, groups of healthy adult males inhaled gold nanoparticles with primary particle sizes of 4.1 nm (n = 10 subjects) and 34 nm (n = 9 subjects) as agglomerates of 17.8 nm (GSD, 1.2) and 52.4 nm (GSD, 1.4). The authors observed higher gold concentrations in the blood following inhalation of the smaller than larger primary sized particles. However, relative to the larger particles, the aerosol concentration of the smaller sized particles was, on average, 1.3 times higher (192 vs. 146 µg/m^3) and the predicted deposition is about double (total deposition fractions are 72 and 35% for smaller and larger agglomerates, respectively), leading to an estimated 2.7 times greater dose of the smaller sized particles.[46] This difference in delivered dose may have been adequate to account for differences in the amounts of gold in the blood out to 7 days post-exposure, but not necessarily at the 28 day time point. The authors also observed gold in urine for the smaller particles, but gold in urine was below the limit of detection for the larger particles. The relatively small estimated difference in delivered doses does not appear sufficient to large differences in gold in urine by 28 days post-exposure. This study demonstrates the presence of gold in the blood and urine of humans following the inhalation of gold nanoparticles.

The finding of material in the blood in this human study, Miller et al. (2017), but not prior human studies described above may, in part, be a matter of an increased signal to noise afforded in this new work and/or an indication that there is a difference in particle translocation from the lung depending on the inhaled particle type. There is uncertainty related to the actual fraction of the deposited dose that translocated from the lungs and interpretation of study results. Using data from experiment one (described above), based on the concentration of gold in urine (35 ng/L) at 24 hours and average urinary volume of

[45] The number having detectable gold in blood is based on Figure 1C of Miller et al. (2017).

[46] Deposition estimated using the MPPD model (Version 3.04) for exposure to 17.8 nm (GSD, 1.2) or 52.4 nm (GSD, 1.4) particle agglomerates during two hours of intermittent exercise with 15-minute periods of exposure at rest (V_T, 0.800 L; f, 15 min^{-1}) and 15-minute periods of exposure during exercise (V_T = 1.923 L; f = 26 min^{-1}) and default airway morphology for an adult male (i.e., Yeh/Schum symmetric morphology, FRC of 3.3 L, and upper respiratory tract volume of 0.05 L). A BSA of 2.0 m^2 was assumed (not provided by authors). The breathing pattern for rest was selected to have a minute ventilation of 6 L/min per m^2 BSA based on Mcdonnell et al. (2012). The heavy exercise breathing pattern was selected from ICRP (1994).

2.4 L, it can be estimated that about 84 ng gold was excreted from the body. This can be used as a lower end estimate of translocation from the lungs since (as described below) there is evidence from animal studies of particle accumulation in various organs. Based on the exposure concentration of 116 µg/m^3 and the ventilation rates of 12 L/min at rest and 50 L/min during exercise, the total amount of aerosol inhaled was 430 µg gold. The estimated total deposition fraction of the 18.7 nm (GSD 1.5) agglomerates is 60%.[47] The alveolar deposition fraction during periods of rest and exercise are about 30 and 40%, respectively, giving combined volume-weighted alveolar deposition fraction of 38% of the inhaled aerosol. Based on total deposition, about 0.03% translocation may have occurred given the urinary excretion at 24 hours (i.e., 0.084/256). It may be more appropriate to consider deposition in the alveolar region since the movement of particles from the gastrointestinal tract into circulation is minimal by comparison to that from the alveolar region (Kreyling et al., 2014). Translocation from the alveolar deposition to urinary excretion at 24 hours is estimated to be around 0.05% (i.e., 0.084/163). Based on the log-log plot in Figure 3i of Kreyling et al. (2014), excretion via urine as a percent of material in the lungs not cleared in 24 hours by mucus clearance in rats is about 0.42% for 2.8 nm particles and 0.006% for 5 nm particles, which provides an estimate of 0.05% for 3.8 nm particles by linear interpolation on log-log scale. The comparisons developed herein place the urinary elimination by 24 hours of 3.8 nm gold particles in humans by Miller et al. (2017) as nearly identical to those obtained in rats by Kreyling et al. (2014).

A greater amount of information on particle translocation from the lungs is available from animal studies. These studies fairly consistently show that a small portion (generally <1%) of particles delivered to the lungs via inhalation or instillation are translocated from the pulmonary surfaces to extrapulmonary organs. For example, as reviewed in the last PM ISA (U.S. EPA, 2009), extrapulmonary translocation was described for poorly soluble ultrafine gold and Ir particles. In male Wistar-Kyoto rats exposed by inhalation to ultrafine gold particles (5−8 nm), Takenaka et al. (2006) reported a low, but significant, fraction (0.03 to 0.06% of lung concentration) of gold in the blood from 1 to 7 days post inhalation. Semmler et al. (2004) also found small but detectable amounts of poorly soluble Ir particle (15 and 20 nm CMD) translocation from the lungs of female Wistar-Kyoto rats to secondary target organs like the liver, spleen, brain, and kidneys. Each of these organs contained about 0.2% of deposited Ir. The peak levels in these organs were found 7 days post inhalation. The translocated particles were largely cleared from extrapulmonary organs by 20 days and Ir levels were near background at 60 days post inhalation. Particles may have been distributed systemically via the gastrointestinal tract. Immediately after the 6-hour inhalation exposure, 18 ± 5% of the deposited Ir particles had already cleared into the gastrointestinal tract. After 3 weeks, 31 ± 5% of the deposited particles were retained in the lung. By 2 and 6 months post inhalation, lung retention was 17 ± 3 and 7 ± 1%, respectively. The particles appeared

[47] For 18.7 nm (GSD 1.5) using MPPD (Version 3.04) with intermittent exercise as described for Experiment Two. Although the authors provided a BSA of 2.76 m^2 in their Table S1, a BSA of 2.0 m^2 was assumed as a more reasonable value for males being 180 cm height and 79 kg mass. Breathing patterns used for Experiment Two were used again here.

to be cleared predominantly from the peripheral lung via the mucociliary escalator into the GI tract and were found in feces.

A considerable number of new studies have become available since the last PM ISA (U.S. EPA, 2009). Studies continue to show the translocation of a small fraction of particles following inhalation or instillation increases with decreasing particle size (Kreyling et al., 2014; Kreyling et al., 2009). However, the dissolution of poorly soluble particles increases with decreasing pH and decreasing particle size (Kreyling et al., 2002; Kreyling and Scheuch, 2000; Kreyling, 1992). Dissolution and absorption of UFPs in the gastrointestinal tract subsequent to clearance from the respiratory tract cannot be fully discounted as contributing to organ concentrations of inhaled or instilled particles. The organ distribution of particles may differ depending on the route by which they are reaching circulation. For example, in humans, the liver receives about 6.5% of arterial blood flow and all blood flow coming from the GI tract (ICRP, 2002). Additionally, the proteins that particles may encounter and potentially bind to will vary depending on the route by which they entered circulation. Recognizing such issues, a series of experiments have been conducted to quantify translocation using a ^{198}Au gamma-spectrometry[48] in female Wistar-Kyoto rats (8−10 weeks old, 250 g body weight) of negatively charged gold nanoparticles of 1.4, 2.8, 5, 18, 80, and 200 nm primary particle size and positively charged 2.8 nm primary particle size following intratracheal instillation (Kreyling et al., 2014), ingestion (Schleh et al., 2012), and intravenous delivery (Hirn et al., 2011). Although additional studies have become available since the last PM ISA, the primary focus will be on the careful comparison across these routes of delivery.

Following particle instillation, Kreyling et al. (2014) measured translocation from the lungs as a function of peripheral lung dose (i.e., ignoring particles found in the trachea, GI tract, and feces). Translocation from the lung by 24 hours of particles with a negative surface charge decreased from 5.6% for 1.4 nm particles, to 3.2% for 2.8 nm, to 0.22% for 5 nm, to 0.12% for 18 nm, to only 0.06% for 80 nm, and 0.2% for 200 nm particles.[49] Most of the translocation from the lungs appears to have occurred within 1−3 hours post-instillation, but continued up to 24 hours for the largest, 200 nm particles. The estimated translocation excluded the fraction of particles found in the trachea, GI tract and feces by 24 hours post-instillation, which was 30% (averaged across all particle sizes) of the instilled dose.[50] Potential GI tract absorption was considered negligible since a prior study by Schleh et al. (2012) of particle ingestion found only a small fraction of particles entered circulation (0.37% for 1.4 nm particles, 0.37% for 2.8 nm, 0.05% for 5 nm, 0.12% for 18 nm, 0.03% for 80 nm, and 0.01% for 200 nm particles).[51] Considering the fraction of instilled particles found in GI tract and feces and GI absorption of particles, about 4% (median of all particle sizes) to 7% (mean of all particle sizes) of the apparent translocation from the lung may have derived from the GI tract (i.e., 93−96% of the particles appearing in

[48] Gamma-spectrometry is a highly sensitive technique relative to inductively coupled plasma mass spectrometry.
[49] Values from Figures 2B and 6A of Kreyling et al. (2014) for the 24-hour time point.

circulation were derived from the lung).[52] For both instillation and ingestion, less positively charged than negatively charged 2.8 nm particles entered circulation. The organ distribution of particles following intravenous administration differed greatly from instillation. At 24 hours post intravenous delivery, 51% of 1.4 nm particles, 82% of 2.8 nm particles, and 92−97% of 5−200 nm particles were found in the liver (Hirn et al., 2011). Of the material translocating from the lungs following instillation, independent of particle size, only about 10% of particles are found in the liver with the majority (43% of 1.4 nm; 55% of 7 nm; 71% of 18 nm; 96% of 80 nm) of translocated particles found in the carcass (skeleton, soft tissues, and fat) (Kreyling et al., 2014). This difference in organ distribution following intravenous versus instillation was attributed to the proteins that particles may have encountered and bound with in the lungs prior to entering circulation. This series of studies shows that translocation of particles from the lungs occurs in a size-dependent manner, that GI absorption of particles cleared from the respiratory tract is a relatively minor route into circulation, and that organ distribution can vary depending on how particles are delivered to animals.

Following translocation from the lung or intravenous injection, particles appear to be rather rapidly cleared from the blood. This clearance from the blood occurs due to accumulation in extrapulmonary organs and elimination from the body. The blood concentrations of the smallest gold nanoparticles studied (1.4 nm) are 46% cleared in rats by one-hour post-injection and by 93% at 24 hours post-injection.[53] By 24 hours, about 10% of 1.4 nm particles had moved, in roughly equal portions, into feces and urine. Larger nanoparticles (18 and 80 nm) were roughly 99% cleared from blood by one-hour post-injection. By 24 hours post-injection, most of the organ retention, 92−97% for 5−200 nm particles, is in the liver (Hirn et al., 2011). Of these larger particles eliminated (0.1 to 1%) by 24 hours post-injection, most is via the feces.[54] Others have also reported similar dependence of organ accumulation of particle size in mice, with smaller gold nanoparticles (1.5−5 nm) persisting more in blood and excreted via urine than larger (30−70 nm) nanoparticles (Miller et al., 2017; Yang et al., 2014). This was similarly demonstrated in humans with 4.1 nm particles found in urine, but not 34.3 nm particles (Miller et al., 2017). A limited number of studies have shown the continued existence in the blood at 28 days post-delivery of inhaled gold nanoparticles (4.1 and 34.3 nm) in humans and instilled TiO_2 (70 nm) in rats (Kreyling et al., 2017b; Miller et al., 2017). It is likely that the particles in the blood at 28 days post-delivery were due to additional movement/clearance from the lungs.

The long-term health implications of translocation following acute or chronic PM exposures is uncertain. Heringa et al. (2018) recently reported the existence of TiO_2 in the livers and spleens of humans (9 F, 6 M; 84 ± 13 years) on autopsy. The average titanium content in was 40 µg/kg (TiO_2 mass/tissue mass) in the liver and 80 µg/kg in the spleen. Two of the subjects had received titanium implants, but had titanium content below the limit of detection in the liver and low amounts in the spleen

[52] Kreyling et al. (2017b) reported that at 24-hour post-instillation, 5% of TiO_2 (70 nm) reaching the blood was absorbed in the GI tract (i.e., 95% crossed the alveolar air-blood barrier). Due to long-term clearance of the lung, this percentage increased to 13% by 7 days post instillation and 21% at 28 days post instillation.
[53] Data from Table S1 of Semmler-Behnke et al. (2014).
[54] Data from Figure S4 of Semmler-Behnke et al. (2014).

relative to the other individuals. Titanium dioxide particles having diameters of 85−440 nm were identified. By count with a limit of detection at 85 nm, nearly 27% of the particles in the liver and 21% of the particles in the spleen were ≤100 nm. By count, about 75% of particles were ≤200 nm. Gamma-spectrometry studies of 70 nm TiO_2 particle translocation in rats show about 4% translocation into circulation following intratracheal instillation and about 0.6% following ingestion (Kreyling et al., 2017b; Kreyling et al., 2017c). As occurs for gold nanoparticles instillation, the translocated TiO_2 distribute around the body and accumulate in organs, but are found primarily (91% at 24-hour post instillation) in the carcass (skeleton, soft tissues, and fat). This differs from 24 hours post-intravenous injection where TiO_2 accumulates predominately (95.5%) in the liver (Kreyling et al., 2017a). Following rather high doses (25−30 mg/day) of ingested TiO_2 nanoparticles (10 nm) to rat dams from gestational day 2 to 21, pups sacrificed 1 day after birth have increased titanium content in the hippocampus (Mohammadipour et al., 2014). Quantification of translocation to fetuses is provided in Section 4.3.3.3. Particle accumulation in the liver and spleen of autopsied humans is consistent with accumulation in these organs in rodents following intratracheal instillation and ingestion of particles.

4.3.3.3 Transplacental Barrier Transport

A number of studies have become available since the last PM ISA (U.S. EPA, 2009) examining particle translocation to the fetus. The route of exposure in these studies is generally oral or intravenous delivery. These papers may be important regardless of the delivery method (with the exception of intraperitoneal) since they add biological plausibility for effects during pregnancy. However, as indicated in Section 4.3.3.2.2, the sites of accumulation differ greatly between intravenous delivery versus instillation into the lung and ingestion. Specifically, the majority of particles found in circulation following intravenous delivery accumulate in the liver, whereas as the majority of particles are found in the carcass (skeleton, soft tissues, and fat) following instillation and ingestion.

The primary focus herein is given to Semmler-Behnke et al. (2014). This study utilizes the highly sensitive ^{198}Au gamma-spectrometry technique and provides a mass balance for the full body and excrement. This study was also discussed in Section 4.3.3.2.2 and was conducted by the same German research group having many years of experience and numerous publications evaluating particle deposition, clearance, and translocation in humans and rodents. The principal finding of the Semmler-Behnke et al. (2014) study relevant to this section is the accumulation in rat fetuses following delivery of particles at gestational Day 18. This time point was selected because the nutrition of the fetus is primarily the dam's blood versus the yoke sac earlier in gestation. Following intravenous injection, 0.06% of 1.4 nm and 0.004% of 18 nm gold nanoparticles were found in fetuses. No 80 nm particles (<0.0004%, the detection limit) were found in fetuses. The authors attributed the decreasing translocation as a function of increasing particle size to the role of transtrophoblasitic channels (canaliculi of 20−25 nm in diameter) in transporting particles from the maternal blood to the fetuses. The organ distribution between pregnant and nonpregnant rats was generally similar. Yang et al. (2014) also reported similar organ distributions

between pregnant and nonpregnant animals at 5 hours post intravenous injection of gold nanoparticles (1.5, 4.5, 13, 30, and 70 nm diameter). Tsyganova et al. (2014) found increased gold content in liver and spleen of fetuses following intravenous injection of gold nanoparticles (5 and 30 nm) into pregnant rats. Following rather high doses (25−30 mg/day) of ingested TiO_2 nanoparticles (10 nm) to rat dams from gestational day 2 to 21, pups sacrificed 1 day after birth have increased titanium content in the hippocampus (Mohammadipour et al., 2014). Overall, these studies show that a small fraction of nanoparticles entering circulation may reach fetuses.

4.3.4 Factors Modulating Particle Clearance

4.3.4.1 Age

It was previously concluded that there appeared to be no clear evidence for any age-related differences in clearance from the lung or total respiratory tract, either from child to adult, or young adult to elderly (U.S. EPA, 2004, 1996). Studies showed either no change or some slowing in mucus clearance with age after maturity. Although some differences in alveolar macrophage function were reported between mature and senescent mice, no age-related decline in macrophage function had been observed in humans. A comprehensive review of the literature provided in the last PM ISA (U.S. EPA, 2009) supported a decrease in mucociliary clearance with increasing age beyond adulthood in humans and animals. Limited animal data also suggest macrophage-mediated alveolar clearance may also decrease with age. This evidence is briefly paraphrased below.

Ho et al. (2001) demonstrated that nasal mucociliary clearance rates were about 40% lower in old (age >40−90 years) versus young (age 11−40 years) men and women. Tracheal mucus velocities in elderly (or aged) humans and beagle dogs are about 50% that of young adults (Whaley et al., 1987; Goodman et al., 1978). Several human studies have demonstrated decreasing rates of mucociliary particle clearance from the large and small bronchial airways with increasing age (Svartengren et al., 2005; Vastag et al., 1985; Puchelle et al., 1979). Linear fits to the data show that rapid clearance (within 1 hour) from large bronchi and prolonged clearance (between 1−21 days) from the small bronchioles in an 80-year old is only about 50% of that in 20-year old (Svartengren et al., 2005; Vastag et al., 1985). One study reported that alveolar particle clearance rates decreased by nearly 40% in old versus young rats (Muhle et al., 1990). Another study has reported that older rats have an increased susceptibility to pulmonary infection due to altered alveolar macrophage function and slowed bacterial clearance (Antonini et al., 2001). Although data are somewhat limited, they consistently show a depression of clearance throughout the respiratory tract with increasing age from young adulthood in humans and laboratory animals.

4.3.4.2 Sex

Sex was not found to affect clearance rates in prior reviews (U.S. EPA, 2004, 1996). Studies included in the most recent review (U.S. EPA, 2009) also showed that human males and females have similar nasal mucus clearance rates (Ho et al., 2001), tracheal mucus velocities (Yeates et al., 1981), and large bronchial airway clearance rates (Vastag et al., 1985).

4.3.4.3 Respiratory Tract Disease

At the time of the last two reviews (U.S. EPA, 2004, 1996), it was well recognized that obstructive airways disease may influence both the site of initial deposition and the rate of mucociliary clearance from the airways. When deposition patterns are matched, mucociliary clearance rates are reduced in patients with COPD relative to healthy controls. The effects of acute bacterial/viral infections and cough on mucociliary clearance were briefly summarized in Section 10.4.2.5 (U.S. EPA, 1996) and Section 6.3.4.4 (U.S. EPA, 2004) of past reviews. While cough is generally a reaction to some inhaled stimulus, in some cases, especially respiratory disease, it can also serve to clear the upper bronchial airways of deposited substances by dislodging mucus from the airway surface. One of the difficulties in assessing effects on infection on mucociliary clearance is that spontaneous coughing increases during acute infections. Cough has been shown to supplement mucociliary clearance of secretions, especially in patients with obstructive lung disease and primary ciliary dyskinesia.

Using a bolus technique to target specific lung regions, Möller et al. (2008) examined particle clearance from the ciliated airways and alveolar region of healthy subjects, smokers, and patients with COPD. Airway retention after 1.5 hours was significantly lower in healthy subjects (89 ± 6%) than smokers (97 ± 3%) or COPD patients (96 ± 6%). At 24 and 48 hours, retention remained significantly higher in COPD patients (86 ± 6% and 82 ± 6%, respectively) than healthy subjects (75 ± 10% and 70 ± 9%, respectively). However, these findings are confounded by the more central pattern of deposition in the healthy subjects than in the smokers and COPD patients. Alveolar retention of particles was similar between the groups at 48 hours post-inhalation.

The effect of asthma on lung clearance of particles may depend on disease status. Lay et al. (2009) found significantly ($p < 0.01$) more rapid particle (0.22 µm) mucociliary clearance over a 2-hour period post-inhalation in mild asthmatics than in healthy volunteers. Although the pattern of deposition tended to be more central in the asthmatics, there was not a statistically significant difference from healthy controls ($p = 0.24$). The extent of central relative to peripheral airways deposition was well correlated with the lung retention at 2 hours post-inhalation in the subjects with asthma ($r = -0.78$, $p < 0.01$) but not the healthy subjects. In vivo uptake by airway macrophages in mild asthmatics was also enhanced relative to healthy volunteers ($p < 0.01$). In an ex vivo study, airway macrophages from individuals with more severe asthma had impaired phagocytic capacity relative to less severely affect

asthmatics and healthy volunteers (Alexis et al., 2001). Lay et al. (2009) concluded that enhanced uptake and processing of particulate antigens could contribute to the pathogenesis and progression of allergic airways disease in asthmatics and may contribute to an increased risk of exacerbations with particulate exposure.

Chen et al. (2006) investigated the effect of endotoxin on the disposition of particles. Healthy rats and those pretreated with endotoxin (12 hours before particle instillation) were instilled with ultrafine (56.4 nm) or fine (202 nm) particles. In healthy rats, there were no marked differences in lung retention or systemic distribution between the ultrafine and fine particles. In healthy animals, UFPs were primarily retained in lungs (72 ± 10% at 0.5−2 hours; 65 ± 1% at 1 day; 62 ± 5% at 5 days). Particles were also detected in the blood (2 ± 1% at 0.5−2 hours; 0.1 ± 0.1% at 5 days) and liver (3 ± 2% at 0.5−2 hours; 1 ± 0.1% at 5 days) of the healthy animals. At 1-day post-instillation, about 13% of the particles were excreted in the urine or feces of the healthy animals. In rats pretreated with endotoxin, by 2 hours post-instillation, the UFPs accessed the blood (5 vs. 2%) and liver (11 vs. 4%) to a significantly greater extent than fine particles. The endotoxin-treated rats also had significantly greater amounts of UFPs in the blood (5 vs. 2%) and liver (11 vs. 3%) relative to the healthy control rats. This study demonstrates that acute pulmonary inflammation caused by endotoxin increases the migration of UFPs into systemic circulation.

Adamson and Prieditis (1995) investigated the possibility that particle deposition into an already injured lung might affect particle retention and enhance the toxicity of "inert" particles. Bleomycin was instilled into mice to induce epithelial necrosis and subsequent pulmonary fibrosis. Instilled 3 days following bleomycin treatment, while epithelial permeability was compromised, carbon black particles in treated mice were translocated to the inter-stitium and showed increased pulmonary retention relative to untreated mice. When instilled at 4 weeks post bleomycin treatment, after epithelial integrity was restored, carbon black particle retention was similar between treated and untreated mice with minimal translocation to the inter-stitium. The instillation of carbon particles did not appear to increase lung injury in the bleomycin treated mice at either time point. This study shows that integrity of the epithelium affects particle retention and translocation into interstitial tissues.

4.3.4.4 Particle Overload

Unlike other laboratory animals, rats appear susceptible to "particle overload" effects due to impaired macrophage-mediated alveolar clearance. Numerous reviews have discussed this phenomenon and the difficulties it poses for the extrapolation of chronic effects in rats to humans (Oberdorster, 2002; ILRI Risk Science Institute, 2000; Miller, 2000; Oberdorster, 1995; Morrow, 1994). Large mammals have slow pulmonary particle clearance and retain particles in interstitial tissues under normal conditions, whereas rats have rapid pulmonary clearance and retain particles in alveolar macrophages (Snipes, 1996). With chronic high doses of PM there is a shift in the pattern of dust accumulation and response from that

observed at lower doses in rat lungs (Snipes, 1996; Vincent and Donaldson, 1990). Rats chronically exposed to high concentrations of insoluble particles experience a reduction in their alveolar clearance rates and an accumulation of interstitial particle burden (Bermudez et al., 2004; Bermudez et al., 2002; Warheit et al., 1997; Oberdörster et al., 1994a; Oberdörster et al., 1994b; Ferin et al., 1992). With continued exposure, some rats eventually develop pulmonary fibrosis and both benign and malignant tumors (Warheit et al., 1997; Lee et al., 1986; Lee et al., 1985a, b). Oberdorster (2002, 1996) proposed that high-dose effects observed in rats may be associated with two thresholds. The first threshold is the pulmonary dose that results in a reduction in macrophage-mediated clearance. The second threshold, occurring at a higher dose than the first, is the dose at which antioxidant defenses are overwhelmed and pulmonary tumors develop. Intrapulmonary tumors following TiO_2 exposures are exclusive to rats and are not found in mice or hamsters (Mauderly, 1997). Moreover, Lee et al. (1985a) noted that the squamous cell carcinomas observed with prolonged high concentration TiO_2 exposures developed from the alveolar lining cells adjacent to the alveolar ducts, whereas squamous cell carcinomas in humans which are generally linked with cigarette smoking are thought to arise from basal cells of the bronchial epithelium. Quoting Lee et al. (1986), "Since the lung tumors were a unique type of experimentally induced tumor under exaggerated exposure conditions and have not usually been seen in man or animals, their relevance to man in questionable."

4.3.5 Summary

For any given particle size, the pattern of particle deposition influences clearance by partitioning deposited material between regions of the respiratory tract. Particles depositing in the mouth may generally be assumed to be swallowed or removed by expectoration. About 80% of particles deposited in nasal passages and the majority deposited in the tracheobronchial airways move via mucociliary transport towards the nasopharynx and are swallowed. The primary alveolar clearance mechanism of poorly soluble particles is macrophage phagocytosis and migration to terminal bronchioles where the cells are cleared by the mucociliary escalator. Movement of particles into the lymphatics, both as free particles and in macrophages, also contributes to alveolar clearance. Clearance from both the tracheobronchial and alveolar region is more rapid in rodents than humans. Mucociliary and macrophage-mediated clearance decreases with age beyond adulthood.

A small fraction of nanoparticles (≤100 nm) depositing in the alveolar region translocate rapidly (≤1 hour) from the lungs in a size dependent manner. The fraction of nanoparticles translocating from the peripheral lung into circulation is generally low (less than a fraction of a percent) for larger nanoparticles (18−80 nm), but can approach several percent for extremely small particles (1.4−2.8 nm). Particle translocation has not been reported for particles larger than 200 nm. Translocation has now been reported in both a human study as well as numerous animal studies. Of particles found in circulation following delivery to the lung, the majority (~95%) arrive via the lung's air blood barrier with the remainder (~5%) coming from gastrointestinal absorption. These particles are cleared from circulation fairly rapidly (hours

to days) by accumulation predominately in the skeleton, soft tissues, and fat and secondarily by accumulation within the liver and spleen. Particles injected into circulation, however, accumulate predominately within the liver, suggesting a differing protein corona from those derived from the lung and gastrointestinal tract. Following nanoparticle inhalation or ingestion, particles may be identified in the blood out to a month post-delivery. This longer-term presence of particles in the blood is believed to result from continued particle clearance from the lung. Some limited new evidence in rodents suggests a small fraction of nanoparticles may also reach fetuses.

The translocation of particles from the olfactory mucosa via axons to the olfactory bulb has been reported in primates, rodents, and freshwater pike for numerous compounds of varying composition, particle size, and solubility. The rate of translocation is rapid, perhaps less than an hour. Axonal transport of poorly soluble particles is thought to be limited to those under 200 nm in diameter. It is unclear to what extent translocation to the olfactory bulb and other brain regions may occur. The most extensive study of olfactory translocation has been for manganese compounds. For manganese particles, most of the manganese found in brain regions beyond the olfactory bulb is believed to derive from the blood rather than from the olfactory bulb. New particle deposition modeling suggests that deposition on the olfactory mucosa with subsequent translocation to the olfactory bulb may be important in humans as well as rodents.

CHAPTER 5 RESPIRATORY EFFECTS

Summary of Causality Determinations for Short- and Long-Term Particulate Matter (PM) Exposure and Respiratory Effects

This chapter characterizes the scientific evidence that supports causality determinations for short- and long-term PM exposure and respiratory effects. The types of studies evaluated within this chapter are consistent with the overall scope of the ISA as detailed in the Preface (see Section P 3.1). In assessing the overall evidence, strengths and limitations of individual studies were evaluated based on scientific considerations detailed in the Appendix. The evidence presented throughout this chapter support the following causality determinations. More details on the causal framework used to reach these conclusions are included in the Preamble to the ISA (U.S. EPA, 2015).

Size Fraction	Causality Determinations
Short-term exposure	
$PM_{2.5}$	Likely to be causal
$PM_{10-2.5}$	Suggestive of, but not sufficient to infer
UFP	Suggestive of, but not sufficient to infer
Long-term exposure	
$PM_{2.5}$	Likely to be causal
$PM_{10-2.5}$	Inadequate
UFP	Inadequate

5.1 Short-Term $PM_{2.5}$ Exposure and Respiratory Effects

The 2009 PM ISA (U.S. EPA, 2009) concluded that a "causal relationship is likely to exist" between short-term $PM_{2.5}$ exposure and respiratory effects (U.S. EPA, 2009).[55] This conclusion was based mainly on epidemiologic evidence demonstrating associations between short-term $PM_{2.5}$ exposure and various respiratory effects. The more limited evidence from controlled human exposure and animal toxicological studies provided coherence and biological plausibility for a subset of respiratory effects for which $PM_{2.5}$-related associations were observed in epidemiologic studies. In addition, the 2009 PM ISA described epidemiologic evidence as consistently showing $PM_{2.5}$-associated increases in hospital

[55] As detailed in the Preface, risk estimates are for a 10 μg/m^3 increase in 24-hour average $PM_{2.5}$ concentrations unless otherwise noted.

admissions and emergency department (ED) visits for chronic obstructive pulmonary disease (COPD) and respiratory infection among adults or people of all ages, as well as increases in respiratory mortality. Epidemiologic evidence was inconsistent for hospital admissions or ED visits for asthma but supported associations with increased respiratory symptoms and decreases in lung function in children with asthma. Studies examining copollutant models showed that $PM_{2.5}$ associations with respiratory effects were robust to inclusion of CO or SO_2 in the model, but often were attenuated with inclusion of O_3 or NO_2. Evidence supporting an independent effect of $PM_{2.5}$ exposure on the respiratory system was provided by animal toxicological studies of $PM_{2.5}$ concentrated ambient particles (CAPs) demonstrating changes in some pulmonary function parameters, as well as inflammation, oxidative stress, injury, enhanced allergic responses, and reduced host defenses. Many of these effects have been implicated in the pathophysiology for asthma exacerbation, COPD exacerbation, or respiratory infection. Some of these effects were also observed with diesel exhaust (DE) or woodsmoke exposures; however, there was no attempt to attribute the effect to the particulate or gaseous components of the mixture. In the few controlled human exposure studies conducted in individuals with asthma or COPD, $PM_{2.5}$ exposure mostly had no effect on respiratory symptoms, lung function, or pulmonary inflammation. Short-term $PM_{2.5}$ exposure was not clearly related to respiratory effects in healthy people. Evidence integrated across scientific disciplines linked respiratory effects to several $PM_{2.5}$ components such as elemental carbon/black carbon (EC/BC), organic carbon (OC), and metals and $PM_{2.5}$ sources such as wildfires and traffic. However, there were few studies on any given component or source, and disparate outcomes were examined across studies and disciplines, complicating the overall interpretation of results. As a result, the 2009 PM ISA did not make a conclusion with respect to PM sources and components specifically for respiratory effects, but broadly concluded that "many [components] of PM can be linked with differing health effects and the evidence is not yet sufficient to allow differentiation of those components or sources that are more closely related to specific health outcomes" (U.S. EPA, 2009).

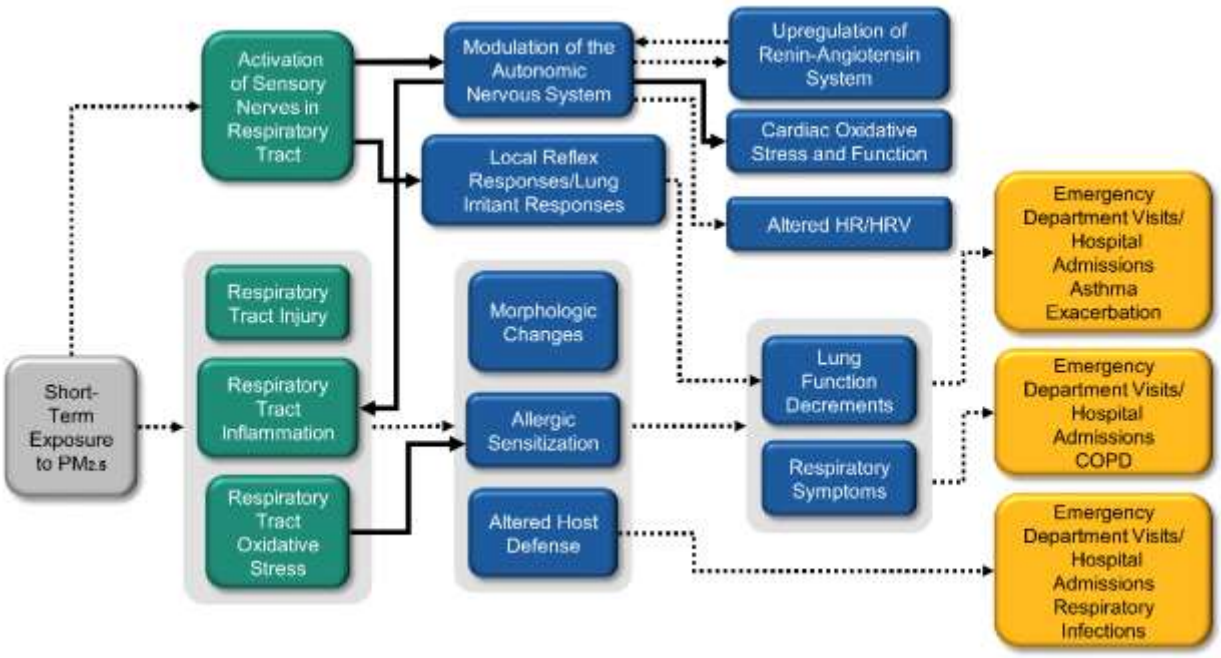
The following section on short-term $PM_{2.5}$ exposure and respiratory effects opens with a discussion of biological plausibility (Section 5.1.1) that provides background for the subsequent sections in which groups of related endpoints are presented in the context of relevant disease pathways. The organization of sections by outcome group aims to clearly characterize the extent of coherence among related endpoints (e.g., hospital admissions, symptoms, inflammation) and biological plausibility of $PM_{2.5}$ effects. These outcome groups include asthma exacerbation (Section 5.1.2), COPD exacerbation (Section 5.1.4), respiratory infection (Section 5.1.5), combinations of respiratory-related disease hospital admissions and ED visits (Section 5.1.6), and respiratory mortality (Section 5.1.9). New to this ISA are distinct discussions of allergy exacerbation (Section 5.1.3), respiratory effects in healthy populations (Section 5.1.7), and respiratory effects in populations with cardiovascular disease (Section 5.1.8). Section 5.1.10 comprises an integrated discussion of policy-relevant considerations across the epidemiologic studies evaluated within Section 5.1. The evaluation of whether there is evidence of differential associations by various $PM_{2.5}$ components and sources, compared to $PM_{2.5}$ mass, is detailed in Section 5.1.11.

5.1.1 Biological Plausibility

This section describes biological pathways that potentially underlie respiratory health effects resulting from short-term exposure to $PM_{2.5}$. Figure 5-1 graphically depicts the proposed pathways as a continuum of upstream events, connected by arrows, that may lead to downstream events observed in epidemiologic studies. This discussion of "how" short-term exposure to $PM_{2.5}$ may lead to respiratory health effects contributes to an understanding of the biological plausibility of epidemiologic results evaluated later in Section 5.1.

Once $PM_{2.5}$ deposits in the respiratory tract, it may be retained, cleared, or solubilized (see CHAPTER 4). Insoluble and soluble components of $PM_{2.5}$ may interact with cells in the respiratory tract, such as epithelial cells, inflammatory cells, and sensory nerve cells. One way in which this may occur is through reduction-oxidative (redox) reactions. As discussed in Section 2.3.3, PM may generate reactive oxygen species (ROS) and this capacity is termed "oxidative potential." Furthermore, cells in the respiratory tract may respond to the presence of PM by generating ROS. Further discussion of these redox reactions, which may contribute to oxidative stress, is found in Section 5.1.1 of the 2009 PM ISA (U.S. EPA, 2009). In addition, poorly soluble particles may translocate to the interstitial space beneath the respiratory epithelium and accumulate in the lymph nodes (see CHAPTER 4). Immune system responses due to the presence of particles in the interstitial space may contribute to respiratory health effects.

Evidence that short-term exposure to $PM_{2.5}$ may affect the respiratory tract generally informs two proposed pathways (Figure 5-1). The first pathway begins with injury, inflammation, and oxidative stress responses, which are difficult to disentangle. Inflammation generally occurs as a consequence of injury and oxidative stress, but it can also lead to further oxidative stress and injury due to secondary production of ROS by inflammatory cells. The second pathway begins with the activation of sensory nerves in the respiratory tract that can trigger local reflex responses and transmit signals to regions of the central nervous system that regulate autonomic outflow.



Note: The boxes above represent the effects for which there is experimental or epidemiologic evidence, and the dotted arrows indicate a proposed relationship between those effects. Solid arrows denote direct evidence of the relationship as provided, for example, by an inhibitor of the pathway or a genetic knock-out model used in an experimental study. Shading around multiple boxes denotes relationships between groups of upstream and downstream effects. Progression of effects is depicted from left to right and color-coded (gray, exposure; green, initial event; blue, intermediate event; orange, apical event). Here, apical events generally reflect results of epidemiologic studies, which often observe effects at the population level. Epidemiologic evidence may also contribute to upstream boxes. When there are gaps in the evidence, there are complementary gaps in the figure and the accompanying text below.

Figure 5-1 Potential biological pathways for respiratory effects following short-term $PM_{2.5}$ exposure.

Injury, Inflammation, and Oxidative Stress

Regarding the first pathway, a large body of evidence from controlled human exposure (Section 5.1.7.2) and animal toxicological studies (Section 5.1.7.3 and Section 5.1.8) found injury, inflammation, and oxidative stress responses in healthy individuals and animals. These responses are highly variable. In studies involving concentrated ambient particles (CAPs) exposure, variability may be due to differences in concentration and sources of $PM_{2.5}$ present in the airshed. Multiday exposures generally resulted in more robust responses than exposures of a few hours. Some studies in humans and animals that examined markers in bronchoalveolar lavage fluid (BALF) found increased numbers of macrophages and neutrophils. Animal toxicological studies examining responses in lung tissue found markers of injury and oxidative stress, such as increased lung water and protein carbonyl content (Rhoden et al., 2004; Gurgueira et al., 2002), and markers of inflammation such as recruitment of macrophage populations (Xu et al., 2013). Other studies found evidence of mild morphologic changes, such as hyperplasia of the bronchoalveolar duct (Batalha et al., 2002) and changes in the mucus content of the nasal epithelium (Yoshizaki et al., 2016), that could be downstream effects of inflammation following

inhalation of $PM_{2.5}$. Inflammation may lead to other downstream effects, such as lung function decrements. A decrease in maximal mid-expiratory flow coupled with a decrease in oxygen saturation, possibly indicating dysfunction of small peripheral airways, was observed in healthy humans following inhalation of $PM_{2.5}$ (Gong et al., 2005). It is not clear whether the decrement in lung function seen in this study was due to inflammation or to autonomic nervous system (ANS) responses, which are discussed below.

Some experimental evidence focuses on respiratory responses in specific disease states, such as asthma and COPD, in which inflammation is known to play an important role. In animal models of allergic airway disease, which share many phenotypic features with asthma in humans, short-term exposure to $PM_{2.5}$ led to morphologic changes due to allergic responses and airway remodeling (Section 5.1.2.4). These morphologic changes could lead to lung function decrements and respiratory symptoms, both of which are associated with $PM_{2.5}$ concentrations in epidemiologic panel studies of humans with asthma (Section 5.1.2.2 and Section 0). Further, evidence from epidemiologic panel studies in children with asthma linked $PM_{2.5}$ concentrations to the inflammatory marker leukotriene E4, asthma symptoms, medication use (Section 5.1.2.2 and Section 5.1.2.4) and decrements in lung function (Section 0). Overall, these results provide plausibility for epidemiologic findings of hospital admissions and ED visits for asthma (Section 5.1.2.1).

Injury and inflammatory responses to inhaled CAPs were more robust in animal models of COPD than in healthy animals (Saldiva et al., 2002; Kodavanti et al., 2000; Clarke et al., 1999). Lung function-related changes in oxygen saturation, FEV_1, and tidal volume were seen in controlled human exposure studies involving human subjects with COPD and in animal models of COPD following short-term exposure to $PM_{2.5}$ (Gong et al., 2005; Saldiva et al., 2002; Clarke et al., 1999) and provide plausibility for epidemiologic findings of exacerbation of COPD (Section 5.1.4). Whether these COPD-related changes in lung function were due to inflammation or to ANS responses, which are discussed below, is not clear.

In animal toxicological studies, inhalation of $PM_{2.5}$ resulted in additional effects on the immune system subsequent to respiratory tract inflammation and oxidative stress. Allergic sensitization occurred in one study using diesel exhaust particles (DEPs) (Whitekus et al., 2002). It was blocked by treatment with antioxidants (depicted by the solid line connecting oxidative stress and allergic sensitization in Figure 5-1), indicating a role for oxidative stress in mediating the response. Allergic sensitization is an early step in the development of an allergic phenotype, which could contribute to both lung function decrements and respiratory symptoms. Another study found altered macrophage function and increased susceptibility to an infectious following inhalation of CAPs (Zelikoff et al., 2003). This demonstration of impaired host defense provides plausibility for epidemiologic findings of respiratory infection (Section 5.2.6).

Activation of Sensory Nerves

Regarding the second pathway, activation of sensory nerves, animal toxicological studies described in the previous ISA and later in this chapter demonstrated changes in respiratory rate and lung volumes (i.e., rapid, shallow breathing) (Section 5.1.7 and Section 5.1.8). These responses are characteristic of lung irritant responses. Activation of sensory nerves in the respiratory tract can trigger local reflex responses resulting in lung irritation. Evidence that lung irritant responses are mediated by parasympathetic pathways involving the vagus nerve is provided by a study in which DEPs were intra-tracheally instilled into a rodent (Mcqueen et al., 2007) (depicted as a solid line connecting activation of sensory nerves and local reflex responses in Figure 5-1). In this study, pretreatment with atropine, an inhibitor of parasympathetic pathways, and vagotomy, which involves severing of the vagus nerve, blocked the irritant response to DEP. Lung irritation serves as an adaptive response to a noxious chemical that can potentially decrease exposure to that chemical. While some studies in humans and animals involving inhalation of $PM_{2.5}$ found FEV_1 changes, it is not clear whether this effect was mediated by lung irritant responses or by inflammation.

Activation of sensory nerves in the respiratory tract can also transmit signals to regions of the central nervous system that regulate autonomic outflow and influence all the internal organs, including the heart. Involvement of specific receptors on the sensory nerves, the transient receptor potential (TRP) sensory nerve receptors, was demonstrated by (Ghelfi et al., 2008), since TRP antagonists blocked downstream effects of exposure to $PM_{2.5}$ on the heart (depicted by the solid line connecting activation of sensory nerves and cardiac oxidative stress and function in Figure 5-1). In this study, modulation of the ANS resulted in altered autonomic outflow, which was manifest as a change in heart rate (see Section 8.1.1 and Section 6.1.1).

Furthermore, studies suggest connections between $PM_{2.5}$-mediated modulation of the ANS and other effects. A study in mice found that short-term exposure to $PM_{2.5}$ increased sympathetic nervous system (SNS) activity, as indicated by increased norepinephrine levels in lung and brown adipose tissue (Chiarella et al., 2014). Furthermore, inhalation of $PM_{2.5}$ increased BALF cytokine levels, an effect which was enhanced by β_2 adrenergic receptor agonists, which mimic the actions of norepinephrine. Using knock-out mice lacking the β_2 adrenergic receptor specifically in alveolar macrophage, it was demonstrated that inhalation of $PM_{2.5}$ enhanced cytokine release from alveolar macrophages. This involvement of the SNS in $PM_{2.5}$-mediated inflammatory responses is depicted by the solid line connecting modulation of the ANS and respiratory tract inflammation in Figure 5-1. The SNS is one arm of the ANS (the other arm being the parasympathetic nervous system). This is likely to represent a positive feed-back mechanism by which ANS responses may enhance inflammation. Another study found upregulation of the renin-angiotensin system (RAS), as indicated by an increase in mRNA for angiotensin receptor Type 1 and angiotensin converting enzyme, in the lung (Aztatzi-Aguilar et al., 2015). Angiotensin receptor Type 1 mediates the effects of angiotensin II, which is a potent vasoconstrictor and mediator in the vasculature. The SNS and the RAS are known to interact in a positive feedback fashion

(Section 8.1.2) with important ramifications in the cardiovascular system. However, it is not known whether SNS activation or some other mechanism mediated the changes in the RAS observed in the respiratory tract in this study.

Summary

As described here, there are two proposed pathways by which short-term exposure to $PM_{2.5}$ may lead to respiratory health effects. One pathway involves respiratory tract injury, inflammation, and oxidative stress that may lead to morphologic changes and lung function decrements, which are linked to asthma and COPD exacerbations. Respiratory tract inflammation may also lead to altered host defense, which is linked to increased respiratory infections. The second pathway involves the activation of sensory nerves in the respiratory tract leading to lung function decrements, which are linked to asthma and COPD exacerbations. While experimental studies involving animals or human subjects contribute most of the evidence of upstream effects, epidemiologic studies found associations between exposure to $PM_{2.5}$ and both respiratory tract inflammation and lung function decrements. Together, these proposed pathways provide biological plausibility for epidemiologic evidence of respiratory health effects and will be used to inform a causality determination, which is discussed later in the chapter (Section 5.1.12).

5.1.2 Asthma Exacerbation

Asthma is a chronic inflammatory lung disease characterized by reversible airway obstruction and increased airway responsiveness. Exacerbation of disease is associated with symptoms such as wheeze, cough, chest tightness, and shortness of breath. Symptoms may be treated with asthma medication, and uncontrollable symptoms may lead to seeking medical treatment. Previous findings linking short-term $PM_{2.5}$ exposure to asthma exacerbation, particularly from epidemiologic studies of children, comprised one line of evidence informing the determination of a likely to be causal relationship with respiratory effects. Some incoherence was noted in the evidence for children with asthma in that $PM_{2.5}$ concentrations were associated with respiratory symptoms and lung function decrements but inconsistently and imprecisely associated with hospital admissions and ED visits for asthma. However, the main uncertainty was whether $PM_{2.5}$ exposure had an effect independent of correlated copollutants. In the few epidemiologic studies that examined copollutant confounding, $PM_{2.5}$ associations with asthma-related effects did not always persist in models that included O_3, NO_2, CO, or SO_2. Further, in the 2009 PM ISA, coherence between evidence for allergic responses and epidemiologic findings for asthma exacerbation was not assessed for short-term $PM_{2.5}$ exposure. In controlled human exposure and animal toxicological studies, short-term $PM_{2.5}$ exposure induced allergic inflammation, which is part of the pathophysiology for allergic asthma. Allergic asthma is the most common asthmatic phenotype in children, and allergic inflammation could link $PM_{2.5}$ exposure and asthma exacerbation.

In characterizing the current state of the evidence, this section begins by considering the effects of short-term exposure to $PM_{2.5}$ on clinical indicators of asthma exacerbation (i.e., hospital admissions, ED visits, and physician visits for asthma) and then considers respiratory symptoms and asthma medication use in people with asthma. The evaluation follows with a consideration of the effects of short-term exposure to $PM_{2.5}$ on lung function, which may indicate airway obstruction and poorer control of asthma. The last section describes the evidence for subclinical effects such as pulmonary inflammation and oxidative stress resulting from short-term exposure to $PM_{2.5}$.

In addition to examining the relationship between short-term $PM_{2.5}$ exposure and asthma exacerbation, some epidemiologic studies often conduct analyses to assess whether the associations observed are due to chance, confounding, or other biases. As such, this evidence across epidemiologic studies is not discussed within this section, but evaluated in an integrative manner and focuses specifically on those analyses that address policy-relevant issues (Section 5.1.10), and includes evaluations of copollutant confounding (Section 5.1.10.1), model specification (Section 0), lag structure (Section 5.1.10.3), the role of season and temperature on $PM_{2.5}$ associations (Section 5.1.10.4), averaging time of $PM_{2.5}$ concentrations (Section 5.1.10.5), and concentration-response (C-R) and threshold analyses (Section 5.1.10.6). The studies that inform these issues and evaluated within these sections are primarily epidemiologic studies that conducted time-series or case-crossover analyses examining asthma hospital admissions and ED visits.

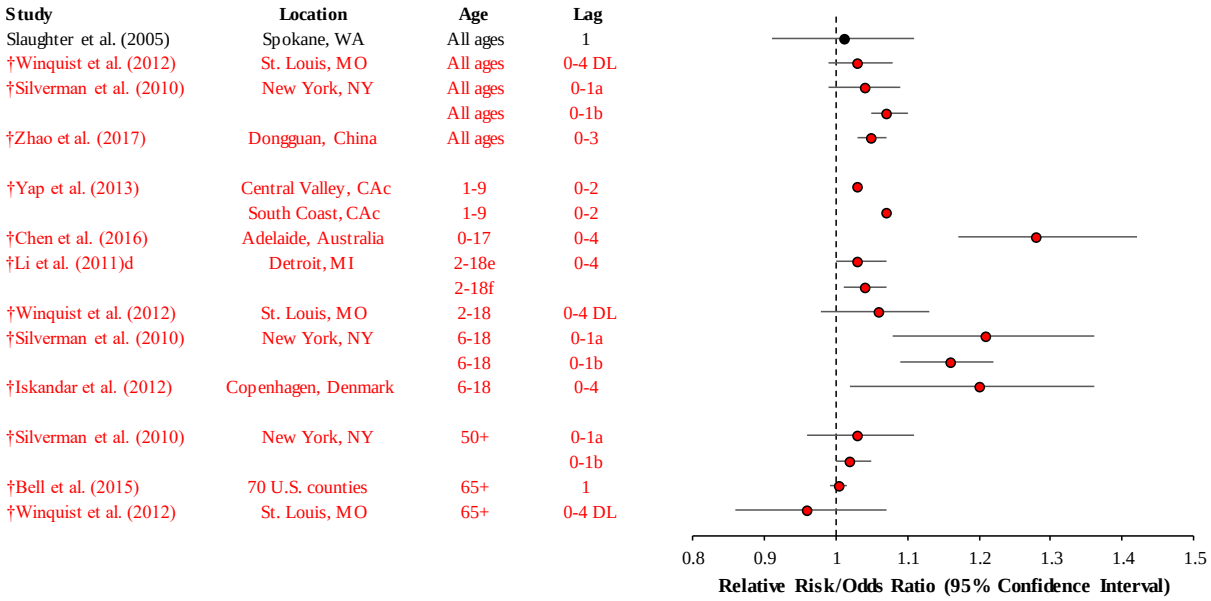
5.1.2.1 Hospital Admissions and Emergency Department (ED) Visits

The 2009 PM ISA reported inconsistent evidence of associations between short-term increases in $PM_{2.5}$ concentration and hospital admissions and ED visits for asthma in children, but generally consistent positive associations in studies focusing on adults and people of all ages combined (U.S. EPA, 2009). However, the evaluation of results from studies conducted in populations of children is complicated by the difficulty in reliably diagnosing asthma in children <5 years of age because young children often have transient wheeze (NAEPP, 2007). The inclusion of children <5 years of age may add some uncertainty to the results of studies focusing on all children, but the few studies that presented results in children older than 5 years did indicate $PM_{2.5}$-associated increases in asthma hospital admissions and ED visits. The examination of potential copollutant confounding was not thoroughly considered by the studies evaluated in the 2009 PM ISA but provided some evidence that $PM_{2.5}$-asthma hospital admission and ED visit associations are robust to the inclusion of gaseous pollutants in copollutant models. Across studies, associations were observed for a range of lags, with evidence that risk estimates for asthma hospital admissions and ED visits increased in magnitude for longer or cumulative lags.

Asthma hospital admissions and ED visit studies are evaluated separately because only a small percentage of asthma ED visits result in a hospital admission. As a result, asthma ED visits may represent less severe outcomes compared to asthma hospital admissions. For each of the studies evaluated in this

section, Table 5-1 presents the air quality characteristics of each city, or across all cities, the exposure assignment approach used, and information on copollutants examined in each asthma hospital admission and ED visit study. Other recent studies of asthma hospital admissions and ED visits are not the focus of this evaluation because they did not address uncertainties and limitations in the evidence previously identified, and therefore, do not directly inform the discussion of policy-relevant considerations detailed in Section 5.1.10. Additionally, many of these studies were conducted in small single cities, encompassed a short study duration, or had insufficient sample size. The full list of these studies can be found here: (https:/hero.epa.gov/hero/particulate-matter).

Recent studies expand the evidence base from the 2009 PM ISA (U.S. EPA, 2009) with respect to the evaluation of asthma hospital admissions and further reinforce the results reported in studies that examined asthma ED visits. As summarized in Figure 5-2- and Figure 5-3, both studies of hospital admissions and ED visits report evidence of consistent positive associations when examining children and people of all ages, with inconsistent evidence of associations with short-term $PM_{2.5}$ exposure for older adults (i.e., generally >65 years of age). These results are further supported by meta-analyses that include studies reviewed in and published since the 2009 PM ISA (Fan et al., 2015; Zheng et al., 2015). The results from asthma hospital admission and ED visit studies are supported by a study focusing on asthma physician visits in Atlanta, for the initial time period of the study, but this pattern of associations was not observed for the later time period (Sinclair et al., 2010). However, it is important to note that the severity of a $PM_{2.5}$-related asthma exacerbation, personal behavior such as delaying a visit to the doctor for less severe symptoms, and insurance type (i.e., physician visits which often are ascertained for members of a managed care organization) may dictate whether an individual visits the doctor or a hospital, making it difficult to readily compare results between studies focusing on physician visits versus hospital admissions and ED visits.



Note: †Studies published since the 2009 PM ISA. Black text = U.S. and Canadian studies included in the 2009 PM ISA. a = Intensive Care Unit (ICU) hospital admissions; b = non-ICU hospital admissions; c = values of confidence intervals not reported, but above the null; d = combination of hospital admissions and ED visits; e = time-series model results; f = case-crossover model results. Corresponding quantitative results are reported in Supplemental Material (U.S. EPA, 2018).

5.1.2.1.1 Hospital Admissions

Across recent studies, evidence supports an association between short-term $PM_{2.5}$ exposure and asthma hospital admissions, particularly in analyses of children and people of all ages (Figure 5-2). This evidence is supported by studies that examined associations with $PM_{2.5}$ within a state, across multiple cities, or individual cities. In 12 California counties encompassing the south coast and central valley, Yap et al. (2013) focused on examining the influence of socioeconomic status (SES) on hospital admissions for pediatric (children ages 1 to 9 years) respiratory conditions associated with $PM_{2.5}$ exposure (CHAPTER 12). For childhood asthma hospital admissions, the authors reported positive associations across each individual city with varying width of confidence intervals, resulting in relative risks for south coast and central valley combined ranging from 1.03−1.07 at lag 0−2 days. While Yap et al. (2013) reported evidence of positive associations in children, Bell et al. (2015) in a study of 213 U.S. counties focusing on older adults (i.e., ≥65 years of age), 70 of which had asthma data, did not observe an increase in asthma hospital admissions (RR = 1.00 [95% CI: 0.99, 1.01]; lag 1), but the authors only examined single-day lags.

Additional single-city studies conducted in the U.S., Canada, and internationally further examined associations between short-term $PM_{2.5}$ exposure and asthma hospital admissions in different age groups (i.e., people of all ages, children, and older adults). In New York City, Silverman and Ito (2010) focused on asthma hospital admissions consisting of severe episodes that required a stay in the intensive care unit (ICU) and those that did not (non-ICU) across several different age ranges. Due to the focus on both $PM_{2.5}$ and O_3, the study authors limited analyses to the warm season (April−August). The authors examined people of all ages as well as children and adults. An increased risk for total asthma hospital admissions (combined ICU and non-ICU) for children 6−18 years of age was reported for $PM_{2.5}$ (RR = 1.16 [95% CI: 1.10, 1.22]; lag 0−1). An elevated risk due to $PM_{2.5}$ exposure was also evident when examining both ICU and non-ICU admissions for children 6−18 years of age (Figure 5-2). Results similar in magnitude were observed for both children and people of all ages, with associations smaller in magnitude and with wider confidence intervals for ages 50 and older. The results of Silverman and Ito (2010) are consistent with a study conducted by Winquist et al. (2012) in St. Louis, MO that also examined associations across several age ranges. Winquist et al. (2012), reported the strongest evidence of an association when examining people of all ages and children 2−18 years of age, with no evidence of an association for older adults (Figure 5-2). Kim et al. (2012) in a study in Denver, CO examined a longer lag structure, a 14-day distributed lag model, and reported evidence of a positive association between short-term $PM_{2.5}$ exposure and asthma hospital admissions for people of all ages (quantitative results not presented). However, Liu et al. (2016) in a study conducted in the greater Houston area, did not report evidence of an association with $PM_{2.5}$ and unscheduled hospital admissions (quantitative results not presented). It is important to note that the population examined in Liu et al. (2016) consisted of individuals with private insurance, which differs from the other studies evaluated in this section that did

not differentiate amongst insurance coverage when identifying hospital admissions; therefore, the results may not be comparable.

Studies that examined several age ranges tended to indicate stronger associations, in both magnitude and precision, for children. Additional studies focusing only on children provide supporting evidence for associations between short-term $PM_{2.5}$ exposure and asthma hospital admissions. Li et al. (2011) in Detroit, MI; Chen et al. (2016) in Adelaide, Australia; and Iskandar et al. (2012) in Copenhagen, Denmark all reported evidence of positive associations at lag 0−4 days (Figure 5-2).

5.1.2.1.2 Emergency Department (ED) Visits

Similar to hospital admission studies, recent ED visit studies provide evidence of generally consistent positive associations with short-term $PM_{2.5}$ exposures, particularly when examining children and people of all ages (Figure 5-3). However, compared to the hospital admission studies, the magnitude of the association tends to be smaller for ED visits. The evidence supporting an association between short-term $PM_{2.5}$ exposure and asthma ED visits is derived from studies conducted over an entire state, across multiple cities, or in individual cities. Additional studies focusing on exposure-related issues, such as exposure assignment (Sarnat et al., 2013b; Strickland et al., 2011) and air exchange rates (Sarnat et al., 2013a), have also focused on examining the relationship between short-term $PM_{2.5}$ exposure and asthma ED visits. They provide additional supporting evidence, but are characterized in CHAPTER 3 (Section 3.3.2.1 and Section 3.3.2.4.2).

Both Malig et al. (2013) and Ostro et al. (2016) in multilocation studies conducted in California that focused on people of all ages, 35 counties and 8 metropolitan areas, respectively, provided evidence of positive associations at lag 0. Ostro et al. (2016) reported an OR = 1.01 (95% CI: 1.00, 1.02), and Malig et al. (2013) reported an OR = 1.02 (95% CI: 1.01, 1.03). These results are consistent with Weichenthal et al. (2016) in a study that encompassed Ontario, Canada that also reported a positive association with asthma ED visits for people of all ages but encompassed a multiday lag of 0−2 days. Krall et al. (2016) in a study of four U.S. cities (i.e., Atlanta, GA; Birmingham, AL; St. Louis, MO; and Dallas, TX) that primarily focused on $PM_{2.5}$ sources also reported positive associations with asthma/wheeze ED visits in city-specific analyses for people of all ages at lag 3 (quantitative results not presented). Additional evidence from single-city studies conducted in St. Louis, MO (Sarnat et al., 2015; Winquist et al., 2012) and Seoul, South Korea (Kim et al., 2015) report associations similar in magnitude to the multilocation studies, but with wider confidence intervals (Figure 5-3). However, Byers et al. (2015) did not report evidence of an association for asthma hospital admissions for people of all ages in a study conducted in Indianapolis, IN (RR = 0.99 [95% CI: 0.98, 1.01]; lag 0−2).

While a few of the studies that conducted analyses focusing on people of all ages also include analyses focusing on other age ranges including children (Byers et al., 2015; Winquist et al., 2012), several recent studies focus exclusively on the relationship between short-term $PM_{2.5}$ exposure and

asthma ED visits in children. Both Winquist et al. (2012) and Byers et al. (2015) reported associations larger in magnitude in children compared to people of all ages combined in St. Louis, MO (RR = 1.05 [95% CI: 1.02, 1.09]; lag 0−4) and Indianapolis, IN (RR = 1.01 [95% CI: 0.98, 1.05]; lag 0−2), respectively. The results of Winquist et al. (2012) and Byers et al. (2015) are consistent with single-city (Strickland et al., 2010) and whole state (Xiao et al., 2016; Gleason and Fagliano, 2015; Strickland et al., 2015) analyses that focused on pediatric asthma ED visits (Figure 5-3), with ORs and RRs across studies ranging from 1.01−1.05. An additional multicity study encompassing three U.S. cities (i.e., Atlanta, GA, St. Louis, MO; and Dallas, TX), which also examined associations in older adults, provides additional support for the associations observed in other recent studies focusing on children (RR = 1.03 [95% CI: 1.01, 1.05]; lag 0−2) (Alhanti et al., 2016).

Most of studies that examined the association between short-term $PM_{2.5}$ exposure and asthma ED visits focused on analyses for people of all ages and/or children, with a more limited number of studies examining potential $PM_{2.5}$ effects in adults and older adults (Alhanti et al., 2016; Byers et al., 2015; Winquist et al., 2012). Both Byers et al. (2015) in Indianapolis, IN and Winquist et al. (2012) in St. Louis, MO reported evidence of a null association with asthma ED visits in adults 45 and older, and 65 and older, respectively (Figure 5-3). However, Alhanti et al. (2016) in three U.S. cities reported a RR = 1.03 (95% CI: 0.99, 1.06) at lag 0−2. Although Alhanti et al. (2016) included St. Louis, MO in the three U.S. cities examined, when examining city-specific results, the overall association is heavily influenced by Atlanta, GA with the St. Louis, MO result being consistent with that reported in Winquist et al. (2012).

5.1.2.1.3 Summary of Asthma Hospital Admissions and Emergency Department (ED) Visits

Building off the evidence detailed in the 2009 PM ISA (U.S. EPA, 2009), recent epidemiologic studies strengthen the evidence for a relationship between short-term $PM_{2.5}$ exposure and asthma-related hospital admissions and between short-term $PM_{2.5}$ exposure and ED visits in analyses of children and people of all ages. Evidence for a relationship in older adults continues to be inconsistent. The main results of studies detailed within this section are supported by analyses that examined specific policy-relevant issues as detailed in Section 5.1.10. Specifically, analyses of potential copollutant confounding provide evidence that $PM_{2.5}$ associations are relatively unchanged in models with gaseous pollutants and $PM_{10–2.5}$, but the evidence is more limited for $PM_{10–2.5}$ (Section 5.1.10). Although in some instances the results from copollutant models are attenuated, they remain positive overall. The associations observed across studies were found to be robust in sensitivity analyses that examined alternative model specifications to account for temporal trends as well as the potential confounding effects of weather.

Additionally, the overall body of evidence indicating a relationship between short-term $PM_{2.5}$ exposure and asthma hospital admissions and ED visits is supported by studies that conducted analyses to further elucidate this relationship. Across studies that examined whether there was evidence of seasonal

patterns, studies that divided the year into warm and cold season reported associations larger in magnitude for the warmer months. These results are supported by studies that examined all four seasons of the year, but they also indicate that effects may be strongest over more defined periods of the year (i.e., the spring) (Section 5.1.10.4.1). Additionally, examinations of the concentration-response (C-R) relationship provide some evidence for a linear relationship for short-term $PM_{2.5}$ exposure and asthma hospital admissions and ED visits. However, complicating the interpretation of these results is both the lack of thorough empirical evaluations of alternatives to linearity as well as the results from cutpoint analyses that provide some potential indication for nonlinearity in the relationship between short-term $PM_{2.5}$ exposure and asthma hospital admission and ED visits (Section 5.1.10.6).

5.1.2.2 Respiratory Symptoms and Asthma Medication Use in Populations with Asthma

Studies evaluating the effects of short-term $PM_{2.5}$ exposure on respiratory symptoms and asthma medication use consisted solely of epidemiologic studies. Results will be discussed separately for children with asthma and for adults with asthma.

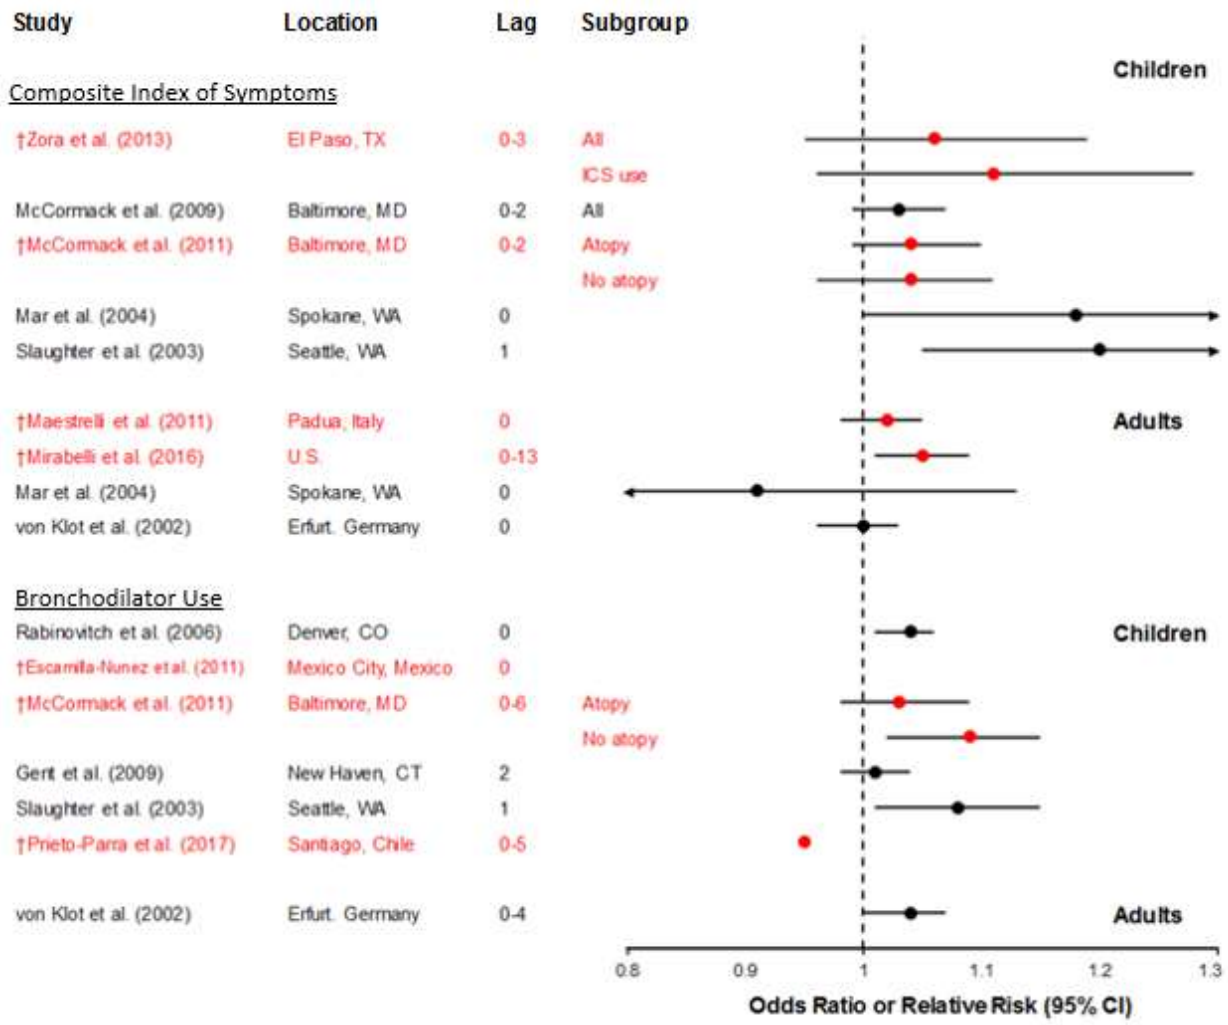
Children

Uncontrollable respiratory symptoms, such as cough, wheeze, sputum production, shortness of breath, and chest tightness, can lead people with asthma to seek medical care. Thus, along with medication use in children, studies examining the relation between $PM_{2.5}$ and increases in asthma symptoms may provide support for the observed increases in asthma hospital admissions and ED visits in children, as discussed in Section 5.1.2.1. A limited number of panel studies reviewed in the 2009 PM ISA (U.S. EPA, 2009) provide evidence of an association between $PM_{2.5}$ and respiratory symptoms (Mar et al., 2004; Gent et al., 2003; Slaughter et al., 2003) and medication use (Gent et al., 2009; Rabinovitch et al., 2006; Slaughter et al., 2003) in children with asthma. In studies that examined copollutant confounding, associations between $PM_{2.5}$ and asthma severity were robust to the inclusion of CO in a copollutant model (Slaughter et al., 2003), while $PM_{2.5}$ associations with persistent cough, chest tightness, and shortness of breath no longer persisted in models adjusting for O_3 (Gent et al., 2003).

A few recent studies provide some additional evidence of an association between $PM_{2.5}$ and a composite index of multiple symptoms (Figure 5-4). In a panel study including 90 schoolchildren with asthma in Santiago, Chile, $PM_{2.5}$ concentrations were associated with increases in coughing and wheezing, as well as a composite index of respiratory symptoms (Prieto-Parra et al., 2017). The observed associations were strongest in magnitude for 7-day average $PM_{2.5}$. Similarly, among children at two schools in El Paso, TX, 5-day average $PM_{2.5}$ concentrations measured outside of the schools were associated with poorer asthma control scores, which reflect symptoms and activity levels (Zora et al., 2013). The two schools included in the study differed in nearby traffic levels but varied similarly in

outdoor $PM_{2.5}$ concentration over time (Section 3.4.3.1). In contrast, students attending schools with varying nearby traffic levels were also examined in the Bronx, NY, though asthma symptoms were not associated with outdoor school or total personal $PM_{2.5}$ concentrations (Spira-Cohen et al., 2011). A low correlation between school and personal $PM_{2.5}$ concentrations (r = 0.17) and a reportedly high proportion of time spent indoors (89%), suggests that personal $PM_{2.5}$ exposure was largely influenced by indoor rather than ambient sources. In an additional study related to respiratory symptoms, asthma-related school absence was associated with 19-day average $PM_{2.5}$ concentrations in a U.S. multicity study (O'Connor et al., 2008). Notably, confounding by meteorological factors is difficult to control with long averaging times. Study-specific details, including cohort descriptions and air quality characteristics are highlighted in Table 5-2.

In addition to respiratory symptoms, recent studies of medication use in children add to the limited evidence base, providing some additional evidence of $PM_{2.5}$-associated increases in the use of bronchodilators, which can provide quick relief from asthma symptoms (Figure 5-4). Panel studies of schoolchildren with asthma in Denver, CO (Rabinovitch et al., 2011) and Mexico City (Escamilla-Nuñez et al., 2008) observed associations between $PM_{2.5}$ concentrations and bronchodilator use. Escamilla-Nuñez et al. (2008) reported comparable associations using lag 0 and 5-day average $PM_{2.5}$, while Rabinovitch et al. (2011) observed associations that were stronger in magnitude when estimated using 2-day moving average $PM_{2.5}$ compared to single-day lags. In contrast, $PM_{2.5}$ concentrations were associated with decreased bronchodilator use in a panel study in Santiago, Chile (Prieto-Parra et al., 2017).



Note: †Studies published since the 2009 PM ISA. Studies in black were included in the 2009 PM ISA. Effect estimates are standardized to a 10 μg/m^3 increase in 24-hour average $PM_{2.5}$. CI = confidence interval, ICS = inhaled corticosteroid. Lag times reported in days. Corresponding quantitative results are reported in Supplemental Material (U.S. EPA, 2018).

†Studies published since the 2009 PM ISA.

Recent evidence of associations from studies that measured $PM_{2.5}$ concentrations outside of children's schools, representing exposure where children spend a large part of their day, increases confidence in the associations observed. Additionally, recruitment mostly occurred at schools; thus, the study populations were likely representative of the general population of children with asthma. The representativeness of results is also supported by the high follow-up participation rates (79–95%; Table 5-2). Meanwhile, potential copollutant confounding remains a source of uncertainty given the lack of studies that report copollutant models. In limited copollutant results described in the 2009 PM ISA (U.S. EPA, 2009), $PM_{2.5}$ associations appeared robust to adjustments for CO, but not O_3, despite high copollutant correlation ($r > 0.7$) (Gent et al., 2003; Slaughter et al., 2003). Recent studies show moderate correlations ($0.4 < r < 0.7$) for $PM_{2.5}$ with O_3 and NO_2 (Table 5-2), though only a single study presented copollutant models. The association between $PM_{2.5}$ and asthma control in schoolchildren was attenuated but still positive with adjustment for NO_2, O_3, benzene, or toluene, which were all weakly to moderately correlated ($r < 0.5$) with $PM_{2.5}$ (Zora et al., 2013). Further discussion of copollutant confounding is provided in Section 5.1.10.1.

Adults

Studies evaluated in the 2009 PM ISA (U.S. EPA, 2009) reported inconsistent evidence of an association between $PM_{2.5}$ and respiratory symptoms and medication use in adults with asthma. Recent studies provide limited evidence of association between $PM_{2.5}$ and respiratory symptoms or markers for medication use in adults with asthma (Figure 5-4). A U.S.-wide cross-sectional analysis indicates increases in any asthma symptom with increases in county-average $PM_{2.5}$ concentrations modeled by CMAQ (Mirabelli et al., 2016). Analysis of the concentration-response relationship isolates the association to lower concentrations, ranging from 4.0 to 7.1 $\mu g/m^3$. However, this study is limited by its cross-sectional design, and residual confounding may arise from the 14-day $PM_{2.5}$ averaging time and lack of consideration of confounding by community-level SES. A recent study in Milan, Italy measured levels of the beta-agonist salbutamol in untreated wastewater samples to estimate the daily population-level use of short-acting beta-antagonists (Fattore et al., 2016). Single-day $PM_{2.5}$ lags, ranging from 0 to 10 days, were associated with increases in daily defined doses of short-acting beta-antagonists, with associations that were strongest in magnitude at lags 7 and 8 (RR = 1.07 [95% CI: 1.02, 1.12]). The validity and reliability of wastewater levels of medication as an indicator for medication use is untested, but previous results show increases in self-reported beta-agonist and ICS use with increases in $PM_{2.5}$ concentrations averaged over 5 days (von Klot et al., 2002). Other recent studies of associations between personal exposure to $PM_{2.5}$ and respiratory symptoms, examined in aggregate or individually, are limited by simple correlation analyses on observations (Larsson et al., 2010) or by temporal mismatch between 2-day $PM_{2.5}$ exposure and 4-week symptom interval (Maestrelli et al., 2011).

5.1.2.3 Lung Function Changes in Populations with Asthma

Studies evaluating the effects of short-term $PM_{2.5}$ exposure on lung function consisted solely of epidemiologic studies. Results will be discussed separately for children with asthma and for adults with asthma. Some studies in adults employed scripted exposures to further inform the relationship between short-term $PM_{2.5}$ exposure and lung function. Scripted studies measuring personal ambient $PM_{2.5}$ exposures are designed to minimize uncertainty in the $PM_{2.5}$ exposure metric by always measuring $PM_{2.5}$ at the site of exposure, ensuring exposure to sources of $PM_{2.5}$ and measuring outcomes at well-defined lags after exposure.

Children

Lung function metrics can indicate airway obstruction, which is the defining characteristic of asthma. Further, specific lung function metrics, such as FEV_1, have been shown to have prognostic value for asthma exacerbation (Pijnenburg et al., 2015), such that $PM_{2.5}$-related decrements in lung function may provide support for the observed increases in asthma hospital admissions and ED visits in children, as discussed in Section 5.1.2.1. In the 2009 PM ISA (U.S. EPA, 2009), several panel studies of children with asthma provide generally consistent evidence of an association between short-term $PM_{2.5}$ concentrations and decreased FEV_1. $PM_{2.5}$ exposure in particular microenvironments was also associated with lung function decrements in studies examined in the 2009 PM ISA. In Seattle, decrements in some measures of lung function (PEF, MEF, FEV_1) were associated with $PM_{2.5}$ concentrations (Allen et al., 2008; Trenga et al., 2006). Based on the ratio of personal to ambient sulfur concentrations, total personal $PM_{2.5}$ exposure was partitioned into ambient-generated and nonambient-generated fractions. Only the ambient-generated $PM_{2.5}$ was associated with lung function decrements (FEV_1, PEF, MEF) (Allen et al., 2008). $PM_{2.5}$ concentrations at fixed-site monitors were associated with larger decrements in FEV_1 among children with asthma in Denver, CO after adjusting for an estimate of the ambient-generated portion based on the ratio of personal to ambient sulfur concentrations (Strand et al., 2006). Notably, there was a lack of studies that examined potential confounding by copollutants, raising uncertainties about the independence of the observed associations.

Several recent studies continue to provide evidence of an association between short-term $PM_{2.5}$ exposure and FEV_1 decrements in children with asthma. As in studies of respiratory symptoms in children with asthma (Section 5.1.2.2), lung function studies followed children with asthma in an array of cities in the U.S., Canada, and Asia (Table 5-3) that are similar to the locations of studies that examined asthma hospital admissions and ED visits (Section 5.1.2.1). In Riverside and Whittier, CA, personal $PM_{2.5}$ and monitor $PM_{2.5}$ concentrations were associated with decreased FEV_1 (Delfino et al., 2008). Associations were strongest in magnitude for personal $PM_{2.5}$ exposures, particularly those for 1 and 8-hour max concentrations, suggesting that peak exposures in a certain microenvironment may have increased relevance to lung function. Similarly, among children attending two schools with varying nearby traffic levels in the Bronx, NY, Spira-Cohen et al. (2011) reported decrements in FEV_1 in relation to personal

$PM_{2.5}$ concentrations averaged in the 12 hours prior to spirometry. The authors did not observe a similar association with $PM_{2.5}$ exposure estimated from monitors outside of the schools. In Windsor, Canada, in another panel of schoolchildren with asthma, Dales et al. (2009) observed associations between 24-hour average $PM_{2.5}$ concentrations and nighttime FEV_1 decrements, as well as 12-hour average $PM_{2.5}$ and diurnal FEV_1. $PM_{2.5}$ exposure was estimated from a city monitor, though most panel subjects reportedly lived within 10 km downwind of the monitor. In contrast with evidence of a relationship between FEV_1 and short-term exposure to $PM_{2.5}$, Smargiassi et al. (2014) reported that lung function was not associated with personal $PM_{2.5}$ in a panel study following 72 children with asthma for 10 consecutive days in Montreal, Canada.

Within studies that compared multiple exposure assignment methods, FEV_1 decrements were larger in relation to $PM_{2.5}$ exposure estimated from personal samplers compared to fixed-site monitors (Spira-Cohen et al., 2011; Delfino et al., 2008). This is generally consistent with evidence from the 2009 PM ISA (U.S. EPA, 2009) and potentially indicates reduced exposure measurement error in the personal exposure measures. The errors and uncertainties related to various exposure assignment methods (Section 3.3.5), and the relation between personal and ambient concentrations (Section 3.4.1.3) are discussed in further detail in CHAPTER 3. These results for personal exposure also provide some indication that $PM_{2.5}$ exposure in microenvironments may have an independent effect on lung function. However, uncertainties remain regarding the independent effect of $PM_{2.5}$ given the limited number of studies that examine potential copollutant confounding and the general limitations of copollutant models. A single recent study examined copollutant models, reporting diurnal and nighttime FEV_1 associations with $PM_{2.5}$ that were robust to adjustment for O_3 (Dales et al., 2009). Nighttime FEV_1 associations were also generally unchanged in models including NO_2 or SO_2, while diurnal FEV_1 decrements were attenuated, but still negative. Notably, the correlation between $PM_{2.5}$ and O_3 (r = 0.26) was much lower than $PM_{2.5}$-NO_2 (r = 0.68) and $PM_{2.5}$-SO_2 (r = 0.43) correlations. Further discussion of copollutant confounding is provided in Section 5.1.10.1.

A few recent studies also examine other lung function metrics. In the study of schoolchildren in New York, discussed previously, Spira-Cohen et al. (2011) observed an association between 12-hour average personal $PM_{2.5}$ exposure and PEF decrements. As with the examination of FEV_1, the authors did not observe an association with $PM_{2.5}$ at school-site monitors. In a panel study of children receiving long-term in-hospital care in Yotsukaido, Japan, $PM_{2.5}$ concentrations averaged over the 24 hours prior to spirometry were associated with both morning and evening PEF decrements (Yamazaki et al., 2011). Given the severity of asthma in this population, the results might not be applicable to the general population with asthma. PEF decrements were also associated with 24-hour average $PM_{2.5}$ concentrations in a panel of schoolchildren in Seoul, South Korea (Hong et al., 2010). While the authors examined several single-day lags, ranging from 0 to 4 days, they only observed an association at lag 0. As discussed previously, Smargiassi et al. (2014) reported that personal $PM_{2.5}$ exposure was not related to an array of lung function metrics, including FVC and $FEF_{25–75\%}$.

In summary, recent studies add to the existing evidence linking short-term $PM_{2.5}$ exposure to decrements in FEV_1 in children with asthma. While the previously existing evidence base for $PM_{2.5}$-related decrements in PEF is less consistent than that for FEV_1, a few recent studies provide generally consistent evidence indicating an association. Importantly, uncertainty regarding potential copollutant confounding remains.

†Studies published since the 2009 PM ISA.

1

Adults

A single study evaluated in the 2009 PM ISA (U.S. EPA, 2009) examined the association between short-term exposure to $PM_{2.5}$ and lung function in adults with asthma. In a panel of 60 adults with asthma in London, average $PM_{2.5}$ concentrations measured over a 2-hour outdoor walk was associated with decrements in FEV_1 and $MMEF_{25–75\%}$, but not FVC (McCreanor et al., 2007). Studies published since the completion of the 2009 PM ISA have been limited in number and results are inconsistent. Mirabelli et al. (2015) studied adults with asthma in Atlanta and reported decreased FEV_1 associated with 2-hour average personal $PM_{2.5}$ exposure measured 3 hours prior to spirometry. $PM_{2.5}$ concentrations were measured during scripted commutes through rush hour traffic, resulting in higher exposure levels. The observed associations were stronger in magnitude and more precise in participants with poorly controlled asthma. In contrast, in Padua, Italy, Maestrelli et al. (2011) tested the relationship between FEV_1 and 24-hour average personal $PM_{2.5}$ exposure the day before spirometry and reported no association in adults with asthma. This study was limited by a design that designated six single-day examination visits across a 2-year period, precluding the opportunity to examine alternative exposure lags. Additionally, low variability in personal $PM_{2.5}$ measurements may have contributed to the lack of an observed association.

5.1.2.3.1 Controlled Human Exposure Studies

Individuals with pre-existing airway diseases such as asthma, may suffer increased deleterious health effects from exposure to PM compared with individuals without pre-existing airway disease. Increased susceptibility of a $PM_{2.5}$-related health effect may be associated with specific mechanisms known to underlie the pathology of asthma, namely elevated inflammation and altered immune activity. However, there is little evidence from studies evaluated in the 2009 PM ISA (U.S. EPA, 2009) that exposure to $PM_{2.5}$ results in decrements in lung function in individuals with asthma. Although a study evaluated in the 2009 PM ISA Petrovic et al. (2000) observed that a 2-hour exposure to $PM_{2.5}$ CAPs (92 $\mu g/m^3$) resulted in decreases in thoracic gas volume in healthy volunteers, other measures of lung function (spirometry, diffusing capacity, airway resistance) were unaffected. This general lack of effect of $PM_{2.5}$ exposure on lung function has also been shown in a study investigating the exposure of individuals with asthma to $PM_{2.5}$ CAPs (Gong et al., 2003). A recent study examining the respiratory effects of $PM_{2.5}$ on individuals with asthma has been conducted by (Urch et al., 2010) using a CAP facility for $PM_{2.5}$ located in downtown Toronto, Canada (study details in Table 5-4). Exposure to either $PM_{2.5}$ CAPs alone or in addition to O_3 was not observed to affect any measurement of pulmonary function, breathing parameters (tidal volume, breathing frequency, minute ventilation), or airway responsiveness (PC20), compared to filtered air control exposures. The lack of effect of $PM_{2.5}$ CAPs on respiratory function observed in Urch et al. (2010) is consistent with the results of previous controlled human exposure studies in which worsening of pulmonary function was not observed.

Table 5-4 Study-specific details from a controlled human exposure study of short-term $PM_{2.5}$ exposure and lung function in individuals with asthma.

Study	Study Design	Disease Status; n; Sex	Exposure Details (Concentration; Duration; Comparison Group	Endpoints Measured
Urch et al. (2010)	Blinded randomized block design	Healthy nonsmokers (13) and individuals with asthma (10); n = 23; 11 M, 12 F	$PM_{2.5}$ CAPs only: 64 ± 3 or 140 ± 6 μg/m^3 $PM_{2.5}$ CAPs + O_3: 68 ± 5 or 142 ± 7 μg/m^3 $PM_{2.5}$ + 119 ± 1 ppb O_3 Comparison group for both groups was filtered air; all exposures were for 2 h carried out at rest	Spirometry (pre-, 10-min, and 20-h post-exposure): Flow-volume, DLCO, MV, VT

CAPs = concentrated ambient particles; DLCO = diffusion capacity for CO; MV = minute volume; VT = tidal volume.

5.1.2.3.2 Animal Toxicological Studies

The 2009 ISA for PM (U.S. EPA, 2009) evaluated a limited number of inhalation studies examining pulmonary function in animal models of allergic airway disease, which share phenotypic features with asthma in humans. One study reported increased airway responsiveness to methacholine, as indicated by Penh, following short-term exposure to DE. However, this study did not distinguish between effects due to particles and gases in the mixture. No additional studies have become available since that time. In many animal studies, changes in ventilatory patterns are assessed using whole-body plethysmography, for which measurements are reported as Penh. Some investigators consider Penh solely an indicator of altered ventilatory timing (see Section 5.1.7.4) in the absence of other measurements to confirm changes in airway responsiveness.

5.1.2.3.3 Summary of Lung Function in Populations with Asthma

Overall, panel studies in children with asthma find generally consistent evidence of associations between short-term $PM_{2.5}$ exposure and lung function decrements. However, uncertainty regarding potential copollutant confounding remains. Evidence is more limited and less consistent in panel studies involving adults with asthma. Further, several controlled human exposure studies failed to observe lung function decrements in adults with asthma following short-term $PM_{2.5}$ exposure. No studies have examined this endpoint in animal models of allergic disease, which share many phenotypic features with asthma in humans.

5.1.2.4 Subclinical Effects Underlying Asthma Exacerbation

Studies evaluating the effects of short-term $PM_{2.5}$ exposure on subclinical effects consisted solely of epidemiologic studies. Results are discussed separately for children with asthma and adults with asthma. Some studies in adults employed scripted exposures to further inform this relationship. Scripted studies measuring personal ambient $PM_{2.5}$ exposures are designed to minimize uncertainty in the $PM_{2.5}$ exposure metric by always measuring $PM_{2.5}$ at the site of exposure, ensuring exposure to sources of $PM_{2.5}$ and measuring outcomes at well-defined lags after exposure.

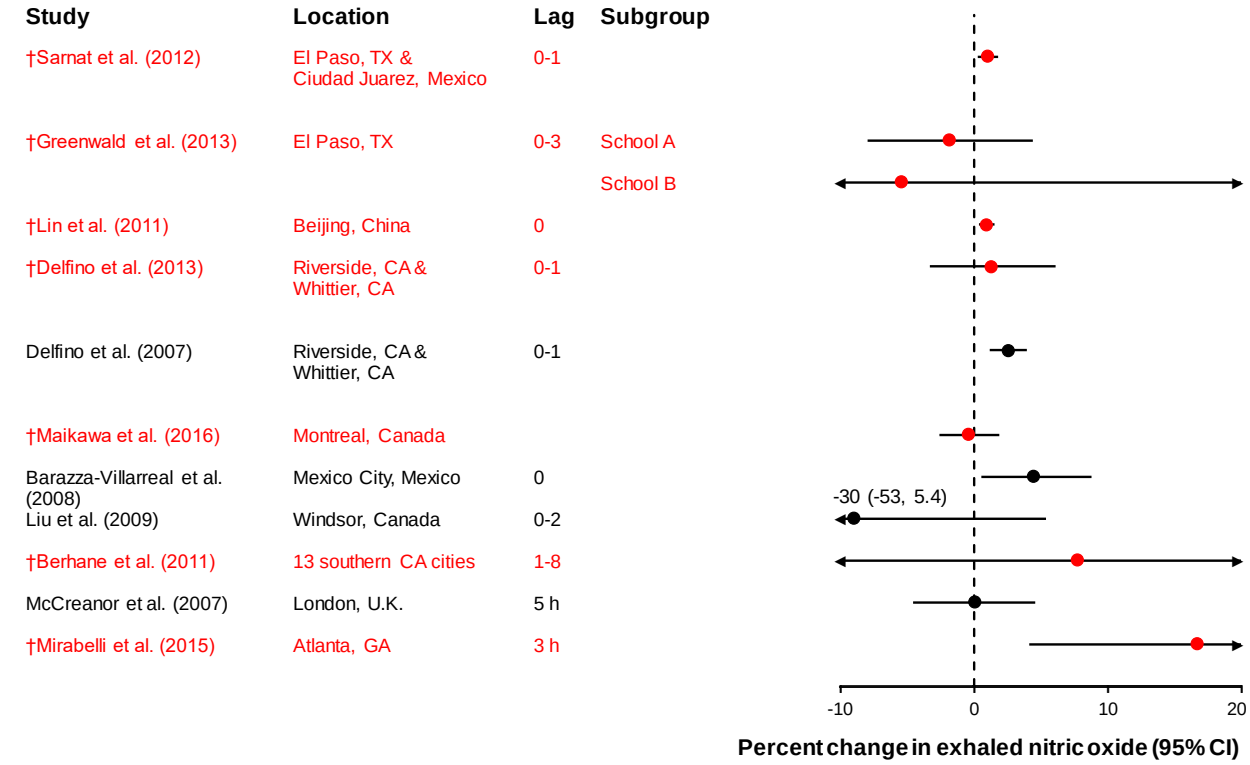
Children

Evidence described in the preceding sections for $PM_{2.5}$-related increases in asthma hospital admissions, asthma ED visits, and respiratory symptoms and lung function in children with asthma indicates a potential link between $PM_{2.5}$ exposure and asthma exacerbation. The 2009 PM ISA (U.S. EPA, 2009) also described generally consistent epidemiologic evidence linking increases in pulmonary inflammation in children with asthma to short-term personal $PM_{2.5}$ exposure and ambient $PM_{2.5}$ concentrations. Most studies examined exhaled nitric oxide (eNO) as an indicator of pulmonary inflammation. The relevance of eNO to asthma exacerbation is well supported. Levels of eNO have been associated with eosinophil counts (Brody et al., 2013), which mediate inflammation in allergic asthma. Further, eNO is higher in people with asthma and increases during acute exacerbation (Soto-Ramos et al., 2013; Kharitonov and Barnes, 2000). In the U.S., associations between short-term $PM_{2.5}$ exposure and eNO were observed in panel studies of children with asthma in southern California (Delfino et al., 2006) and Seattle (Allen et al., 2008; Koenig et al., 2005). In Seattle, total personal $PM_{2.5}$ exposure was partitioned into ambient-generated and nonambient-generated fractions based on the ratio of personal to ambient sulfur concentrations. Only the ambient-generated $PM_{2.5}$ was associated with pulmonary inflammation (Allen et al., 2008). Associations were also observed in most (Liu et al., 2009; Murata et al., 2007; Fischer et al., 2002), but not all (Holguin et al., 2007), studies of children outside of the U.S.

Several recent studies provide less consistent evidence of an association between short-term $PM_{2.5}$ exposure and pulmonary inflammation in children with asthma (Figure 5-5). Study-specific details, including cohort descriptions and air quality characteristics are highlighted in Table 5-5. Among children at four schools in the neighboring cities of El Paso, TX and Ciudad Juarez, Mexico, eNO was associated with 48-hour average outdoor $PM_{2.5}$ (Sarnat et al., 2012). Notably, the observed association was largely driven by results from children in one school (Ciudad Juarez) with the highest mean $PM_{2.5}$ concentrations. While Sarnat et al. (2012) reported a small, imprecise association between 2-day average outdoor $PM_{2.5}$ concentration and eNO in El Paso, a follow-up study of children in the same schools in El Paso observed null associations for 4-day average outdoor $PM_{2.5}$ concentrations (Greenwald et al., 2013). Ambient $PM_{2.5}$ concentrations across the two studies were similar (Table 5-5). A reanalysis of Delfino et al. (2006) confirmed that eNO was not associated with $PM_{2.5}$ concentrations measured at fixed-site monitors within 12 km of subjects' residences in a panel study of children with asthma in southern California (Delfino et

al., 2013). However, Delfino et al. (2006) did report an association with personal $PM_{2.5}$ in the initial study. In contrast to evidence of an association between personal $PM_{2.5}$ exposure an eNO, Maikawa et al. (2016) observed a negative association between previous-day personal $PM_{2.5}$ exposures and eNO in 62 children with asthma in Montreal, Canada.

Other recent studies that used fixed-site monitors to estimate short-term $PM_{2.5}$ concentrations reported more consistent evidence of an association between $PM_{2.5}$ and pulmonary inflammation in children with asthma. Panel studies of children in Beijing, China (Lin et al., 2011) and southern California (Berhane et al., 2011) reported eNO associations with 24-hour average $PM_{2.5}$ concentrations on the same day of examination and 7-day average concentrations prior to examination, respectively. Additionally, a panel study of schoolchildren with asthma in Denver, CO (Rabinovitch et al., 2011) indicated a $PM_{2.5}$ association with increases in urinary leukotriene E4, a cytokine involved in inflammation that is found to increase during asthma exacerbation. Results were similar by asthma severity, but varied across years, with the $PM_{2.5}$-associated increases in urinary leukotriene E4 limited to 2 of the first 3 study years. Only some children overlapped across years, and $PM_{2.5}$ concentrations were slightly higher in Year 3 (Rabinovitch et al., 2011).



CI = confidence interval.

Note: Studies in red with a dagger are recent studies. Studies in black were included in the 2009 PM ISA. Effect estimates are standardized to a 10 μg/m^3 increase in 24-hour average $PM_{2.5}$. Lag times reported in days. Corresponding quantitative results are reported in Supplemental Material (U.S. EPA, 2018).

†Studies published since the 2009 PM ISA.

1

The inconsistency in recent findings, as related to the 2009 PM ISA, is not explained by lower $PM_{2.5}$ concentrations in recent studies (Table 5-5) but may be influenced by location-specific differences in PM sources, study populations, or building infiltration characteristics (Section 3.4). Studies evaluated in the 2009 PM ISA observed associations in locations representing a wide range of $PM_{2.5}$ concentrations. Additionally, a strength of previously reviewed studies of pulmonary inflammation is examination of the hourly lag structure of $PM_{2.5}$ associations. Most (Rabinovitch et al., 2006; Mar et al., 2005) results indicated an increase in inflammation with increases in $PM_{2.5}$ concentrations averaged over the preceding 1 to 11 hours. Associations were also observed with 1-hour or 8-hour max $PM_{2.5}$ that were larger in magnitude than those for 24-hour average $PM_{2.5}$ (Delfino et al., 2006; Rabinovitch et al., 2006). Other results indicate that $PM_{2.5}$ exposure may have a rapid and transient effect on pulmonary inflammation in people with asthma. For Seattle, WA and Riverside and Whittier, CA, distributed lag models show an increase in eNO with the 1-hour average $PM_{2.5}$ concentration up to 5 or 10 hours prior but not with longer lags of 24−48 hours (Delfino et al., 2006; Mar et al., 2005). This may suggest that some recent studies have examined exposure windows that were too long to detect an association, though Berhane et al. (2011) observed eNO associations with cumulative average $PM_{2.5}$ up to 30 days.

Additionally, recent studies of pulmonary inflammation do not establish an independent association with $PM_{2.5}$ exposure. A recent study presents $PM_{2.5}$ associations that are attenuated, but still positive in copollutant models with NO_2, SO_2, or CO (Lin et al., 2011). In a study evaluated in the 2009 PM ISA, personal $PM_{2.5}$ associations with eNO were robust to NO_2 adjustment (Delfino et al., 2006). The result for personal exposure supports an association with $PM_{2.5}$ that is independent of NO_2 exposure based on comparable exposure measurement error and low correlation (r = 0.30). However, the limited number of studies examining additional copollutants, in addition to some inconsistency in the observed associations in recent studies, leaves uncertainty as to whether $PM_{2.5}$ exposure leads to an increase in pulmonary inflammation in children with asthma. Further discussion of copollutant confounding is provided in Section 5.1.10.1.

Adults

Studies evaluated in the 2009 PM ISA (U.S. EPA, 2009) provided contrasting evidence of an association between short-term exposure to $PM_{2.5}$ and lung function in adults with asthma. In a panel of 60 adults with asthma in London, average $PM_{2.5}$ concentrations measured over a 2-hour outdoor walk was not associated with eNO measurements taken 3 to 7 hours post-exposure (McCreanor et al., 2007). In contrast, in a panel of older adults in Seattle, $PM_{2.5}$ concentrations measured outside of residences were associated with eNO in subjects with asthma. Recent studies are limited in number and results are also inconsistent (Figure 5-5). Mirabelli et al. (2015) studied adults with asthma in Atlanta and reported increased in eNO associated with 2-hour average personal $PM_{2.5}$ exposure measured 0, 1, 2, and 3 hours prior to spirometry. $PM_{2.5}$ concentrations were measured during scripted commutes through rush hour traffic, resulting in higher exposure levels. The observed associations were stronger in magnitude in

participants with poorly controlled asthma. In contrast, in Padua, Italy, Maestrelli et al. (2011) tested the relationship between eNO and 24-hour average personal $PM_{2.5}$ exposure the day before spirometry and reported negative associations in adults with asthma. This study was limited by a design that designated six single-day examination visits across a 2-year period, precluding the opportunity to examine alternative exposure lags.

5.1.2.4.1 Controlled Human Exposure Studies

There were no studies evaluated in the 2009 PM ISA (U.S. EPA, 2009) that specifically investigated the association between PM2.5 CAPs exposure and subclinical effects underlying asthma exacerbation. Recently, Urch et al. (2010) investigated the respiratory effects of short-term exposure to PM2.5 on individuals with asthma by using a CAP facility for PM2.5 located in downtown Toronto, Canada (study details in Table 5-6) and found little change in sputum total cell counts, neutrophils, or macrophages when compared to pre-exposure levels.

Table 5-6 Study-specific details from a controlled human exposure study of short-term $PM_{2.5}$ exposure and subclinical effects underlying asthma exacerbation.

Study	Study Design	Disease Status; n; Sex	Exposure Details (Concentration; Duration; Comparison Group)	Endpoints Measured
Urch et al. (2010)	Blinded randomized block design	Healthy nonsmokers (13) and individuals with asthma (10); n = 23; 11 M, 12 F	$PM_{2.5}$ CAPs only: 64 ± 3 or 140 ± 6 μg/m^3 $PM_{2.5}$ CAPs + O_3: 68 ± 5 or 142 ± 7 μg/m^3 $PM_{2.5}$ + 119 ± 1 ppb O_3 Comparison group for both groups was filtered air; all exposures were for 2 h carried out at rest	Sputum (pre- and 3- and 20-hour post-exposure): IL-6, IL-8, and IL-10, TNF-α, leukotriene-B, differential cell counts Venous blood (pre-, 10-min, and 3- and 20-h post-exposure): IL-6, TNF-α

CAPs = concentrated ambient particles; IL-6 = Interleukin-6; IL-8 = Interleukin-8; IL-10 = Interleukin-10; O_3 = ozone; TNF-α = tumor necrosis factor α.

5.1.2.4.2 Animal Toxicological Studies

Animal toxicological studies have focused on exacerbation of asthma in the context of allergic airway disease. Allergic airway disease (asthma, rhinitis, etc.) is a type of immune hypersensitivity that is mediated by immunoglobulin E (IgE). Development of allergic airway disease requires sensitization (immunization) that requires, presentation of a foreign antigen by antigen-presenting cells (dendritic cells

and macrophage subsets) to T-lymphocytes, the activation and clonal expansion of B-cells, and finally production of antigen-specific antibody (IgE) that binds to the antigen. Secondary exposure of previously sensitized individuals to the antigen (challenge, or elicitation phase), will activate IgE-mediated pathways that result in eosinophil recruitment, mucus production, and reactive airways.

The 2009 PM ISA (U.S. EPA, 2009) reviewed the evidence that exposure to $PM_{2.5}$ exacerbated allergic responses in laboratory rodents with pre-existing allergic airway disease. Several studies involved multiday exposures of ovalbumin (OVA)-sensitized and challenged Brown Norway rats to $PM_{2.5}$ CAPs. Increased nasal and airway mucosubstances, pulmonary inflammation, and retention of anthropogenic trace elements (La, V, Mn, S) in lung tissue were observed following 4−5 days of exposure to $PM_{2.5}$ CAPs in Detroit, MI (Harkema et al., 2004; Morishita et al., 2004). A 13-day exposure to $PM_{2.5}$ CAPs in Grand Rapids, MI resulted in no changes in BALF cells or gene expression in the whole lung (Heidenfelder et al., 2009). However, enhanced OVA-specific IgE and Muc5AC responses to ovalbumin (OVA) were observed. In addition, $PM_{2.5}$ CAPs exposure resulted in enhanced allergic bronchiolitis and alveolitis, as well as in epithelial hypertrophy and mucus cell metaplasia, which are characteristic of airway epithelial remodeling. Another study showed that enhancement of allergic responses in mice depended on proximity to the PM source following multiday exposure to roadway $PM_{2.5}$ CAPs in Los Angeles (Kleinman et al., 2005). Additionally, a single acute exposure to reaerosolized diesel exhaust particles (DEP) resulted in dose-dependent increases in levels of the Th2 cytokine IL-4 in BALF in allergic mice (Farraj et al., 2006a, b).

Recently, Harkema et al. (2009) extended their field studies in Detroit to determine if $PM_{2.5}$ CAPs inhalation would modify the allergic responses during the process of allergen challenge of sensitized rats. Ovalbumin-sensitized Brown Norway rats that were exposed to Detroit summertime $PM_{2.5}$ CAPs for the same 3 consecutive days of intra-nasal OVA challenge had increased lavaged total protein, secreted mucosubstances (Muc5AC), and numbers of lymphocytes and eosinophils compared to filtered air-exposed, allergic rats ($p < 0.05$). $PM_{2.5}$ CAPs exposure did not increase OVA-specific IgE levels in BALF above that seen in response to OVA alone. Decreases in pulmonary gene expression of TNFα, IL-10, and IFNγ (putative Th1 mediators) were also detected in $PM_{2.5}$ CAPs-exposed, OVA-challenged rats ($p \leq 0.05$). Using the same exposure protocol but in different rats and on different days when $PM_{2.5}$ CAPs concentration was lower; inflammation responses were unaffected by $PM_{2.5}$ CAPs exposure. In addition to having greater $PM_{2.5}$ CAPs concentration the first exposure study consisted of $PM_{2.5}$ that had more iron, sulfate, nitrate, and PAH content than during the second exposure study. Additional study details, for this recent study and a related one, are found in Table 5-7.

Table 5-7 Study-specific details from animal toxicologic studies of subclinical effects underlying asthma exacerbation.

Study/Study Population	Pollutant	Exposure	Endpoints
Harkema et al. (2009) Species: Rat Sex: Male Strain: Brown Norway Age/weight: 10−12 weeks	$PM_{2.5}$ CAPs Detroit, MI (urban residential) Particle size: 0.66−0.79 µm Control: Filtered air	Route: Whole-body inhalation exposure Dose/concentration: Period 1: 596 µg/m³ Period 2: 356 µg/m³ Duration: 8 h/day, 3 days, two exposure periods in July Time to analysis: 24 h All animals sensitized to OVA. $PM_{2.5}$ CAPs inhalation during OVA challenge	Histopathology of nose and lung—light microscopy, airway labelling index BALF cells Gene expression-cytokines and Muc5AC
Wagner et al. (2012) Species: Rat Strain: Brown Norway Sex: Male Age/weight: 10−12 weeks	$PM_{2.5}$ CAPs Urban Grand Rapids, MI Urban Detroit, MI Particle sizes: $PM_{2.5}$ Control: HEPA-filtered control air	Route: Whole-body inhalation Dose/concentration (D) Detroit 542 µg/m³ (GR) Grand Rapids 519 µg/m³ Dose/concentration 8 h × 1 day; begun 30 min after intra-nasal OVA challenge Duration of exposure: 8 h Time to analysis: 16 h post exposure	PM characterization Histopathology—lung BALF cells Lung injury—BALF protein BALF-Muc5AC content

BALF = bronchoalveolar lavage fluid; CAPs = concentrated ambient particles; HEPA = high efficiency particulate absorber; Muc5AC = Mucin 5AC, oligomeric mucus/gel-forming; OVA = ovalbumin.

Morphologic responses to short-term $PM_{2.5}$ CAPs exposure was also examined by (Harkema et al., 2009). Both the nose and the lung were evaluated for histologic changes and epithelial cell proliferation. No additional effect on OVA-induced allergic rhinitis was seen in the animals exposed to $PM_{2.5}$ CAPs. However, exposure to $PM_{2.5}$ CAPs resulted in a greater severity of allergic bronchiolitis and alveolitis in OVA-sensitized and challenged rats. More severe mucus cell metaplasia was found, as evidenced by increased amounts of intra-epithelial mucosubstances in conducting airways ($p \leq 0.05$). Epithelial cell proliferation, as measured by labelling index in the airways, was not altered by $PM_{2.5}$ CAPs exposure. When the same exposure protocol was used but in different rats and on different days when $PM_{2.5}$ CAPs concentration was considerably lower, morphologic responses were unaffected by $PM_{2.5}$ CAPs exposure.

The OVA-allergic Brown Norway rat model was also used to compare the effects of $PM_{2.5}$ CAPs exposure that were derived from two dissimilar urban airsheds in Grand Rapids or Detroit MI (Wagner et

al., 2012). Ovalbumin-sensitized rats were challenged with intra-nasal OVA and 30 minutes later breathed similar concentrations of $PM_{2.5}$ CAPs for 8 hours. Exposure to Detroit $PM_{2.5}$ CAPs, which were characterized by high sulfates and local industrial emissions (high Pb, Zn, and V content), enhanced eosinophilic inflammation ($p < 0.05$), mucus hypersecretion ($p < 0.05$), and mucous cell metaplasia. However, the opposite responses were seen when allergic rats inhaled Grand Rapids $PM_{2.5}$ CAPs, which were dominated by a large spike in morning traffic emissions (NO_2, CO, EC), but had low sulfates throughout the 8-hour exposure. Allergen-induced increases in airway eosinophils ($p < 0.05$), mucus hypersecretion ($p < 0.05$), and mucous cells were reversed in rats exposed to Grand Rapids $PM_{2.5}$ CAPs.

In summary, several studies provide evidence that exposure to $PM_{2.5}$ CAPs and DEP exacerbates allergic responses. In addition, one study found that $PM_{2.5}$ CAPs exposure resulted in an inhibition of allergic responses. These disparate findings may be due to source-related differences in the composition of $PM_{2.5}$ CAP due to different locations where the CAPs were collected.

5.1.2.4.3 Summary of Subclinical Effects Underlying Asthma Exacerbation

Overall, panel studies in children with asthma provide some evidence of associations between short-term $PM_{2.5}$ exposure and inflammatory markers although uncertainty regarding potential copollutant confounding remains. Results were more consistent with shorter lag times. Evidence is mainly negative in panel studies and controlled human exposure studies involving adults with asthma. Further, several studies found that short-term $PM_{2.5}$ exposure led to allergic inflammation and airway remodeling in animal models of allergic disease, which share many phenotypic features with asthma in humans. However, in studies of $PM_{2.5}$ CAPs, the response was dependent on concentration and source profile of the airshed.

5.1.2.5 Summary of Asthma Exacerbations

Recent epidemiologic studies strengthen the evidence for a relationship between short-term $PM_{2.5}$ exposure and asthma exacerbation in children. In particular, recent studies add evidence supporting associations between short-term $PM_{2.5}$ concentration and asthma hospital admissions, ED visits, and physician visits in children. Additional evidence of $PM_{2.5}$-related increases in asthma symptoms, lung function decrements, and pulmonary inflammation is provided by recent panel studies in children with asthma. Findings were not entirely consistent, but overall several well-conducted studies measuring total personal exposure, residential outdoor concentration, and school outdoor $PM_{2.5}$ concentration observed associations with asthma-related effects. Evidence for a relationship between short-term $PM_{2.5}$ exposure and asthma exacerbation in adults continues to be inconsistent.

Evidence from experimental studies provides biological plausibility for associations seen in epidemiologic studies between short-term $PM_{2.5}$ exposure and asthma exacerbation. Although controlled

human exposure studies were inconsistent in showing effects on lung function and pulmonary inflammation in individuals with asthma, animal toxicological studies demonstrated allergic inflammation, enhanced serum IgE, and airway remodeling in animal models of allergic airway disease. These changes may lead to lung function decrements and respiratory symptoms, which were observed in epidemiology studies in relation to $PM_{2.5}$ exposure (Figure 5-1).

Across the indicators of asthma exacerbation, associations continue to be observed with 24-hour average $PM_{2.5}$ concentrations from the same day, from the few preceding days, or averaged over a few days (Section 5.1.10). Evidence does not clearly point to a stronger effect for a particular exposure lag. Recent epidemiologic studies add evidence from copollutant models that show that $PM_{2.5}$ associations are independent of a copollutant among NO_2, CO, and O_3. Based on more limited investigation, there is evidence that $PM_{2.5}$ associations may be modified by these copollutants and aeroallergens. Other copollutants largely are unexamined. While there are some results from copollutant models based on personal exposure measurements that may have less differential exposure measurement error, scarce application of copollutant models limits the ability to analyze potential for confounding. Thus, as in the 2009 ISA for PM (U.S. EPA, 2009), uncertainty remains in distinguishing an independent effect of $PM_{2.5}$ exposure on asthma exacerbation.

5.1.3 Allergy Exacerbation

Animal toxicological studies reviewed in the 2009 PM ISA (U.S. EPA, 2009) provided evidence that $PM_{2.5}$ can facilitate delivery of allergenic material to the airways, promote allergic sensitization, and exacerbate allergic responses. Meanwhile, epidemiologic evidence was limited, with a single study reporting an association between short-term $PM_{2.5}$ concentrations and hospital admissions for allergic rhinitis in children in Turkey (Tecer et al., 2008). Recent evidence that $PM_{2.5}$ exposure enhances allergic inflammation in animal models of allergic airway disease, described in Section 5.1.2.4, not only supports $PM_{2.5}$-related asthma exacerbation but also indicates that $PM_{2.5}$ exposure could affect respiratory responses in people with allergies, but not asthma. Several recent epidemiologic studies add to the evidence base, but do not consistently link short-term $PM_{2.5}$ exposure to allergy exacerbation in children or adults. Recent studies examined an array of outcomes, including allergy symptoms, and lung function changes and pulmonary inflammation in populations with allergies. Notably, lung function can decrease during an allergy exacerbation due to airway obstruction caused by Th2 cytokine mediated inflammation, making lung function and pulmonary inflammation relevant markers of allergy exacerbation.

While Tecer et al. (2008) found evidence of an association between short-term $PM_{2.5}$ concentrations and allergic rhinitis hospitalizations in children, Villeneuve et al. (2006) did not observe an association between short-term $PM_{2.5}$ and physician visits for allergic rhinitis in individuals 65 years of age and older in Toronto. The authors examined single-day lags ranging from 0 to 7 days and reported mostly null associations, with some small positive and negative associations depending on the lag day.

The comparative results of the studies may be indicative of age-related differences in allergic rhinitis sensitivity to $PM_{2.5}$, but differences in study design and location make it difficult to draw conclusions. Other recent studies examined the relationship between short-term exposure to $PM_{2.5}$ and skin allergies, including urticaria (Kousha and Valacchi, 2015) and atopic dermatitis symptoms (Song et al., 2011). Kousha and Valacchi (2015) monitored ED visits for urticaria in relations to short-term $PM_{2.5}$ concentrations in Windsor, Ontario. The authors only analyzed single-day lags, ranging from 0 to 7 days prior to ED visits, and reported associations at lags 1 (OR = 1.07 [95% CI: 0.99, 1. 16]), 2 (1.14 [1.04, 1. 22]), and 3 (1.07 [0.99, 1. 16]), with generally null results at other examined lag times. However, there are uncertainties in the urticaria results, because over 67% of the days included in the study period had less than two reported ED visits. Meanwhile, in a study of schoolchildren with atopic dermatitis in South Korea, $PM_{2.5}$ measured on the school rooftop was not associated with self-reported symptoms of itchy skin (Song et al., 2011).

As mentioned previously, lung function changes and pulmonary inflammation in populations with allergies may serve as markers of allergy exacerbation. In Mexico City, Barraza-Villarreal et al. (2008) examined the association between short-term $PM_{2.5}$ concentrations and several lung function and pulmonary inflammation metrics in schoolchildren with and without asthma. The authors reported that 72% of the 50 subjects without asthma were atopic, leading them to repeat the analysis in a subgroup of atopic children. In the subgroup analysis, $PM_{2.5}$ concentrations were positively associated with FeNO, a measure of airway inflammation, but no quantitative results were presented. The authors presumably did not observe similar associations with the other metrics examined in the main analysis, including IL-8, FEV_1, FVC, and $FEV_{25–75}$.

In summary, recent animal toxicological studies expand the existing evidence base, providing additional support for the biological plausibility of $PM_{2.5}$-related allergy exacerbation. In contrast, a limited number of epidemiologic studies provide inconsistent evidence of an association across multiple endpoints, including a variety of allergic symptoms, and lung function changes and pulmonary inflammation in people with existing allergies.

5.1.4 Chronic Obstructive Pulmonary Disease (COPD) Exacerbation

Chronic obstructive pulmonary disease (COPD) is a lung disease characterized by destruction of alveolar tissue, airway remodeling, and airflow limitation. Reduced airflow is associated with decreased lung function, and clinical symptoms demonstrating exacerbation of COPD include cough, dyspnea, sputum production, and shortness of breath. Severe exacerbation can lead to ED visits or hospital admissions. The epidemiologic studies evaluated in the 2009 PM ISA (U.S. EPA, 2009) provided evidence of consistent positive associations between short-term $PM_{2.5}$ exposure and increases in hospital admissions and ED visits for COPD. Experimental studies evaluated in the 2009 PM ISA and the 2004 PM AQCD (U.S. EPA, 2004) provide biological plausibility for effects seen in epidemiologic studies. A

limited number of controlled human exposure and animal toxicological studies demonstrated changes in lung function-related parameters, as well as lung injury and inflammation. Recent studies of the relationship between short-term $PM_{2.5}$ exposure and COPD exacerbation mainly examine hospital admissions and ED visits and are generally consistent in showing associations with $PM_{2.5}$. A small body of studies expand the evidence base and show associations with respiratory symptoms and pulmonary inflammation in adults with COPD, in some cases with measures of personal $PM_{2.5}$. Results for lung function changes are inconsistent. Thus, there is variable coherence among various endpoints linked to COPD exacerbation.

In addition to examining the relationship between short-term $PM_{2.5}$ exposure and COPD exacerbation, some epidemiologic studies often conduct analyses to assess whether the associations observed are due to chance, confounding, or other biases. As such, this evidence across epidemiologic studies is not discussed within this section, but evaluated in an integrative manner and focuses specifically on those analyses that address policy-relevant issues (Section 5.1.10), and includes evaluations of copollutant confounding (Section 5.1.10.1), model specification (Section 0), lag structure (Section 5.1.10.3), the role of season and temperature on $PM_{2.5}$ associations (Section 5.1.10.4), averaging time of $PM_{2.5}$ concentrations (Section 5.1.10.5), and concentration-response (C-R) and threshold analyses (Section 5.1.10.6). The studies that inform these issues and evaluated within these sections are primarily epidemiologic studies that conducted time-series or case-crossover analyses focusing on COPD hospital admissions and ED visits.

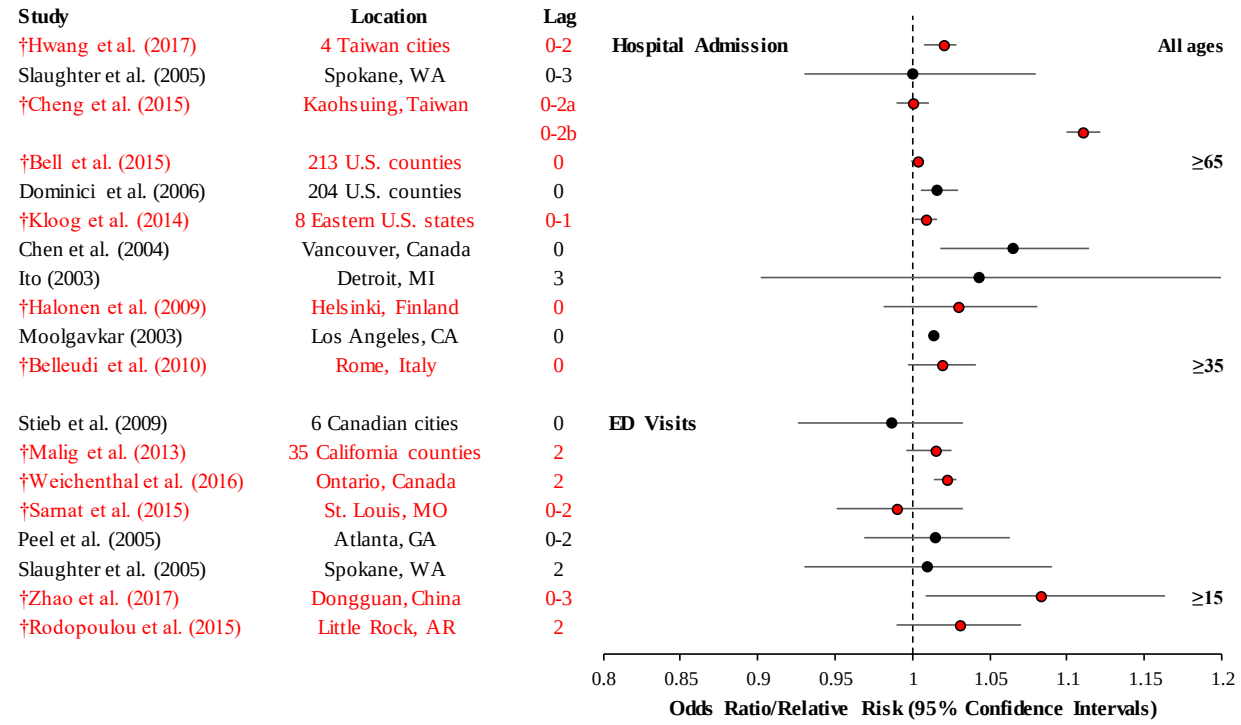
5.1.4.1 Hospital Admissions and Emergency Department (ED) Visits

Associations between short-term exposure to $PM_{2.5}$ and hospital admissions and ED visits for COPD were generally positive among the multicity and single-city studies conducted in the U.S. and Canada and evaluated in the 2009 PM ISA (U.S. EPA, 2009). Multicity studies reviewed in the 2009 PM ISA examining $PM_{2.5}$ and hospital admissions for COPD reported both null [a Canadian study, (Stieb et al., 2009)] and positive [a U.S. study, (Dominici et al., 2006)] associations between COPD hospital admissions and $PM_{2.5}$. The results from multicity studies were supported by single-city studies conducted in the U.S. and Canada that reported positive associations between short-term exposure to $PM_{2.5}$ and hospital admissions and ED visits for COPD.

Recent studies examining associations between short-term $PM_{2.5}$ exposure and COPD hospital admissions and ED visits generally support the positive associations reported in the 2009 PM ISA. These recent studies report positive associations across both multi- and single-city studies, especially for hospital admissions in populations 65 and older (see Figure 5-6, Table 5-8). However, most of the recent studies that examine short-term $PM_{2.5}$ exposure and COPD ED visits consist of single-city studies.

For each of the studies evaluated in this section, Table 5-8 presents the air quality characteristics of each city, or across all cities, the exposure assignment approach used, and information on copollutants

examined in each COPD hospital admission and ED visit study. Other recent studies of COPD hospital admissions and ED visits are not the focus of this evaluation because they did not address uncertainties and limitations in the evidence previously identified, and, therefore, do not directly inform the discussion of policy-relevant considerations detailed in Section 5.1.10. Additionally, many of these studies were conducted in small single cities, encompassed a short study duration, or had insufficient sample size. The full list of these studies can be found here: https://hero.epa.gov/hero/particulate-matter.



Note: †Studies published since the 2009 PM ISA. Black text = U.S. and Canadian studies included in the 2009 PM ISA. Corresponding quantitative results are reported in Supplemental Material (U.S. EPA, 2018).

5.1.4.1.1 Hospital Admissions

Several recent multicity studies conducted in the U.S. examined associations between short-term $PM_{2.5}$ exposure and COPD hospital admissions in individuals 65 years and older. In a multicity study conducted in the Mid-Atlantic region of the U.S., Kloog et al. (2014) examined associations between short-term $PM_{2.5}$ exposure and COPD hospital admissions by assigning exposure using a novel prediction model that combined land use regression with surface measurements of $PM_{2.5}$ concentration and satellite aerosol optical depth, which was also employed in a previous study conducted in New England (Kloog et al., 2012). The authors reported a 0.91% (95% CI: 0.18, 1.64) increase in COPD hospital admissions at model lag 0−1 days.

Bell et al. (2015) also examined COPD hospital admissions in adults ages 65 and older in a multicounty time-series analysis conducted in 213 U.S. counties. However, unlike Kloog et al. (2014), where exposures were assigned using model predictions, Bell et al. (2015) assigned exposures through $PM_{2.5}$ data retrieved from ambient monitors in each county. The authors reported a 0.34% (95% CI: −0.05, 0.74) increase in COPD hospital admissions at lag 0, which is smaller in magnitude than the association observed in Kloog et al. (2014), but may reflect the different exposure assignment approaches (Section 3.4.4.1). Consistent with the U.S. multicity studies, Hwang et al. (2017) also reported a positive association of 2% ([95% CI: 0.8, 2.9]; lag 0−2) with COPD hospital admissions in a study of four cities in southwestern Taiwan focusing on people of all ages.

Several recent single-city studies in the U.S. reported inconsistent evidence of an association between short-term exposure to $PM_{2.5}$ and hospital admissions for COPD. Kim et al. (2012) found no evidence of an association with COPD hospital admissions in Denver, Colorado (quantitative results not reported). Several single-city international studies examined the association with COPD hospital admissions and support the evidence reported in the U.S. multicity studies. A single-city study conducted in Rome, Italy focusing on adults aged 35 years and older investigated the association between $PM_{2.5}$ and COPD hospital admissions in a case-crossover analysis (Belleudi et al., 2010). Effects were assessed at several single- (0−6) and multiday lags (0−1, 0−2, 0−5 and 0−6 days). The association for $PM_{2.5}$ at a 0-day lag was positive but with wide confidence intervals (1.88% [95% CI: −0.27, 4.09]). The evidence observed using a shorter distributed lag is consistent with the lag structure of associations observed in the other COPD hospital admission studies, although in many instances the lags examined were selected a priori. In a similar fashion, Halonen et al. (2009a) observed a 3% increase (95% CI: −1.9, 8.1) at lag 0 in a model adjusted for O_3 for hospital admissions in Helsinki, Finland, but with a wide confidence interval due to the low count of hospital admissions compared to other studies. Cheng et al. (2015), examining hospital admissions in a case-crossover study in Kaohsiung, Taiwan, found no association between $PM_{2.5}$ at a 0−2-day lag (RR 1.00, 95% CI: 0.98, 1.03).

5.1.4.1.2 Emergency Department (ED) Visits

Several recent multicity studies conducted in the U.S. examined associations between short-term $PM_{2.5}$ exposure and COPD ED visits. In a multicity study conducted in 35 California counties, Malig et al. (2013) examined the association between short-term $PM_{2.5}$ exposures and respiratory ED visits, including COPD. In a time-stratified case-crossover analysis, the authors examined single-day lags and reported positive associations at lags 1 and 2 days, with the most precise estimate at lag 2 (1.47% [95% CI: 0.40, 2.6]). In a copollutant model with $PM_{10-2.5}$, the $PM_{2.5}$ association was relatively unchanged (1.58% [95% CI: 0.56, 2.62]) [Malig et al. (2013) and supplemental data file available on HERO]. The positive association observed in the multicounty study conducted by Malig et al. (2013) is supported by a study conducted in Little Rock, AR (Rodopoulou et al., 2015) that observed a 3.08% increase (95% CI: −0.98, 7.30) in COPD ED visits at lag 2. Rodopoulou et al. (2015) also examined the $PM_{2.5}$-COPD ED visits association in a copollutant model with O_3 and reported that the association remained positive, but confidence intervals increased in size (2.86% [95% CI: −1.35, 7.24]). A multicity case-crossover study of 15 cities in Ontario, Canada found an increase on the same order (2.2%) with higher precision (95% CI: 1.4, 2.9) than (Rodopoulou et al., 2015) using a 3-day mean lag structure.

In contrast, Sarnat et al. (2015) in a time-series study of $PM_{2.5}$ and cardiorespiratory ED visits in the St. Louis Missouri-Illinois (MO-IL) metropolitan area also reported no evidence of an association with COPD ED visits. The authors used 3-day unconstrained distributed lag models (i.e., lag 0−2) to allow for comparison of relationships among the multiple components and outcomes with potentially different lag structures. There was no evidence of an association between $PM_{2.5}$ and COPD ED visits (RR: 0.99 [95% CI: 0.95, 1.03]).

5.1.4.1.3 Summary of Chronic Obstructive Pulmonary Disease (COPD) Hospital Admissions and Emergency Department (ED) Visits

Consistent with the 2009 PM ISA (U.S. EPA, 2009), several recent studies examined COPD hospital admissions and ED visits and report generally positive associations with $PM_{2.5}$, with more recent multicity studies focusing on hospital admissions for older individuals (i.e., 65 years of age and older). Recent multicity studies conducted in the U.S., as well as single-city studies, that focused on individuals 65 years of age and older reported positive associations between short-term $PM_{2.5}$ exposure and COPD hospital admissions. Associations of short-term $PM_{2.5}$ exposure and ED visits, although generally positive, were less precise due to most studies being conducted in individual cities. The results from the studies evaluated in this section are supported by a recent meta-analysis of 12 studies, some of which were reviewed in the 2009 PM ISA that reported a 3.1% (95% CI: 1.6,4.6) increase in COPD hospital admissions (Li et al., 2015a). As detailed in Section 5.1.10.1, the assessment of potential copollutant confounding in studies of COPD hospital admissions and ED visits was limited, but provided evidence that associations were relatively unchanged in copollutant models. Additionally, although not extensively examined, studies generally provide evidence of larger associations in the cold or winter season compared

to warmer months (Section 5.1.10.4.1). However, it should be noted studies that examined seasonal patterns of associations did not examine potential copollutant confounding by season.

5.1.4.2 Respiratory Symptoms and Medication Use

A single study reviewed in the 2009 PM ISA (U.S. EPA, 2009) examined respiratory symptoms and medication use in adults with COPD and observed inconsistent evidence of an association with $PM_{2.5}$ across three single-day lags (Silkoff et al., 2005). A limited number of recent studies available for review followed populations comprised of adults with moderate or severe COPD. The results were not entirely consistent, though there was some evidence to indicate associations between $PM_{2.5}$ concentrations and increases in respiratory symptoms in adults with COPD. Study-specific details, air quality characteristics, and select results from these studies are highlighted in Table 5-9. Wu et al. (2016) examined the self-reported occurrence of several respiratory symptoms in relation to short-term $PM_{2.5}$ concentrations in a panel study of 23 adults in Beijing. The authors reported associations between most multiday (2−7) average $PM_{2.5}$ concentrations and sore throat, cough, sputum, wheeze, and dyspnea symptoms. Similarly, in a panel of 29 adults in Mexico City, total personal $PM_{2.5}$ exposure was associated with cough and phlegm, though not wheeze (Cortez-Lugo et al., 2015). A notable limitation of the study was high loss to follow-up, with only 4 of the 29 subjects completing all three of the 2-week study phases. In contrast, in a study of adults in Worcester, MA, $PM_{2.5}$ was associated with a decrease in COPD exacerbations, defined as a worsening of respiratory symptoms (Devries et al., 2016). Studies accounted for potential confounding by temperature, season, and time trend and also adjusted for subject characteristics such as COPD severity, race, atopic status, and comorbidity. Few studies examined any copollutants. Associations of $PM_{2.5}$ concentrations with wheeze and dyspnea persisted with adjustment for NO_2 or SO_2 in (Wu et al., 2016). However, correlations for $PM_{2.5}$ with NO_2 and SO_2 were high (r = 0.80, 0.68).

5.1.4.3 Lung Function Changes in Adults with Chronic Obstructive Pulmonary Disease (COPD)

5.1.4.3.1 Epidemiologic Studies

In the 2009 PM ISA (U.S. EPA, 2009), results from a limited number of epidemiologic studies indicated an association between PM and decreased FEV_1 in adults with COPD (Trenga et al., 2006; Ebelt et al., 2005). A few recent studies also evaluated lung function changes in populations with COPD and the results were inconsistent (Table 5-9). Recent studies used trained technicians to measure lung function, but the frequency of measurements varied from daily (Hsu et al., 2011) to less than once per week (Cortez-Lugo et al., 2015). Total personal $PM_{2.5}$ exposure was associated with decreased PEF in adults with COPD in Mexico City, who spent more than 90% of their time indoors (Cortez-Lugo et al.,

2015). As discussed previously, there was high loss to follow-up in this study. Associations were observed with 2-day average exposures lagged 2 or 3 days but not 0 or 1 days. In a small panel study of adults with COPD in New York City, ambient $PM_{2.5}$ concentrations were associated with decreases in PEF at lag 1, but increases in PEF at lag 0 (Hsu et al., 2011). Given the short sampling period (12 days) and relatively small sample size (nine participants), the interpretability of the results is limited.

Table 5-9 Epidemiologic studies of $PM_{2.5}$ and respiratory symptoms, lung function, and pulmonary inflammation in adults with chronic obstructive pulmonary disease.

†Studies published since the 2009 PM ISA.

1

5.1.4.3.2 Controlled Human Exposure Studies

Two studies evaluated in the 2009 PM ISA (U.S. EPA, 2009) provide limited evidence for decreased lung function among subjects with COPD exposed to $PM_{2.5}$ (Gong et al., 2005; Gong et al., 2004). Gong et al. (2004) reported decreases in oxygen saturation among elderly COPD patients, although results were more consistent in elderly subjects without COPD; the authors reported no effects on spirometric measures of lung function. The association between $PM_{2.5}$ and decreased oxygen saturation in COPD patients was confirmed in Gong et al. (2005).

5.1.4.4 Subclinical Effects Underlying Exacerbation of Chronic Obstructive Pulmonary Disease (COPD)

5.1.4.4.1 Epidemiologic Studies

A limited number of studies evaluated in the 2009 PM ISA (U.S. EPA, 2009) reported evidence of an association between short-term $PM_{2.5}$ concentrations and pulmonary inflammation in adults with COPD. Studies examined exhaled nitric oxide (eNO) as an indicator of pulmonary inflammation, a key characteristic of COPD. Additionally, there is evidence that eNO increases during acute COPD exacerbation (Perng and Chen, 2017). Small panel studies of older adults in Steubenville, OH (Adamkiewicz et al., 2004) and Seattle, WA, (Jansen et al., 2005) reported increases in eNO associated with 24-hour average $PM_{2.5}$ concentrations measured at a single fixed-site monitor or outside of participants residences, respectively.

Information from the few available recent studies continues to support a relationship between $PM_{2.5}$ and increases in pulmonary inflammation in adults with COPD. Recent studies evaluated panels of older adults with COPD in Shanghai (Chen et al., 2015b) and Beijing, China (Wu et al., 2016). In both studies, $PM_{2.5}$ was measured at a single fixed-site monitor located within 4 km (Chen et al., 2015b) or 1.6−8.8 km (Wu et al., 2016) of subjects' residences, but information on the variability in $PM_{2.5}$ concentrations in the study areas was not reported. Chen et al. (2015b) observed eNO increases consistent with increases in $PM_{2.5}$ concentrations at 7−12-hour, 13−24-hour, 1-, 2-, and 3−7-day lags. Supporting these findings, the authors also reported associations between $PM_{2.5}$ and decreased methylation of the inducible nitric oxide synthase gene promoter that demonstrated the largest decrements at lag 0−6 hour. Lower methylation is associated with increased gene expression of inducible nitric oxide synthase which mediates production of nitric oxide. Wu et al. (2016) did not examine hourly lags but reported associations between eNO and cumulative average $PM_{2.5}$ concentrations ranging from 1 to 7 days. eNO associations were robust to adjustment for NO_2 but attenuated and no longer positive in two-pollutant models including SO_2 (Wu et al., 2016). However, there were high correlations of $PM_{2.5}$ with NO_2 and

SO_2 (r = 0.80, 0.68). While these studies provide additional support to the previously limited evidence of an association between $PM_{2.5}$ exposure and pulmonary inflammation in adults with COPD, uncertainties remain in attributing the observed increases in pulmonary inflammation to $PM_{2.5}$ exposure, similar to findings for other indicators of COPD exacerbation.

5.1.4.4.2 Controlled Human Exposure Studies

In the 2009 PM ISA (U.S. EPA, 2009), a limited number of studies investigated $PM_{2.5}$-induced health effects in adults with COPD. (Gong et al., 2004) and Gong et al. (2005) found a decrease in columnar epithelia cells ($p < 0.01$) following short-term exposure to $PM_{2.5}$. This effect was more pronounced in healthy subjects compared to those with COPD.

5.1.4.4.3 Animal Toxicological Studies

While no additional toxicological studies on the effects of PM on COPD have become available in recent years, the 2004 PM AQCD (U.S. EPA, 2004) reported several studies which examined the effects of multiday exposure to $PM_{2.5}$ CAPs in rats with experimentally induced bronchitis, an animal model of COPD. Changes in tidal volume, BALF injury markers (protein, albumin, and N-acetyl glutaminidase), and numbers of BALF neutrophils and lymphocytes were greater in bronchitic rats compared to nonbronchitic rats exposed to $PM_{2.5}$ CAPs from Boston (Saldiva et al., 2002; Clarke et al., 1999) and Research Triangle Park, NC (Kodavanti et al., 2000).

5.1.4.5 Summary of Exacerbation of Chronic Obstructive Pulmonary Disease (COPD)

Recent studies generally support an association between short-term increases in $PM_{2.5}$ concentration and exacerbation of COPD. Recent studies expand on the array of COPD-related outcomes and add coherence for the observations of $PM_{2.5}$-related increases in COPD-related hospital admissions and ED visits. Overall, evidence links short-term $PM_{2.5}$ exposure to COPD hospital admissions and ED visits. These findings are supported by recent observations of $PM_{2.5}$-related pulmonary inflammation; evidence for $PM_{2.5}$-related symptoms and decreases in lung function is less consistent. A strength of these studies is their assessment of personal $PM_{2.5}$ exposures. Overall, copollutant confounding was not adequately examined. Thus, it is unclear the extent to which the results can be attributed specifically to $PM_{2.5}$ exposure. However, experimental studies in individuals with COPD and in an animal model of COPD support an independent effect of short-term $PM_{2.5}$ exposure on exacerbation of COPD. Changes in lung function-related parameters (oxygen saturation and tidal volume), as well as lung injury and inflammation were observed following short-term $PM_{2.5}$ CAPs exposure and provide biological plausibility for the findings of epidemiologic studies (Figure 5-1).

5.1.5 Respiratory Infection

The respiratory tract is protected from exogenous pathogens by lung host defenses that include mucociliary clearance, pathogen detoxification, and clearance by alveolar macrophages, as well as innate and adaptive immunity. Impairment of these defense mechanisms can increase the risk of respiratory infection. The 2009 PM ISA (U.S. EPA, 2009) described evidence supporting $PM_{2.5}$-related respiratory infection but there was uncertainty due to a small evidence base relative to those for other respiratory effects. Previous epidemiologic studies consistently observed associations between $PM_{2.5}$ concentrations and hospital admissions or ED visits for indices aggregating various respiratory infections, particularly in U.S. and European cities. Findings from a limited number of studies also supported associations with pneumonia. In the 2004 PM AQCD and the 2009 PM ISA, controlled human exposure studies were not available to assess coherence, but an animal toxicological study demonstrated increased susceptibility to pneumonia infection and altered macrophage function following exposure to $PM_{2.5}$. Hospital admissions and ED visits comprise most of the epidemiologic evidence of respiratory infections and consistently indicate associations for $PM_{2.5}$ concentrations with multiple respiratory infections grouped together but not individually with pneumonia. Interpretation of the evidence, however, is complicated by the variety of respiratory infection outcomes examined.

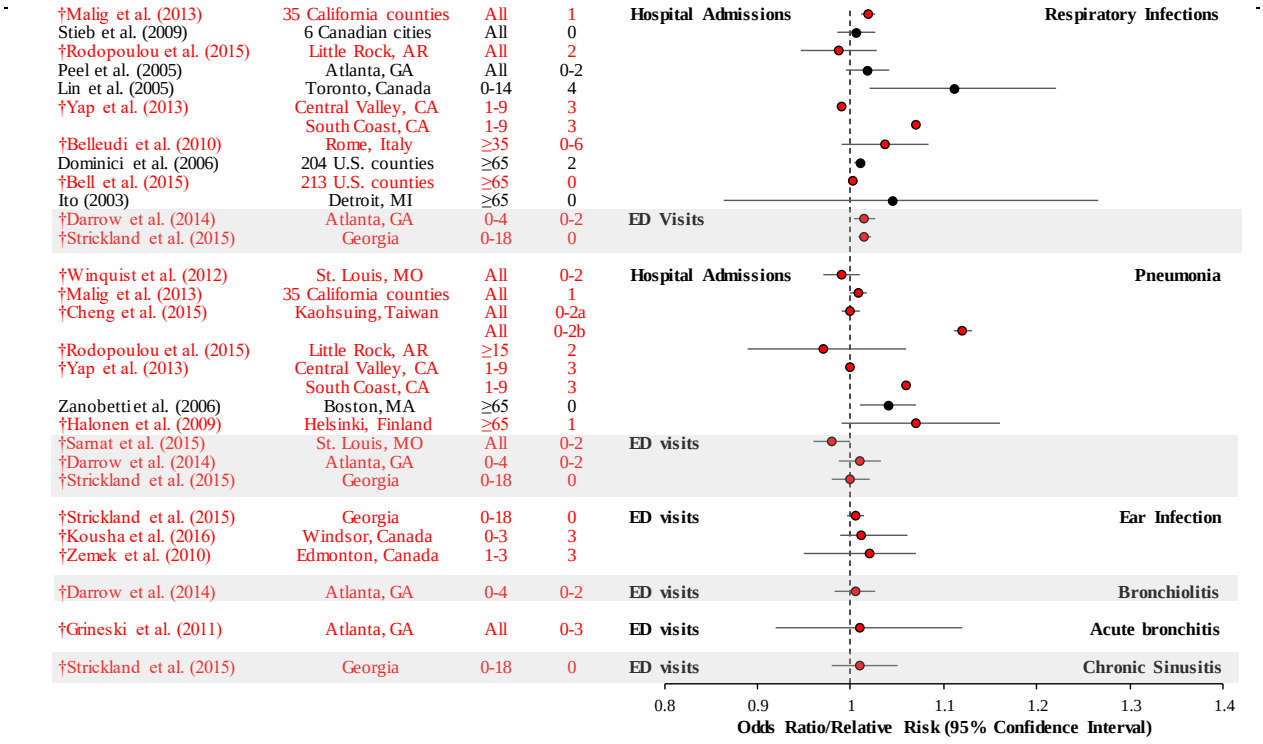
In addition to examining the relationship between short-term $PM_{2.5}$ exposure and respiratory effects, some epidemiologic studies often conduct analyses to assess whether the associations observed are due to chance, confounding, or other biases. As such, this evidence across epidemiologic studies is not discussed within this section, but evaluated in an integrative manner and focuses specifically on those analyses that address policy-relevant issues (Section 5.1.10), and includes evaluations of copollutant confounding (Section 5.1.10.1), model specification (Section 0), lag structure (Section 5.1.10.3), the role of season and temperature on $PM_{2.5}$ associations (Section 5.1.10.4), averaging time of $PM_{2.5}$ concentrations (Section 5.1.10.5), and concentration-response (C-R) and threshold analyses (Section 5.1.10.6). The studies that inform these issues and evaluated within these sections are primarily epidemiologic studies that conducted time-series or case-crossover analyses focusing on respiratory infection hospital admissions and ED visits.

5.1.5.1 Hospital Admissions and Emergency Department (ED) Visits

Associations between short-term $PM_{2.5}$ exposure and hospital admissions and between short-term $PM_{2.5}$ exposure and ED visits for respiratory infections were consistently observed among multicity studies evaluated in the 2009 PM ISA (U.S. EPA, 2009), although the type of respiratory infection examined varied across the studies (i.e., acute bronchitis, bronchiolitis, and pneumonia). Several multicity studies reported associations between short-term $PM_{2.5}$ exposure and pneumonia and acute bronchitis in children. The overall evidence base examining short-term $PM_{2.5}$ exposure and hospital admissions and ED visits for respiratory infections expanded considerably since the 2009 PM ISA. These recent studies

report generally positive associations between $PM_{2.5}$ and hospital admissions and ED visits for pneumonia, ear infections, and all respiratory infections grouped together (see Figure 5-7, Table 5-10). As in the 2009 PM ISA, respiratory infections when combined capture a range of outcomes (pneumonia, ear infections, bronchiolitis, sinusitis), with studies primarily focusing on children.

For each of the studies evaluated in this section, Table 5-10 presents the air quality characteristics of each city, or across all cities, the exposure assignment approach used, and information on copollutants examined in each respiratory infection hospital admission and ED visit study. Other recent studies of respiratory infection hospital admissions and ED visits are not the focus of this evaluation because they did not address uncertainties and limitations in the evidence previously identified, and therefore, do not directly inform the discussion of policy-relevant considerations detailed in Section 5.1.10. Additionally, many of these studies were conducted in small single cities, encompassed a short study duration, or had insufficient sample size. The full list of these studies can be found here: https://hero.epa.gov/hero/particulate-matter.



Note: †Studies published since the 2009 PM ISA. Black text = U.S. and Canadian studies included in the 2009 PM ISA. Corresponding quantitative results are reported in Supplemental Material (U.S. EPA, 2018).

5.1.5.1.1 Hospital Admissions

Studies examined the association between short-term $PM_{2.5}$ exposure and hospital admissions for a variety of respiratory infections. Several recent multicity studies conducted in the U.S. examined associations between short-term $PM_{2.5}$ exposure and hospital admissions for respiratory infections in children age 1 to 9 years (Yap et al., 2013) and in individuals 65 years of age and older (Bell et al., 2015). Yap et al. (2013) evaluated pediatric (children ages 1 to 9 years) hospital admissions for respiratory conditions associated with $PM_{2.5}$ exposures in 12 California counties. For acute respiratory infections, including pneumonia, relative risks (RR) ranged from 1.03 to 1.07 in Los Angeles, Riverside, San Bernardino, and San Diego counties at lags 0−2 days. The association for combined respiratory infection hospital admissions was significantly higher in the south coast than the central valley (RR 1.07 vs. 0.99); confidence intervals were not reported. In addition to this evidence for pediatric infections, in a multicounty time-series analysis of adults conducted in 213 U.S. counties Bell et al. (2015) reported a 0.21% (95% CI: −0.07, 0.49) increase in combined respiratory tract infection hospital admissions among adults aged 65 and older at lag 0.

In addition to the multicity studies presented above, several single-city studies were conducted in the U.S. and internationally that examined respiratory infection hospital admissions. Grineski et al. (2011) primarily focused on examining the effect of dust and low wind events on asthma and acute bronchitis hospital admissions in El Paso, TX. The authors reported imprecise associations with $PM_{2.5}$ and acute bronchitis hospital admissions across both single and multiday lags with an OR = 1.01 (95% CI: 0.92, 1.12) at lag 0−3 days. By contrast, in Denver, CO, Kim et al. (2012) reported no association between $PM_{2.5}$ and pneumonia hospital admissions at any lag when examining a distributed lag model of 0−14 days (quantitative results not presented). Winquist et al. (2012) conducted a study in the St. Louis-MO metropolitan area to evaluate the impact of the type of health care visit on the association with short-term air pollution exposures, including $PM_{2.5}$. This study compared four visit types including ED visits, hospital admissions, hospital admissions that came through the ED, and nonelective hospital admissions. The authors found that compared with ED visits patients, hospital admission patients tended to be older, had evidence of greater severity for some outcomes, and had a different mix of specific outcomes. For pneumonia, associations with $PM_{2.5}$ were positive only among the 2−18-year-old group for ED visits, nonelective hospital admissions, and hospital admissions through ED types of visits. The only positive association was observed for hospital admissions through ED visits (0.43% [95% CI: −0.56, 0.68] at lag 0−4 days. In Rome, Italy, Belleudi et al. (2010) reported evidence of an association between $PM_{2.5}$ and lower respiratory tract infection hospital admissions among adults aged 35 years and older (3.62% [95% CI: −0.96, 8.42]; lag 0−6 DL).

5.1.5.1.2 Emergency Department (ED) Visits

Several recent multicity studies conducted in the U.S. examined associations between short-term $PM_{2.5}$ exposure and respiratory infection-related ED visits. In a multicity study conducted in 35 California counties, Malig et al. (2013) examined the association between short-term $PM_{2.5}$ exposures and ED visits, including pneumonia and acute respiratory infections. Using a time-stratified case-crossover analysis, the authors reported positive associations at 1-day lags between short-term $PM_{2.5}$ and acute respiratory infections (1.9% [95% CI: 1.1, 2.7]) and pneumonia (0.86% [95% CI: −0.06, 1.8]) ED visits in single pollutant models.

The evidence for associations with ED visits from single-city studies also expanded considerably since the 2009 PM ISA (U.S. EPA, 2009). Winquist et al. (2012) observed a positive association for hospital admissions through ED visits, can be compared to a more recent study conducted in the same St. Louis Missouri-Illinois (MO-IL) metropolitan area. However, unlike Winquist et al. (2012), Sarnat et al. (2015) found no evidence of an associations between $PM_{2.5}$ and pneumonia ED visits (RR = 0.98 [95% CI: 0.96, 1.00]) at lag 0−2 days.

Several studies investigated the associations between $PM_{2.5}$ and ED visits related to several respiratory infections in Atlanta, GA. Darrow et al. (2014) conducted an 18-year (1993−2010) study examining the association between $PM_{2.5}$ and pediatric (ages 0−4) ED visits for respiratory infections, including bronchitis and bronchiolitis, pneumonia, and upper respiratory infection (URI). Daily concentrations of ambient air pollution from several networks of ambient monitors were combined using population-weighting. Pneumonia ED visits were positively associated with $PM_{2.5}$ (for children aged 0−4 years, RR = 1.01 [95% CI: 0.99, 1.03]). $PM_{2.5}$ at lag 0−2 days was not associated with an increase in ED visits for bronchiolitis and bronchitis, although some of the point estimates in the children aged 1−4 years were positive, but uncertain for URI and pneumonia. In the same location, Strickland et al. (2015) examined children ages 0−18 years old between 2002−2010 in a case-crossover study using predicted daily $PM_{2.5}$ concentrations from a two-stage spatiotemporal model with geographical weighting. The authors found that the association with ED visits for bronchitis and upper respiratory infection increased slightly at lag 0-day (OR: 1.010 [95% CI: 0.994, 1.027], and OR: 1.015 [95% CI: 1.008, 1.022]). In contrast, the association for pneumonia-related ED visits were essentially null at both a 0-day lag (OR: 0.999 [95% CI: 0.979, 1.019]) and a 1-day lag (OR: 1.001 [95% CI: 0.981, 1.022]).

In contrast to the results of Winquist et al. (2012), other single-city studies such as Darrow et al. (2014), Strickland et al. (2015), and Rodopoulou et al. (2015) found no associations for respiratory infection ED visits. For example, in Little Rock, AR, Rodopoulou et al. (2015) found an association of −1.34% (95% CI: −5.31, 2.79) amongst all age groups using a 2-day lag. The association slightly increased to −0.82% after the inclusion of O_3 in a copollutant model (95% CI: −4.96, 3.50).

5.1.5.2 Outpatient and Physician Visit Studies

A study conducted in Atlanta, GA, Sinclair et al. (2010) examined the association between air pollution and several respiratory-related outpatient visits, including upper and lower respiratory infections. The authors separated the analysis into two consecutive time periods to compare the air pollutant concentrations and relationships for acute respiratory visits for the 25-month time-period examined in a previous study (August 1998−August 2000) and an additional 28-month time-period of available data from the Atlanta Aerosol Research and Inhalation Epidemiology Study (ARIES) (September 2000−December 2002). Across the two-time periods, 24-hour average $PM_{2.5}$ concentrations were lower in the 28-month versus the 25-month time-period (16.2 vs. 18.4 μg/m^3, respectively). A comparison of the two-time periods indicated that associations for $PM_{2.5}$ tended to be larger in the earlier 25-month period compared to the later 28-month period. The highest association with LRI was observed for lag 3−5 in the 25-month time-period (RR: 1.071 [95% CI: 1.003, 1.144]). For URI in the 25-month period, the association was positive at lag 0−2 days (RR: 1.015 [95% CI: 0.990, 1.040]). It should be noted that the severity of a $PM_{2.5}$-related respiratory outcome, personal behavior such as delaying a visit to the doctor for less severe symptoms, and insurance type (i.e., physician visits which often are ascertained for members of a managed care organization) may dictate whether individuals visit the doctor or a hospital, making it difficult to readily compare results between studies focusing on physician visits versus hospital admissions and ED visits.

5.1.5.3 Subclinical Effects Underlying Respiratory Infection

Subclinical effects have been investigated solely in animal toxicological studies. As described in the 2004 PM AQCD (U.S. EPA, 2004), Zelikoff et al. (2003) showed that exposure to $PM_{2.5}$ CAPs in New York City resulted in altered macrophage function in rats. In addition, a greater bacterial burden was found when infection with *S. pneumoniae* was followed 48 hours later by $PM_{2.5}$ CAPs exposure. However, when $PM_{2.5}$ CAPs exposure preceded *S. pneumoniae* infection, it had little effect on bacterial burden. Studies described in the 2009 PM ISA (U.S. EPA, 2009) demonstrated altered susceptibility to infectious agents following exposure to whole motor vehicle exhaust and effects due to metal-enriched particles (i.e., ROFA). Recent studies of respiratory-related infection did not examine the effects of $PM_{2.5}$ CAPs or seek to distinguish between the effect of gaseous and particulate components in a mixture.

5.1.5.4 Summary of Respiratory Infection

The body of evidence for associations between short-term exposure to $PM_{2.5}$ and respiratory infection is comprised mainly of studies of hospital admissions and ED visits. These studies increased in number since the last review. However, because of variability in the type of respiratory infection outcome examined, the overall interpretation of findings is more complicated. Associations reported in single-city

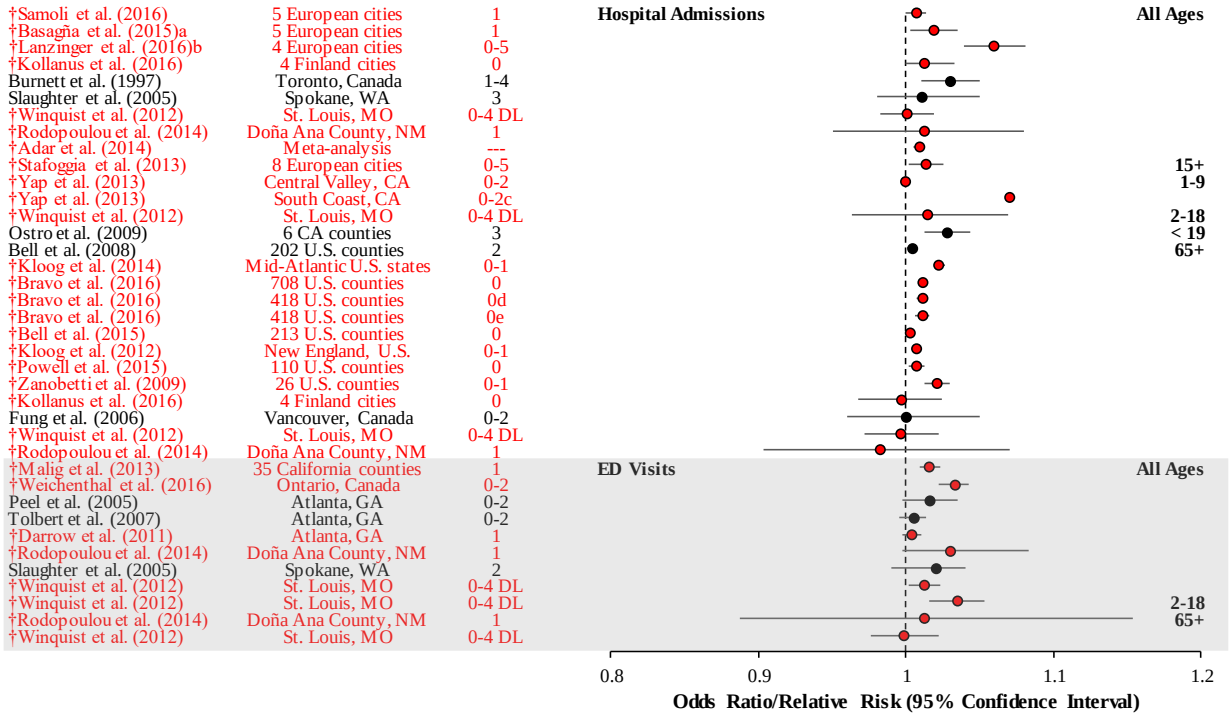
studies were often imprecise, with confidence intervals crossing the null. A few recent single-city studies reported positive associations for acute bronchitis hospital admissions and respiratory tract infection hospital admissions. In several multicity studies, one conducted in the U.S. and one in or Canada, studying $PM_{2.5}$ and hospital admissions for respiratory infections, both reported positive associations. Most single-city studies in the U.S. consistently reported positive associations for pneumonia (adults and children, ages 0−4), but this effect was not observed for bronchiolitis and bronchitis in children ages 0−4. In contrast, a study of acute respiratory infection ED visits reported no evidence of an association with $PM_{2.5}$. However, a single-city U.S. study reported positive associations with outpatient visits for lower and upper respiratory tract infections. Moreover, these studies generally provide inconsistent evidence for seasonal patterns in the strength of association. A single experimental study in animals, demonstrating altered macrophage function and increased susceptibility to pneumonia in response to $PM_{2.5}$ CAPs exposure, supports findings of epidemiologic studies.

5.1.6 Combinations of Respiratory-Related Hospital Admissions and Emergency Department (ED) Visits

In addition to individual respiratory diseases, epidemiologic studies examined respiratory diseases in aggregate where, in some cases, the aggregate represented all respiratory diseases while, in others, a specific combination of respiratory diseases was represented (e.g., COPD, asthma and respiratory infections). In the 2009 PM ISA (U.S. EPA, 2009) there was a small number of studies that examined short-term $PM_{2.5}$ exposure and all respiratory-related diseases in the context of hospital admissions and ED visits. These studies generally encompassed single-city studies and reported evidence of consistent, positive associations when examining effects in children, people of all ages, adults, and older adults (i.e., ≥65 years of age) at lags within the range of 0 to 2 days. However, across these studies the evaluation of potential copollutant confounding was limited to analyses of $PM_{10-2.5}$, with no evaluation of gaseous pollutants. When interpreting these results, it is often difficult to determine if the associations observed indicate that $PM_{2.5}$ may affect the spectrum of respiratory diseases or reflects the evidence supporting associations with specific respiratory diseases, such as asthma.

Studies published since the completion of the 2009 PM ISA (U.S. EPA, 2009) report generally consistent, positive associations across studies of hospital admissions and ED visits for all age ranges, particularly in multicity studies (Figure 5-8). Among studies that examined both combinations of respiratory diseases grouped together and individual respiratory diseases, as detailed in previous sections within this chapter, most observed positive $PM_{2.5}$ associations with asthma (Section 5.1.2), respiratory infection (Section 5.1.5), or both, with results for COPD (Section 5.1.4) being more variable. However, some studies show associations with all three respiratory diseases. For studies that did not observe $PM_{2.5}$-related increases in hospital admissions or ED visits for all respiratory-related diseases, associations were often observed for individual respiratory diseases within the same study, for example asthma [e.g., Yap et al. (2013)]. Similar to the individual respiratory diseases discussed earlier within this

chapter, positive associations with respiratory-related diseases are more consistently observed among children and when examining people of all ages. However, recent studies further expand analyses with older adults, with multicity studies conducted in the U.S. providing evidence of consistent, positive associations between short-term $PM_{2.5}$ exposure and respiratory-related diseases.



DL = distributed lag.

Note: †Studies published since the 2009 PM ISA. Black text: U.S. and Canadian studies included in the 2009 PM ISA. a = five European cities as part of the MED-PARTICLES project; b = only four of the five cities had $PM_{2.5}$ data; c = quantitative data for confidence intervals not reported, but above the null; d = monitoring data result; e = downscaler CMAQ, only counties and days with monitoring data. Corresponding quantitative results are reported in Supplemental Material (U.S. EPA, 2018).

Figure 5-8 Summary of associations from studies of short-term $PM_{2.5}$ exposure and respiratory-related hospital admission and emergency department (ED) visits for a 10 µg/m^3 increase in 24-hour average $PM_{2.5}$ concentrations.

Consistent with earlier sections, the focus of this section is on those studies that address uncertainties and limitations in the evidence for association between short-term $PM_{2.5}$ exposure and respiratory-related hospital admissions and ED visits identified at the completion of the 2009 PM ISA (U.S. EPA, 2009). For each of the studies that evaluated hospital admissions and ED visits for combinations of respiratory-related diseases, Table 5-11 presents the air quality characteristics of each

city, or across all cities, the exposure assignment approach used, and information on copollutants examined. Other recent studies of hospital admissions and ED visits for respiratory-related diseases that did not address uncertainties and limitations in the evidence previously identified are not the focus of this evaluation. Additionally, many of these other studies were conducted in small single cities, encompassed a short study duration, or had insufficient sample size. The full list of these other studies can be found in HERO: https://hero.epa.gov/hero/particulate-matter.

In addition to examining the relationship between short-term $PM_{2.5}$ exposure and respiratory effects, some epidemiologic studies often conduct analyses to assess whether the associations observed are due to chance, confounding, or other biases. As such, this evidence across epidemiologic studies is not discussed within this section, but evaluated in an integrative manner and focuses specifically on those analyses that address policy-relevant issues (Section 5.1.10), and includes evaluations of copollutant confounding (Section 5.1.10.1), model specification (Section 0), lag structure (Section 5.1.10.3), the role of season and temperature on $PM_{2.5}$ associations (Section 5.1.10.4), averaging time of $PM_{2.5}$ concentrations (Section 5.1.10.5), and concentration-response (C-R) and threshold analyses (Section 5.1.10.6). The studies that inform these issues and evaluated within this section consist only of epidemiologic studies that conducted time-series or case-crossover analyses focusing on combinations of respiratory-related ED visits and hospital admissions.

5.1.6.1 Hospital Admissions

Recent studies that examined the association between short-term $PM_{2.5}$ exposure and respiratory-related hospital admissions build upon the evidence detailed in the 2009 PM ISA (U.S. EPA, 2009), particularly the examination of effects in older adults (i.e., ≥65 years of age). Multicity studies conducted in Europe (Lanzinger et al., 2016b; Samoli et al., 2016a; Basagaña et al., 2015) and Finland (Kollanus et al., 2016) that examined people of all ages provide evidence of consistent, positive associations that are similar in magnitude to those reported in the U.S. and Canadian studies evaluated in the 2009 ISA (Figure 5-8). The results from analyses of people of all ages are further supported by Stafoggia et al. (2013) in a study of eight southern European cities that reported a 1.36% (95% CI: 0.23, 2.49) increase in hospital admissions at lag 0−5 days, as well as a meta-analysis conducted by Adar et al. (2014) (RR = 1.01 [95% CI: 1.00, 1.02]). However, single-city studies conducted in St. Louis, MO (Winquist et al., 2012) and Doña Ana County, NM (Rodopoulou et al., 2014), do not provide consistent evidence of an association with respiratory-related diseases in all ages analyses.

Studies that examined the relationship between short-term $PM_{2.5}$ exposure and respiratory-related hospital admissions in children are limited in number, but generally report associations that are similar in magnitude to previous studies. An exception is the study conducted by Yap et al. (2013) in 12 California counties focusing on children 1 to 9 years of age where there was no evidence of an association in the central valley counties (RR = 1.0), but a positive association in the south coast counties was seen (RR = 1.07) at lag 0−2 days. Winquist et al. (2012) also reported a positive association for children in St. Louis, MO, but confidence intervals were wide (RR = 1.02 [95% CI: 0.96, 1.07]; lag 0−4 DL).

Most of the recent studies focusing on respiratory-related hospital admissions focus on older adults, and consisted mostly of multicity or entire state analysis conducted in the U.S. These recent multicity studies report evidence of consistent, positive associations, except the study by Kollanus et al. (2016) in four cities in Finland (Figure 5-8). The associations reported across the U.S. for multicity studies are based on a variety of exposure assignment approaches (see Table 5-11), all of which resulted in associations that are similar in magnitude. In a multicounty time-series analysis conducted in 213 U.S. counties from 1999−2010, Bell et al. (2015) observed a 0.25% (95% CI: 0.01, 0.48) increase in all respiratory hospital admissions at lag 0 among adults aged 65 years and older. In a similar study of 110 U.S. counties, Powell et al. (2015) reported results consistent with Bell et al. (2015) (0.67% [95% CI: 0.14, 1.2]; lag 0). Bell et al. (2014), also examined single-day lags, but in four counties in Connecticut and Massachusetts, and reported evidence of positive associations across lags of 0 to 2 days, albeit with wide confidence intervals (quantitative results not presented). Additional evidence of a positive association between short-term $PM_{2.5}$ exposure and respiratory-related hospital admissions is provided by Zanobetti et al. (2009) in an analysis of 26 U.S. counties where a 2.1% (95% CI: 1.2, 3.0) increase in hospital admissions was reported at lag 0−1. The results from the epidemiologic studies that rely on

community-based monitors are supported by a series of studies that used a combination of monitored, modeled, and in some cases satellite-based $PM_{2.5}$ concentrations. In a multicity study conducted in the New England region of the U.S., Kloog et al. (2012) assessed exposure using a novel prediction model that combined land use regression with surface $PM_{2.5}$ measurements from satellite aerosol optical depth. The authors observed a 0.70% (95% CI: 0.35, 1.05) increase in respiratory-related hospital admissions for a 0−1-day lag. In a sensitivity analysis using monitor-based exposure assessment in the time-series analysis, Kloog et al. (2012) reported similar results (1.51% [95% CI: 0.42, 1.65]), but with slightly larger confidence intervals. Kloog et al. (2014) built upon the exposure assessment used in Kloog et al. (2012) in a study conducted in the Mid-Atlantic region of the U.S. The authors reported a 2.2% (95% CI: 1.9, 2.6) increase in respiratory-related hospital admissions at lag 0−1 day. The results of Kloog et al. (2012) and Kloog et al. (2014) are supported by Bravo et al. (2017) in a study of 708 U.S. counties. The authors examined associations between short-term $PM_{2.5}$ exposure and respiratory-related hospital admissions using three different exposure assessment approaches: (1) a population-weighted average of $PM_{2.5}$ concentration computed in 708 U.S. counties using a downscaled CMAQ model (Section 3.3.2.4.3); (2) a population-weighted average of downscaled CMAQ-simulated $PM_{2.5}$ concentrations computed in the 418 U.S. counties that have monitoring data; and (3) $PM_{2.5}$ concentrations from the 418 U.S. counties with fixed-site monitors. Across these three exposure assignment approaches, the authors reported a relatively consistent percent increase in hospital admissions at lag 0: (1) 1.16% (95% CI: 0.88, 1.45); (2) 1.11 (95% CI: 0.66, 1.56); and (3) 1.10% (95% CI: 0.70, 1.50).

5.1.6.2 Emergency Department (ED) Visits

Compared to studies that examined hospital admissions for respiratory-related diseases, fewer studies focused on ED visits, with the majority examining associations with short-term $PM_{2.5}$ exposure in analyses of all ages. Additionally, a recent study examined associations with PM size fractions smaller than 2.5 µm, but larger than UFP (i.e., number concentration [NC] and surface area concentration [SC] for particles 100−300 nm), which also supports the positive associations with respiratory-related ED visits observed for $PM_{2.5}$ (Leitte et al., 2011). Whereas, many hospital admission studies were conducted over multiple cities or entire states, the ED visit studies are mostly limited to individual cities.

Malig et al. (2013), in a study of 35 California counties, reported a 1.6% (95% CI: 0.98, 2.27) increase in respiratory-related ED visits at lag 1. Building on the previous studies conducted in Atlanta, GA (Tolbert et al., 2007; Peel et al., 2005), Darrow et al. (2011) also examined associations between short-term $PM_{2.5}$ exposures and respiratory-related ED visits, reporting an association similar in magnitude to the previous studies (0.4% [95% CI: −0.2, 1.0]; lag 1). Additionally, Krall et al. (2016) in a study of four U.S. cities (i.e., Atlanta, Birmingham, St. Louis, and Dallas) reported positive associations for each city at lag 0 (quantitative results not presented). Single-city studies conducted in Canada and the U.S. report associations that overall are consistently positive and generally similar in magnitude to Malig et al. (2013) (Figure 5-8). Across the studies evaluated, only Winquist et al. (2012) examined associations

with respiratory related ED visits in children (i.e., 2−18 years of age) in St. Louis, MO, and reported an association larger in magnitude (RR = 1.03 [95% CI: 1.02, 1.05]; lag 0−4 DL) compared to that observed when examining people of all ages (RR = 1.01 [95% CI: 1.0, 1.02]; lag 0−4 DL). Of the few studies that examined effects in older adults (Rodopoulou et al., 2014; Winquist et al., 2012), there was no evidence of an association between short-term $PM_{2.5}$ exposure and respiratory-related ED visits.

5.1.6.3 Summary of Respiratory-Related Hospital Admissions and Emergency Department (ED) Visits

Recent epidemiologic studies that examined short-term $PM_{2.5}$ exposure and hospital admissions and ED visits for respiratory-related diseases generally support the results from studies evaluated in the 2009 PM ISA (U.S. EPA, 2009). Across studies, there is evidence of generally consistent, positive associations among children, with a growing body of evidence, primarily from multicity U.S.-based studies of older adults (Figure 5-8). Additional studies focusing on people of all ages, also provide evidence supporting an association with $PM_{2.5}$, with most of the studies conducted in individual cities.

The main results of studies detailed within this section are supported by analyses that examined specific policy-relevant issues as detailed in Section 5.1.10. Compared to the 2009 PM ISA (U.S. EPA, 2009), recent studies provide a more extensive examination of potential copollutant confounding, but overall the assessment is limited to only a few studies. These studies demonstrate that associations between short-term $PM_{2.5}$ exposure and respiratory-related hospital admissions and ED visits are relatively unchanged in models with gaseous pollutants and $PM_{10-2.5}$ (Section 5.1.10.1). In addition to copollutant confounding, several studies examined the influence of alternative model specifications on the $PM_{2.5}$ association with respiratory-related hospital admissions and ED visits and found that associations remained relatively unchanged when accounting for temporal trends and weather covariates using different specifications (Section 0). Analyses that focused on whether there are differences by season provide some evidence that $PM_{2.5}$ associations are larger in magnitude during the warmer months, but some studies reported larger associations during the colder months (Section 5.1.10.4.1). The difference in associations by season could reflect geographic variability that continues to be observed in multicity studies. However, to date it remains unclear what factors contribute to the observed geographic variability in $PM_{2.5}$ associations with respiratory-related diseases (Bell et al., 2009a).

While studies evaluated in the 2009 PM ISA (U.S. EPA, 2009) tended to support $PM_{2.5}$ associations within the first few days after exposure (i.e., lag 0 to 3 days), recent studies support that evidence and provide initial evidence indicating that $PM_{2.5}$ effects may be more prolonged, ranging from 0−5 days (Section 5.1.10.3). To date, there are very few studies that have examined subdaily averaging times of $PM_{2.5}$ concentrations (Section 5.1.10.5). In terms of respiratory-related hospital admissions and ED visits, available evidence indicates that subdaily averaging times do not result in stronger associations with respiratory-related hospital admissions and ED visits compared to a 24-hour averaging time (Section 5.1.10.5). Lastly, recent evaluations of the C-R relationship between short-term $PM_{2.5}$ exposure

and respiratory-related hospital admissions and ED visits provides evidence of a linear relationship, but this assessment is based on rather limited analyses that did not empirically evaluate alternatives to linearity (Section 5.1.10.6).

5.1.7 Respiratory Effects in Healthy Populations

The 2009 PM ISA (U.S. EPA, 2009) did not have a delineated discussion of respiratory effects in healthy populations, but relevant epidemiologic studies provided inconsistent evidence for $PM_{2.5}$-related decreases in lung function and increases in pulmonary inflammation, and no evidence for increases in respiratory symptoms in individuals with no underlying respiratory disease. Controlled human exposure studies evaluated in the 2009 PM ISA provided no evidence for changes in lung function and limited evidence for pulmonary inflammation, while animal toxicological studies more consistently provided evidence for $PM_{2.5}$ exposure-related effects.

To characterize the current state of the evidence, this section focuses on results specific to healthy populations. Some studies employed scripted exposures in an attempt to further inform the relationship between short-term $PM_{2.5}$ exposure and respiratory effects. Scripted studies measuring personal ambient $PM_{2.5}$ exposures are designed to minimize uncertainty in the $PM_{2.5}$ exposure metric by always measuring $PM_{2.5}$ at the site of exposure, ensuring exposure to sources of $PM_{2.5}$ and measuring outcomes at well-defined lags after exposure.

There are recent epidemiologic studies in populations with 13−28% prevalence of asthma, COPD, or atopy, some of which indicate $PM_{2.5}$-associated increases in respiratory effects. However, these studies are not evaluated in this section, as it is not known whether the results apply to the healthy portion of the population or are instead driven solely by an association in individuals with pre-existing respiratory conditions, these studies can be found in HERO (https://hero.epa.gov/hero/particulate-matter). Further, these studies do not provide additional insight on issues such as copollutant confounding, effects at low $PM_{2.5}$ exposure concentrations, or critical exposure periods.

5.1.7.1 Epidemiologic Studies

The 2009 PM ISA (U.S. EPA, 2009) evaluated a limited number of epidemiologic studies that examined respiratory effects in healthy populations. A study of adult school crossing guards in New Jersey observed decreases in lung function associated with 1-hour max $PM_{2.5}$ concentrations (Fan et al., 2008). In contrast, Holguin et al. (2007) did not observe an association between $PM_{2.5}$ and lung function or lung inflammation in a study of school children in Ciudad Juarez, Mexico. Several recent studies are available for evaluation, with most focusing on lung function changes and/or lung inflammation in healthy populations. Study-specific details, including cohort descriptions and air quality characteristics are highlighted in Table 5-2.

Respiratory Symptoms

While respiratory symptoms are frequently studied in populations with pre-existing respiratory conditions, such as asthma or COPD, the outcome is less often examined in healthy populations. As such, only a single recent study is available for review. In a study of school children in Santiago, Chile, 7-day average PM2.5 was associated with increased odds of cough and a composite index of respiratory symptoms (Prieto-Parra et al., 2017). The associations were relatively unchanged in two-pollutant models with PM10, NO2, SO2, or O3. However, copollutant correlations were not reported, limiting the interpretability of the copollutant models.

Lung Function Changes

The majority of recent studies on lung function changes in relation to $PM_{2.5}$ concentrations examined adults during scripted exposures and exposure interventions. Studies examining lung function changes in adults after commuting in cars, buses, or on bicycles, did not observe associations between personal ambient $PM_{2.5}$ exposure and FEV_1 (Mirabelli et al., 2015; Weichenthal et al., 2011; Zuurbier et al., 2011b). In a study of adults commuting 2 hours through Atlanta traffic, Mirabelli et al. (2015) reported $PM_{2.5}$-related decreases in FVC immediately after the commute. The association appeared to be transient, with no association observed 3 hours post-commute.

A number of studies in the U.S. (Mirowsky et al., 2015), Canada (Dales et al., 2013), and Europe (Matt et al., 2016; Kubesch et al., 2015; Steenhof et al., 2013; Strak et al., 2012) used quasi-experimental designs to assign participants to either rest or exercise in different locations with notable pollutant contrasts. Similar to the studies of scripted commutes through traffic, many of these quasi-experimental studies observed null associations between lung function and $PM_{2.5}$ (Kubesch et al., 2015; Mirowsky et al., 2015; Strak et al., 2012). In contrast, Dales et al. (2013) observed decreases in FEV_1 and $FEF_{25-75\%}$ associated with 8-hour average $PM_{2.5}$ concentrations in Sault Ste. Marie, Canada. Associations were observed despite low mean concentrations of 8-hour average $PM_{2.5}$. Additionally, in Barcelona, Spain, Matt et al. (2016) reported that healthy adults experienced decreased FEV_1 associated with 2-hour average $PM_{2.5}$ immediately after exposure. Notably, $PM_{2.5}$ was associated with increased FEV_1 7 hours after exposure, again indicating potentially transient effects. Another study in China implemented an exposure intervention by moving healthy, nonsmoking adults from an industrial town to a less polluted city for 9 days (Hong et al., 2010). Participants experienced increased FEV_1 and PEF associated with decreased 24-hour average $PM_{2.5}$.

Studies of lung function in healthy children were limited in number. School-children in an agricultural area of Brazil experienced decreases in PEF in association with $PM_{2.5}$ concentrations measured outside of school, averaged over the 6, 12, or 24 hours preceding spirometry (Jacobson et al., 2012). In Seoul, South Korea Hong et al. (2010), composite monitor 24-hour average $PM_{2.5}$ was associated with a small, imprecise decrease in PEFR in schoolchildren at lags 0 and 3, but no other lags

up to 4 days. The location of the monitors relative to the school was not specified, so it is not clear to what degree exposure measurement error might have impacted the results (Section 3.4.2.2).

Subclinical Effects

Most recent studies of subclinical respiratory effects in healthy populations examined exhaled nitric oxide (eNO) as an indicator of pulmonary inflammation. Many of the same studies that were evaluated in the previous subsection on lung function also measured eNO. As such, the majority of recent studies similarly examined adults during scripted exposures. Studies of adults during and after commuting in cars, buses, or on bicycles, generally observed associations between personal ambient $PM_{2.5}$ exposure and subclinical respiratory effects (Mirabelli et al., 2015; Weichenthal et al., 2011; Zuurbier et al., 2011b). Mirabelli et al. (2015) observed associations between eNO and $PM_{2.5}$ concentrations during a 2-hour scripted commute through Atlanta traffic. The authors reported $PM_{2.5}$-related increases in eNO levels 0, 1, 2, and 3 hours post-commute. A similar $PM_{2.5}$-related increase in eNO was reported in a group of adults cycling alongside high- and low-traffic roads in Ottawa, Canada (Weichenthal et al., 2011). The observed associations with personal $PM_{2.5}$ concentrations were strongest 2 hours after cycling. Conversely, $PM_{2.5}$ was associated with a decrease in eNO in a study of adults commuting 2 hours by either car, bus, or bike in the Netherlands (Zuurbier et al., 2011b). However, the authors also noted that personal ambient $PM_{2.5}$ was associated with a decrease in Clara cell secretory protein (CC16), a pulmonary biomarker that is often decreased in subjects with lung epithelial damage.

Studies utilizing quasi-experimental designs were less consistent, despite similarly high mean concentrations of $PM_{2.5}$. In New York, $PM_{2.5}$ exposure while walking near high-traffic roads and in a forest was associated with eNO 24 hours after exposure (Mirowsky et al., 2015). However, eNO was not associated with $PM_{2.5}$ in studies where participants were randomized to exercise or rest at locations with air pollution exposure contrasts in Barcelona, Spain (Kubesch et al., 2015) or Utrecht, The Netherlands (Strak et al., 2012). As part of the same project in the Netherlands, Steenhof et al. (2013) reported an association between $PM_{2.5}$ exposure and nasal lavage levels of the pro-inflammatory cytokine, IL-6. The observed association was persistent in two-pollutant models including NO_X, O_3, or SO_2 (Steenhof et al., 2013).

A single study examined subclinical effects in school children. Carlsen et al. (2016) observed a 5.4 ppb (95% CI: −3.1, 13.0 ppb) increase in eNO associated with 2-day average $PM_{2.5}$ at two schools in Umea, Sweden. $PM_{2.5}$ was measured at monitors located within 1.5 km of the two schools. Although copollutant models were not examined, $PM_{2.5}$ was weakly correlated with NO_X and only moderately correlated with O_3.

Table 5-12 Epidemiologic studies of $PM_{2.5}$ and respiratory effects in healthy populations.

5.1.7.2 Controlled Human Exposure Studies

Studies evaluated in the 2009 PM ISA (U.S. EPA, 2009) provided little evidence that exposure to $PM_{2.5}$ results in decrements in lung function in healthy populations. Although Petrovic et al. (2000) observed that a 2-hour exposure to $PM_{2.5}$ (92 µg/m^3) resulted in decreases in thoracic gas volume, other measures of lung function (spirometry, diffusing capacity, airway resistance) were unaffected. No clear effect of short-term exposure to $PM_{2.5}$ on lung function was demonstrated in several studies investigating the exposure of healthy volunteers to $PM_{2.5}$ CAPs (Gong et al., 2003; Ghio et al., 2000; Gong et al., 2000) or urban traffic particles. In a recent study, Huang et al. (2012) exposed healthy volunteers to $PM_{2.5}$ CAPs collected from Chapel Hill, NC. The authors reported no changes in multiple markers of lung function (including FVC, FEV_1, and $FEF_{25–75}$) or in the marker for diffusion capacity DLCO at 1 and 18 hours post exposure (study details in Table 5-13).

The 2009 PM ISA (U.S. EPA, 2009) provided limited evidence that exposure to $PM_{2.5}$ resulted in subclinical or inflammatory effects in healthy populations. Ghio et al. (2000) reported an increase in airway and alveolar neutrophils following exposure to $PM_{2.5}$ CAPs. A follow-up analysis of Ghio et al. (2000) determined the increase in BALF neutrophils was associated with the Fe, SE, and SO_4^{2-} content of the particulate matter (Y-CT et al., 2003). Recently, the healthy population respiratory response to $PM_{2.5}$ has been further examined by Behbod et al. (2013) and Huang et al. (2012). These studies involved exposure to $PM_{2.5}$ CAPs at either approximately 250 µg/m^3 (Behbod et al., 2013) or 90 µg/m^3 for approximately 2 hours (Huang et al., 2012) (additional study details are in Table 5-13). Multiple markers of airway inflammation were measured. Behbod et al. (2013) reported that relative to filtered air, no significant airway (sputum) responses were observed in subjects exposed to Toronto, Ontario $PM_{2.5}$ CAPs. Exposures to relatively lower levels of $PM_{2.5}$ CAPs (approximately 90 µg/m^3) (Huang et al., 2012) corroborated the effects seen in the higher exposure study (Behbod et al., 2013) in that exposure to Chapel Hill NC $PM_{2.5}$ CAPs had no effect on IL-6, IL-8, or α1-antitrypsin in the bronchoalveolar lavage of exposed healthy subjects, although changes in blood parameters were observed (see Section 6.1.11).

Table 5-13 Study-specific details from controlled human exposure studies of short-term $PM_{2.5}$ exposure and respiratory effects in healthy populations.

Study	Study Design	Disease Status; n; Sex; (Age)	Exposure Details (Concentration; Duration; Comparison Group)	Endpoints Measured
Behbod et al. (2013)	Double-blind, randomized cross-over block design	Healthy nonsmokers; n = 35; 11 M, 12 F (18−60 yr)	234.7 µg/m^3 $PM_{2.5}$ CAPs, Toronto, ON. (IQR: 52.4 µg/m^3) for 130 min (120-min exposure + 10 min to complete tests) at rest. Comparison groups were either (1) filtered air or (2) medical air; a minimum 2-week washout period was used between exposures.	Sputum (pre- and 24-hour post-exposure): Total cell and neutrophil counts
Huang et al. (2012)	Not specifically stated	Healthy nonsmokers; n = 23; 15 M, 8 F (20−36 yr)	89.5 ± 10.7 µg/m^3 $PM_{2.5}$ CAPs or 73.4 ± 9.9 µg/m^3 $PM_{2.5}$ CAPs + 0.5 ppm NO_2 for 2 h, Chapel Hill, NC. During exposure, subjects completed four cycles of 15 min each rest or exercise. Comparison group was clean air.	Lung function BAL (18-h post-exposure): IL-6, IL-8, α1-antitrypsin, LDH, differential leucocyte counts

BAL = bronchoalveolar lavage; CAPs = concentrated ambient particles; IL-6 = interleukin-6; IL-8 = interleukin-8; IQR = interquartile range; LDH = lactate dehydrogenase; NO_2 = nitrogen dioxide.

5.1.7.3 Animal Toxicological Studies

Lung Function

The 2004 PM AQCD (U.S. EPA, 2004)and the 2009 PM ISA (U.S. EPA, 2009) reported several animal toxicological studies that measured pulmonary function following single or multiday exposure to $PM_{2.5}$ CAPs. Decreased breathing frequency (or respiratory rate) was observed in dogs exposed to $PM_{2.5}$ CAPs in Boston by tracheostomy exposure (Godleski et al., 2000). In addition, a strong increase in airway irritation, as indicated by decreases in end inspiratory pause and increases in end expiratory pause, pause, and enhanced pause (Penh) was observed (Nikolov et al., 2008). Increased tidal volume was found in rats exposed to $PM_{2.5}$ CAPs in Boston (Clarke et al., 1999) but not in New York City (Gordon et al., 2000). Increases in inspiratory and expiratory times were not seen in Wistar Kyoto rats exposed to $PM_{2.5}$ CAPs in Research Triangle Park, NC (Kodavanti et al., 2005). Results of these studies, showing changes in

breathing frequency and depth of breathing, indicate that short-term $PM_{2.5}$ exposure stimulated lung irritant responses through the activation of sensory nerves and local reflexes.

Recently, Diaz et al. (2013) evaluated the effects of exposure to $PM_{2.5}$ roadway tunnel particles on pulmonary function in Sprague Dawley rats. A 2-day exposure to tunnel particles with gases removed by a denuder resulted in increased rapid shallow breathing, as indicated by increased frequency and decreased tidal volume, minute volume, inspiratory time, and expiratory time ($p < 0.05$). This breathing pattern, as well as the observed decrease in expiratory flow at 50% (EF_{50}) ($p = 0.01$), provide evidence of an irritative respiratory response. A 2-day exposure to a secondary organic aerosol formed from photochemical oxidation of primary tunnel gases (SOA) resulted in increases in pauses, including Penh ($p \leq 0.05$). A 4-day exposure to SOA decreased several parameters including frequency, tidal volume, minute volume, EF_{50}, and Vi, an indicator of respiratory drive ($p < 0.05$). A 4-day exposure to photochemically aged primary particles plus SOA (P + SOA) produced the largest change in breathing parameters including decreased volumes, flow, respiratory drive, and respiratory effort ($p < 0.05$). This pattern is reflective of rapid shallow breathing and suggests an irritative respiratory response with an additional effect at the thoracic level. Additional study details for this study, and other recent toxicological studies, are found in Table 5-14.

The effect of social stress on pulmonary function was examined in older Sprague Dawley rats exposed to $PM_{2.5}$ CAPs in Boston (Clougherty et al., 2010). In stressed animals, $PM_{2.5}$ CAPs exposure was associated with increased breathing frequency ($p = 0.001$), lower tidal volume ($p = 0.001$), lower PEF ($p = 0.003$), and shorter times ($p < 0.001$), suggesting rapid shallow breathing. In unstressed animals, $PM_{2.5}$ CAPs exposure was associated with increased PIF ($p = 0.03$) and greater MV ($p = 0.05$).

Effects on other pulmonary function parameters have been reported. Amatullah et al. (2012) found that a 4-hour exposure of BALB/c mice to $PM_{2.5}$ CAPs in Toronto increased quasi-static elastance of the lung ($p < 0.05$). Yoshizaki et al. (2017) examined sex-related differences in tracheal hyperreactivity of BALB/c mice due to a multiday exposure to $PM_{2.5}$ CAPs in Sao Paulo, Brazil. Tracheal rings from male mice that were exposed to $PM_{2.5}$ CAPs were hyporesponsive to methacholine, a bronchoconstrictor, compared to tracheal rings from male mice exposed to ambient air ($p < 0.05$). Tracheal rings from diestrus female mice that were exposed to $PM_{2.5}$ CAPs responded similarly to methacholine as tracheal rings from female mice exposed to ambient air. However, tracheal rings from estrus and proestrus female mice were hyperresponsive to methacholine compared with air controls ($p < 0.05$).

Table 5-14 Study-specific details from animal toxicologic studies of short-term $PM_{2.5}$ exposure and respiratory effects in healthy animals.

Study/Study Population	Pollutant	Exposure	Endpoints
Amatullah et al. (2012) Species: Mouse Sex: Female Strain: BALB/c Age/weight: 6−8 weeks, 18 g	$PM_{2.5}$ CAPs Toronto Particle size: $PM_{0.15-2.5}$ Control: HEPA filtered air	Route: Nose-only inhalation Dose/concentration: $PM_{0.5-2.5}$ 254 µg/m³ Duration: 4 h Time to analysis: At end of exposure Modifier: Baseline ECG	Pulmonary function BALF Cells
Aztatzi-Aguilar et al. (2015) Species: Rat Sex: Male Strain: Sprague Dawley	$PM_{2.5}$ CAPs Mexico City Particle size: $PM_{2.5}$ Control: Filtered air	Route: Inhalation Dose/concentration: $PM_{2.5}$ 178 µg/m³ Duration: Acute 5 h/day, 3 days Subchronic 5 h/day, 4 days/week, 8 weeks Time to analysis: 24 h	Gene expression and protein levels—lung tissue IL-6, components of the RAS and kallikrein-kinin endocrine system-heme oxygenase-1
Budinger et al. (2011) Species: Mouse Sex: Male Strain: C57BL/6 wild type and IL-6 knockouts Age/weight: 8−12 weeks	$PM_{2.5}$ CAPs Chicago, IL Particle size: $PM_{2.5}$ Control: Filtered ambient air	Route: Whole-body inhalation Dose/concentration: 88.5 ± 13.4 µg/m³ Duration: 8 h/day for 3 days	BALF and lung tissue-protein level and gene expression of inflammatory mediators Plasma—biomarkers of coagulation
Chiarella et al. (2014) Species: Mouse Sex: Male Strain: C57BL/6 wild type and Adrβ knockouts Age/weight: 8−12 weeks	$PM_{2.5}$ CAPs Chicago, IL Particle size: $PM_{2.5}$ Control: Filtered ambient air	Route: Whole-body inhalation Dose/concentration: 109.1 ± 6.1 µg/m³ Duration: 8 h/day for 3 days	BALF and lung tissue—IL-6, norepinephrine Brown adipose tissue—norepinephrine
Clougherty et al. (2010) Species: Rat Sex: Male Age/weight: 12 weeks	$PM_{2.5}$ CAPs Boston Particle size: PM ≤ 2.5 µm Control: Filtered air	Route: Whole-body inhalation Dose/concentration: 374 µg/m³ With large variance Duration: 10 days, 5 h/day Time to analysis: Respiratory data was collected during exposure at 10 min. intervals using Buxco Coexposure: Stress	Pulmonary function • Peak inspiratory flow • Minute volume • Breathing frequency • Inspiratory time • Expiratory time • Expiratory flows • Tidal volume

Table 5-14 (Continued): Study specific details from animal toxicologic studies of short term $PM_{2.5}$ exposure and respiratory effects in healthy animals.

Study/Study Population	Pollutant	Exposure	Endpoints
Diaz et al. (2013) Species: Rat Sex: Male Strain: Sprague-Dawley Age/weight: 250−300 g	Roadway tunnel particles (gases removed by denuder) Primary particles (P) Primary particles and secondary aerosol (P-SOA) Secondary organic aerosol (SOA) Particle size: PM < 2.5 µm Control-Filtered air (oxidizable gases, VOC and particles removed)	Route: Whole-body Inhalation Dose/concentration: P-47.5 µg/m^3 P + SOA-50 µg/m^3 SOA- 48.7 µg/m^3 Duration: 2−4 days, 5 h/day Time to analysis: 24 h or 48 h Coexposure: NO: P- 71.2 ppb P + SOA- 2.1 ppb SOA- 27.1 ppb NO_X: P- 92.6 ppb P + SOA- 37.5 ppb SOA- 56.9 ppb	BALF Cells Lung function • Tidal volume • Minute Volume • Expiratory time • Inspiratory time • Expiratory flow at 50% (flow) • Pause • Enhanced pause • End expiratory pause • End inspiratory pause • Peak of inspiratory flow • Inspiratory time
Kim et al. (2016b) Species: Mouse Strain: Balb/c Sex: Male Age/weight: 6−10 weeks	DEP (NIST SRM) Particle size: Not reported	Route: Inhalation Dose/concentration: 2 mg/m^3 Duration: 1 h/day for 5 days Time to analysis: 9 days	Middle ear: Gene expression microarray and pathway analysis
Mauderly et al. (2011) Species: Mouse/Rat Sex: Male and female Strain: Mouse Age/weight: C57BL/6 (10−13 weeks) A/J (5−8 weeks) BALB/c (3 weeks gestation, 4 weeks after birth) Strain: Rat F344 Age/weight: (7−9 weeks)	Simulated coal emissions low, medium, high doses and high dose filtered groups Particle size: Not reported in this publication. Likely PM < 2.5 Control: Clean air	Route: Whole-body Inhalation Dose/concentration: 1,000, 300, 100 µg/m^3 Duration: 6 mo or 1 week, 7 days/week, 6 h/day	BALF Cells/Cytokines (F344 rats) • MIP-2 • Leukocytes
Plummer et al. (2012) Species: Mouse Sex: Male Strain: C57BL/6 Age/weight: 12−14 weeks, 25−30 g	$PM_{2.5}$ CAPs from Fresno, (F, urban) or Westside (W, rural) locations in California, in two seasons (summer, winter) Particle size: $PM_{2.5}$ Control: Ambient air	Route: Whole-body inhalation Dose/concentration: F/Summer 284 µg/m^3, F/Winter 156 µg/m^3, W/Summer 126 µg/m^3, W/Winter 86 µg/m^3 Duration: 6 h/day for 10 days Time to analysis: 48 hr Note: Composition of $PM_{2.5}$ CAPs defined for organic/elemental carbon, nitriate, sulfate, ammonia, chloride	BALF cells Lung tissue Cytokine/Chemokine Histopathology—lung

Table 5-14 (Continued): Study specific details from animal toxicologic studies of short term $PM_{2.5}$ exposure and respiratory effects in healthy animals.

Study/Study Population	Pollutant	Exposure	Endpoints
Rohr et al. (2010) Species: Rat Strain: Spontaneously hypertensive (SH) Wistar Kyoto (WKY) Sex: Male Age/weight: 11−12 weeks	$PM_{2.5}$ CAPs residential urban Detroit, MI Particle size: $PM_{2.5}$ Control: HEPA-filtered clean air	Route: Whole-body inhalation Dose/concentration: 507 µg/m^3 Duration of exposure: 8 h, 13 consecutive days Time to analysis: 24 h	BALF cells Lung Injury • BALF protein content
Tyler et al. (2016) Species: Mouse Strain: C67BL/6 Age/weight: 6−8 weeks	DEP, resuspended Particle size: 1.5−3.0 µm ± 1.3−1.6 µm Control: Filtered air	Route: Whole-body inhalation Dose/concentration: 315.3 ± 50.7 µg/m^3 Duration: 6 h	BALF cells and cytokines Particle uptake in bronchial macrophages
Xu et al. (2013) Species: Mouse Strain: C57BL/6 Sex: Male Age/weight: 3 weeks	$PM_{2.5}$ CAPs Columbus, OH Particle size: ≤$PM_{2.5}$ Control: Filtered air	Route: Whole-body inhalation Dose/Concentration: 143.8 µg/m^3 Duration: 6 h/day, 5 days/week, 5, 14, 21 days Time to analysis: Immediately post-exposure	Immunohistochemistry—lung BALF cells—flow cytometry
Yoshizaki et al. (2016) Species: Mouse Sex: Male and female Strain: BALB/c Age/Weight: 21 days	$PM_{2.5}$ CAPs Sao Paulo, Brazil Particle size: $PM_{0.1-2.5}$ µm Control: Ambient air	Route: Whole-body Inhalation Dose/Concentration: Cumulative dose × time $PM_{2.5}$: 594 ± 77 µg/m^3 Duration: Multiday Coexposure: Other ambient pollutants and also PM_{10}	Gene expression and protein levels—nasal epithelium AhR, estrogen receptor, cytochrome P450 enzymes Immunohistochemistry—nasal epithelium mucus profile and mucus content
Yoshizaki et al. (2017) Species: Mouse Sex: Male and female (diestrus, proestrus, and estrus) Strain: BALB/c Age/Weight: 21 days	$PM_{2.5}$ CAPs Sao Paulo, Brazil Particle size: Control: Ambient air	Route: Whole-body Inhalation Dose/Concentration: Cumulative dose × time $PM_{2.5}$: 600 µg/m^3 Duration: Multiday Coexposure: Other ambient pollutants, PM_{10}	Ex vivo tracheal rings—reactivity to methacholine BALF cells and cytokines Lung Immunohistochemistry

Adrβ = beta adrenergic receptor; AhR = aryl hydrocarbon receptor; BALF = bronchoalveolar lavage fluid; CAPs = concentrated ambient particles; DEP = diesel exhaust particles; ECG = electrocardiogram; HEPA = high-efficiency particulate absorber; IL-6 = interleukin-6; MIP-2 = macrophage inflammatory protein-2; NIST SRM = National Institute of Standards and Technology Standard Reference Material; NO = nitric oxide; NO_X = oxides of nitrogen; RAS = renin-angiotensin system; VOC = volatile organic carbon.

1

Pulmonary Injury

As described in the 2009 PM ISA (U.S. EPA, 2009), several studies examined pulmonary injury and altered lung barrier/secretory function in response to single or multiday exposure to $PM_{2.5}$ CAPs. While increased BALF protein and lung water content were observed in rats exposed to $PM_{2.5}$ CAPs in Boston (Gurgueira et al., 2002; Clarke et al., 1999), injury indices were not observed in rats exposed to $PM_{2.5}$ CAPs in New York City and Research Triangle Park, NC (Gordon et al., 2000; Kodavanti et al., 2000). Recently, Rohr et al. (2010) exposed Wistar Kyoto rats to residential urban $PM_{2.5}$ CAPs in Detroit, MI for 13 days and found increased BALF protein content ($p < 0.05$). Indices of injury (BALF protein and LDH activity) were not increased by any exposure to San Joaquin Valley $PM_{2.5}$ CAPs despite evidence of inflammation (Plummer et al., 2012). Additional study details are found in Table 5-14.

Pulmonary Oxidative Stress

As described in the 2009 PM ISA (U.S. EPA, 2009), several studies examined oxidative stress in response to $PM_{2.5}$ exposure. Increased lung chemiluminescence, activities of MnSOD and catalase, TBARS, and protein carbonyl content were reported in rats exposed to $PM_{2.5}$ CAPs in Boston (Rhoden et al., 2004; Gurgueira et al., 2002). Pretreatment with the thiol antioxidant N-acetylcysteine blocked PM-mediated oxidative stress in Rhoden et al. (2004). In a recent study, tissue heme oxygenase-1 activity, an index of oxidative stress, was not increased by any exposure to San Joaquin Valley $PM_{2.5}$ CAPs (Plummer et al., 2012) despite evidence of inflammation (Table 5-14).

Pulmonary Inflammation

The 2004 PM AQCD (U.S. EPA, 2004) and 2009 PM ISA (U.S. EPA, 2009) reported several studies that examined the effect of single and multiday exposure to $PM_{2.5}$ on pulmonary inflammation. Exposure to $PM_{2.5}$ CAPS in Boston resulted in increased BALF neutrophils in dogs (exposed by tracheostomy) (Godleski et al., 2000) and increases in BALF neutrophils and lymphocytes in rats (Rhoden et al., 2004; Saldiva et al., 2002; Clarke et al., 1999), while BALF macrophages were decreased (Clarke et al., 1999). Godleski et al. (2002) found concentration-dependent increases in numbers of BALF neutrophils and increases in gene expression of inflammatory mediators following exposure to $PM_{2.5}$ CAPs in Boston. Increases in BALF total cells, neutrophils, and macrophages were also seen in rats exposed to $PM_{2.5}$ CAPs from Fresno, CA (Smith et al., 2003). Exposure of rats to $PM_{2.5}$ CAPs in New York City resulted in increased lavageable cells in one study (Zelikoff et al., 2003) and no increases in inflammatory cells in another (Gordon et al., 2000). Similarly, exposure to $PM_{2.5}$ CAPs in Research Triangle Park, NC had disparate effects in different studies (Kodavanti et al., 2005; Kodavanti et al., 2000). Other studies investigated the effects of exposure to traffic related air pollution, such as whole DE or GE or on-road highway aerosols, on pulmonary inflammation. However, these studies did not distinguish between effects of the gaseous or particulate parts of the mixture.

Similarly, recent studies are not uniform in the observation of inflammation following inhalation exposure to $PM_{2.5}$. Amatullah et al. (2012) found no changes in BALF inflammatory cells immediately following a 4-hour exposure of BALB/c mice to $PM_{2.5}$ CAPs in Toronto (Table 5-14). No increases in BALF inflammatory cells were found in Wistar Kyoto rats exposed for 13 days to $PM_{2.5}$ CAPs in Detroit despite an increase in BALF protein, an index of lung injury (Rohr et al., 2010). In contrast, increases in lung tissue and BALF IL-6 were observed following multiday exposure of C57BL/6 mice to $PM_{2.5}$ CAPs in Chicago (Chiarella et al., 2014; Budinger et al., 2011), and Mexico City (Aztatzi-Aguilar et al., 2015). Budinger et al. (2011) also reported increases in BALF MCP-1 and TNF-α. In IL-6 knock-out mice, short-term $PM_{2.5}$ exposure failed to increase IL-6 levels, while the other two mediators were unaffected. In addition, upregulation of the IL-6 target genes surfactant protein B and tissue factor in lung tissue and thrombin-antithrombin complex in plasma was observed in wild-type, but not in IL-6 knock-out mice. These results demonstrate the involvement of lung IL-6 in mediating systemic increases in thrombin-antithrombin complex, a key mediator of thrombosis. Furthermore, increased numbers of neutrophils in the BALF were found in C57BL/6 mice exposed for 10 days to $PM_{2.5}$ CAPs in California ($p < 0.05$) (Plummer et al., 2012). In this latter study, $PM_{2.5}$ CAPs were collected during two seasons (summer and winter) from an urban (Fresno) and a rural site (Westside) near Fresno. While BALF neutrophils were increased in mice exposed to Westside summer and Westside winter $PM_{2.5}$ CAPs ($p < 0.05$), levels of KC, MCP-1 and IFN-γ were decreased in lung tissue from mice exposed to Fresno summer $PM_{2.5}$ CAPs ($p < 0.05$). This study demonstrates that urban and rural sites within the same airshed and season can have PM with differing ability to produce inflammation.

A time course study of pulmonary inflammation was conducted by Xu et al. (2013) in C57BL/6 mice exposed for 5, 14, and 21 days to $PM_{2.5}$ CAPs in Columbus, OH. No increases in numbers of macrophages or neutrophils were found in BALF. However, immunohistochemically staining of lung tissue showed increases in macrophages (using F4/80 + as the marker) at the three time points ($p < 0.05$), peaking at 5 days. No increases in neutrophils (using NIMPR14 as the marker) were seen in lung tissue. This study is unique in demonstrating early recruitment of macrophages to lung tissue in the absence of neutrophils and is indicative of innate immune system activation.

Other studies examined the effects of source-related $PM_{2.5}$ on pulmonary inflammation. Tyler et al. (2016) exposed C67BL/6 mice to resuspended DEP for 6 hours and found no increase in inflammatory cells or cytokines in the BALF and no increase in particle uptake in bronchial macrophages, despite inflammation in the hippocampus (Section 8.1.3). Diaz et al. (2013) exposed Sprague Dawley rats to three kinds of $PM_{2.5}$—primary particles that were obtained directly from a tunnel with roadway gases removed by a denuder (P), secondary organic aerosol formed from photochemical oxidation of the primary tunnel gases (SOA), and photochemically aged primary particles plus SOA (P + SOA). Lymphocytes in BALF increased following 1-day exposure to P ($p < 0.05$) and 2-day exposure to P + SOA ($p < 0.07$), while neutrophils in BALF increased after 2-day exposure to SOA ($p < 0.01$) and P + SOA ($p < 0.05$). Mauderly et al. (2011) exposed mice and rats for 1 week to simulated coal emissions with and without the addition

of a particle filter. The increase in MIP-2 seen in the BALF of F344 ($p < 0.05$) was prevented by filtration, indicating that the particulate part of the mixture had a role in the pro-inflammatory response.

Two of the aforementioned studies investigated the relationship between pulmonary inflammation and neurohumoral or endocrine pathways. Chiarella et al. (2014) evaluated the role of the SNS in modulating inflammation following exposure to $PM_{2.5}$ using knock-out mice lacking the β_2-adrenergic receptor specifically on macrophages. While wild type C57BL/6 mice exposed for several days to $PM_{2.5}$ CAPs in Chicago had increased IL-6 mRNA and protein in BALF ($p < 0.05$), knock-out mice had a greatly diminished response ($p < 0.05$). This finding implicates agonists of the β_2-adrenergic receptor, i.e., catecholamines, as partly responsible for the effects of $PM_{2.5}$ on IL-6 through the stimulation of β_2-adrenergic receptors on lung macrophages. Supporting evidence was provided by the finding that treatment with an agonist of the β_2-adrenergic receptor enhanced IL-6 levels in the BALF of wild type mice exposed to $PM_{2.5}$ ($p < 0.05$) Additionally, levels of the catecholamine norepinephrine were increased in BALF and brown adipose tissue following $PM_{2.5}$ exposure ($p < 0.05$), indicative of increased sympathetic tone. Taken together, results of this study provide evidence that exposure to $PM_{2.5}$ activated the sympathetic nervous system, which enhanced the release of IL-6 from lung macrophages. Downstream effects of macrophage-derived IL-6 on thrombosis were also examined (see Section 6.1.12).

Aztatzi-Aguilar et al. (2015) evaluated the RAS and kallikrein-kinin endocrine system in the lung in Sprague Dawley rats exposed for several days to $PM_{2.5}$ CAPs in Mexico City. Increased protein expression of IL-6 in lung tissue ($p < 0.05$) was accompanied by increased expression of the angiotensin I receptor gene, reduced angiotensin I receptor protein levels, and increased angiotensin converting enzyme mRNA levels ($p < 0.05$). Protein levels of angiotensin converting enzyme and mRNA levels of angiotensin II receptor mRNA were not impacted. In addition, $PM_{2.5}$ CAPs exposure resulted in increased mRNA levels for kallikrein-1 enzyme ($p < 0.05$). Kallikrein-1 is a serine protease enzyme required to produce kinin peptides, which are necessary to activate bradykinin receptors The RAS mediates vasoconstriction and vascular oxidative stress and inflammation and is counterbalanced by the kallikrein-kinin endocrine system via bradykinin-mediated production of nitric oxide, an important vasodilator. The SNS is known to regulate the endocrine systems. Although not specifically examined in this study, $PM_{2.5}$ exposure-mediated activation of the SNS activation may link $PM_{2.5}$ exposure and the RAS.

Morphology

As described in the 2009 PM ISA (U.S. EPA, 2009), several studies found that exposure to $PM_{2.5}$ CAPs in Boston, MA resulted in mild morphological changes in the lung including hyperplasia of the terminal bronchiolar and alveolar ductal epithelium and pulmonary arteriolar edema (Rhoden et al., 2004; Batalha et al., 2002; Saldiva et al., 2002). Recently, Yoshizaki et al. (2016) evaluated the effects of multiday exposure to Sao Paulo, Brazil $PM_{2.5}$ CAPs on nasal epithelium in male and female BALB/c mice. The influence of estrus cycle in female was also determined. $PM_{2.5}$ CAPs exposure resulted in an

increase in acidic mucus content in males and a decrease in acidic mucus content in females ($p < 0.05$) (Table 5-14). $PM_{2.5}$ CAPs exposure had no effect on neutral mucus content in either male or female mice. In addition, estrus cycle had no effect on mucus content or response to $PM_{2.5}$ CAPs exposure. Upregulation of message and protein levels of estrogen, aryl hydrocarbon receptors, and cytochrome P450 proteins was examined in nasal epithelium. $PM_{2.5}$ CAPs exposure resulted in decreased mRNA levels of estrogen receptor β2 and cytochrome 1b1 in female mice ($p < 0.01$). Female rats in diestrus, but not estrus or proestrus, exhibited decreased mRNA levels of estrogen receptor β2, cytochrome 1b1, and cytochrome 1a2 ($p < 0.05$). Estrogen receptor protein levels were decreased in nasal epithelium and aryl hydrocarbon receptor protein levels were increased in submucosal gland by $PM_{2.5}$ CAPs exposure in female mice ($p < 0.05$). Only female rats in estrus not diestrus or proestrus) exhibited these changes ($p < 0.05$).

Allergic Sensitization

The 2009 PM ISA (U.S. EPA, 2009) described numerous studies demonstrating the adjuvant potential of PM. While most of these studies involved intra-nasal or other noninhalation routes of exposure, one inhalation study demonstrated a strong adjuvant effect of PM (Whitekus et al., 2002). In this study, mice were exposed to resuspended DEP and subsequently challenged with OVA. OVA-specific IgG1 and IgE were enhanced by DEP exposure in the absence of general markers of inflammation. This effect, as well as DEP-mediated lipid peroxidation and protein oxidation, was blocked by pretreatment with the thiol antioxidants N-acetylcysteine and bucillamine. These results indicate that oxidative stress played a role in DEP-mediated allergic sensitization. Recent studies that have become available since the last review, while supportive of the adjuvant potential of $PM_{2.5}$, involve noninhalation routes of exposure (i.e., subcutaneous, intra-peritoneal and oropharyngeal aspiration).

Pathways Related to Otitis Media

Kim et al. (2016b) conducted a transcriptomic analysis in the middle ear following exposure to DEP (Table 5-14). BALB/c mice were exposed to resuspended DEP for several days and gene expression microarray and pathway analysis were performed on tissue collected 9 days later. In the middle ear, numerous genes were upregulated or downregulated because of DEP exposure. Pathway analysis identified several of these genes as potential biomarkers for DEP-related otitis media including cholinergic receptor muscarinic 1, erythropoietin, son of sevenless homolog 1, estrogen receptor 1, cluster of differentiation 4, and interferon α 1.

5.1.7.4 Summary of Respiratory Effects in Healthy Populations

Similar to results described in the 2009 PM ISA (U.S. EPA, 2009), evaluation of the current epidemiologic evidence indicates that short-term $PM_{2.5}$ exposures are inconsistently related to respiratory effects in healthy adults. Where there is supporting evidence, changes tend to be transient and confounding by copollutants is inadequately examined. For general community daily average exposures, there is some consistent epidemiologic evidence for $PM_{2.5}$-related respiratory effects in healthy children, but the evidence is limited in number for any one particular endpoint. In addition to the limited supporting evidence, uncertainties remain as to whether short-term $PM_{2.5}$ exposure leads to overt and persistent respiratory effects in healthy populations or is related to such effects across a wide range of $PM_{2.5}$ concentrations.

Controlled human exposure and animal toxicological studies also examined pulmonary function and inflammation responses to short-term exposure to $PM_{2.5}$ CAPs. While evidence from controlled human exposure studies was inconsistent, animal toxicological studies clearly demonstrated changes in pulmonary function and inflammation. Recent evidence supports the previously observed involvement of lung irritant responses in mediating the changes in respiratory function, such as rapid shallow breathing, seen following exposure to $PM_{2.5}$. BALF cellular infiltrates are commonly found following exposure to $PM_{2.5}$ and appear to primarily involve recruitment of macrophages and neutrophils into the airways. In addition, several studies implicate changes in various cytokines in BALF and lung tissue. Increases in numbers of specific macrophages in lung tissue provides evidence for the activation of innate immunity over several days to several weeks. Pulmonary injury and oxidative stress responses were inconsistent. However, a study evaluated in the 2009 PM ISA demonstrated oxidative stress-mediated allergic sensitization due to inhalation of $PM_{2.5}$. Different regions of the respiratory tract are impacted by short-term $PM_{2.5}$ exposure with morphologic changes observed in the terminal bronchiolar and alveolar regions and changes in mucus profile found in in nasal epithelium. A mechanistic study shows involvement of the SNS in augmenting macrophage-mediated inflammatory effects following exposure to $PM_{2.5}$. In addition, the RAS and kallikrein-kinin endocrine system in the lung were impacted by short-term exposure to $PM_{2.5}$.

Variability in results observed in controlled human exposure and animal toxicological studies could be due to the time points assessed (too long after exposure), the nature of the exposures (dose, particle composition), the sensitivity of the model (species, strain, age, predisposing factors) and the sensitivity of the measurements used. When $PM_{2.5}$ CAPs are used, the composition of the PM, which is related to source and season, could add to this variability. Finally, whether the exposure was a single time or repeated could have a large effect. Repeated exposures, even those less than 30 days, may trigger adaptive physiologic and cellular responses that are not present for very short term single exposure studies, such as single acute exposures.

5.1.8 Respiratory Effects in Populations with Cardiovascular Disease

Given the prevalence of cardiovascular disease in the general population and the inter-relationships between the cardiovascular and respiratory systems, numerous animal toxicological studies have been conducted in animal models of cardiovascular disease. Many of these studies were evaluated in the 2004 PM AQCD and the 2009 PM ISA (U.S. EPA, 2009). Pulmonary function responses were examined following single and multiday exposure of hypertensive rats to $PM_{2.5}$ CAPs from New York, Research Triangle Park, NC, Taiwan, and Boston, MA (Kodavanti et al., 2005; Lei et al., 2004; Nadziejko et al., 2002; Godleski et al., 2000). Alterations in tidal volume and breathing frequency were found, indicating the involvement of lung irritant receptors and the triggering of local reflexes in the response to short-term $PM_{2.5}$ exposure. Multiday exposure of SH rats to $PM_{2.5}$ CAPs in the Netherlands altered levels of BALF CC16 in a concentration-dependent manner (Kooter et al., 2006). CC16 is a secretory product of nonciliated bronchiolar Club cells and is a marker of injury and thought to contribute to the control of inflammation. However, there was no evidence of pulmonary injury (as assessed by BALF LDH levels) in this study or another study involving $PM_{2.5}$ CAPs in Research Triangle Park, NC (Kodavanti et al., 2005). Kooter et al. (2006) also found that a multiday exposure of SH rats to $PM_{2.5}$ CAPs in the Netherlands increased levels of heme oxygenase-1, an indicator of oxidative stress. Several studies in hypertensive rats evaluated pulmonary inflammation following exposure to $PM_{2.5}$ CAPs. While some studies found increased numbers of inflammatory cells in BALF (and even a correlation between $PM_{2.5}$ CAPs concentrations and numbers of neutrophils) (Cassee et al., 2005; Lei et al., 2004), others did not (Kooter et al., 2006; Kodavanti et al., 2005). Campen et al. (2006) found a concentration-dependent effect on inflammation in $PM_{2.5}$ exposed-ApoE knockout mice, a model of atherosclerosis.

A few recent studies add to this evidence base (Table 5-15). Rohr et al. (2010) exposed SH rats to $PM_{2.5}$ CAPs in Detroit and found no evidence of lung injury as assessed by BALF protein levels. Farraj et al. (2015) studied the effect of a 4-hour exposure of SH rats to $PM_{2.5}$ CAPs in two seasons, summer and winter, in Research Triangle Park, NC. Activities of LDH, glutathione S transferase, and CuZn SOD, indicators of injury and oxidative stress, were decreased by exposure to summer $PM_{2.5}$ CAPs but not winter $PM_{2.5}$ CAPs ($p \leq 0.05$). $PM_{2.5}$ CAPs concentration was higher in summer than in winter, but metal exposure concentrations were roughly equivalent. Concomitant exposure to 200 ppb O_3 appeared to have little additional effect on these parameters. No effects on inflammation were found by Rohr et al. (2010) or Farraj et al. (2015). Furthermore, Tyler et al. (2016) conducted an inhalation exposure of ApoE knockout mice to resuspended DEP and found no increase in inflammatory cells or cytokines in the BALF and no increase in particle uptake in bronchial macrophages, despite inflammatory effects in the hippocampus (Section 8.1.3). Overall, short-term $PM_{2.5}$ exposure results in pulmonary effects in some studies but not others. The most consistent evidence is for changes in pulmonary function.

Table 5-15 Study-specific details from animal toxicological studies of short-term $PM_{2.5}$ exposure and respiratory effects in models of cardiovascular disease.

Study/Study Population	Pollutant	Exposure	Endpoints
Farraj et al. (2015) Species: Rat Sex: Male Strain: SH Age/Weight: 12 weeks	$PM_{2.5}$ CAPs Research Triangle Park, NC Particle size: 324 nm summer, 125 nm winter Control: Filtered air	Route: Whole-body inhalation Dose/Concentration: 85-170 µg/m^3 Duration: 4 h Time to analysis: 24 hr Modifier: Telemeter implanted, summer and winter	Lung Injury—BALF LDH activity Inflammation—BALF cells BALF antioxidant enzymes—GST and CuZn SOD
Rohr et al. (2010) Species: Rat Strain: Spontaneously hypertensive (SH) Wistar Kyoto (WKY) Sex: Male Age/Weight: 11−12 weeks	$PM_{2.5}$ CAPs residential urban Detroit, MI Particle sizes: $PM_{2.5}$	Route: Whole-body inhalation Dose/Concentration: 507 µg/m^3 Duration of exposure: 8 h, 13 consecutive days Time to analysis: 24 h	BALF cells Lung Injury • BALF protein content
Tyler et al. (2016) Species: Mouse Strain: ApoE knockout Age/Weight: 6−8 weeks	DEP, resuspended Particle size: 1.5−3.0 µm ± 1.3−1.6 µm Control: Filtered air	Route: Whole-body inhalation Dose/Concentration: 300 µg/m^3 Duration: 6 h	BALF cells and cytokines Particle uptake in bronchial macrophages

ApoE = Apolipoprotein E; BALF = bronchoalveolar lavage fluid; CAPs = concentrated ambient particles; CuZn SOD = copper, zinc superoxide dismutase; GST = glutathione S transferase; LDH = lactate dehydrogenase; SH = spontaneously hypertensive.

5.1.9 Respiratory Mortality

Studies that examine the association between short-term $PM_{2.5}$ exposure and cause-specific mortality outcomes, such as respiratory mortality, provide additional evidence for $PM_{2.5}$-related respiratory effects, specifically whether there is evidence of an overall continuum of effects. The multicity epidemiologic studies evaluated in the 2009 PM ISA provided evidence of consistent positive associations, ranging from 1.0−2.2% for a 10 µg/m^3 increase in 24-hour average $PM_{2.5}$ concentrations, between short-term $PM_{2.5}$ exposure and respiratory mortality (U.S. EPA, 2009). However, compared to associations between short-term $PM_{2.5}$ exposure and cardiovascular and total (nonaccidental) mortality, confidence intervals were larger due to respiratory mortality comprising a smaller percentage of all mortalities. Across studies, the $PM_{2.5}$ effect on respiratory mortality was observed to be immediate with associations occurring in the range of lag 0 to 2 day(s). A limitation within the evidence was that multicity studies did not extensively examine potential copollutant confounding, but evidence from

single-city studies suggested that the $PM_{2.5}$-respiratory mortality relationship was not confounded by gaseous copollutants. Additionally, there was limited coherence across epidemiologic and controlled human exposure studies, which complicated the interpretation of the associations observed for short-term $PM_{2.5}$ exposure and respiratory mortality.

Recent multicity epidemiologic studies along with meta-analyses provide additional evidence of generally consistent positive associations between short-term $PM_{2.5}$ exposure and respiratory mortality (Figure 11-2). In addition to providing evidence that supports the rather immediate timing of respiratory mortality effects (i.e., lag 0 to 1 days), some recent studies also provide initial evidence that respiratory mortality effects due to short-term $PM_{2.5}$ exposure may be more prolonged (i.e., lags >2 days). Unlike the studies evaluated in the 2009 PM ISA (U.S. EPA, 2009), some recent studies have also further evaluated the $PM_{2.5}$-respiratory mortality relationship by examining cause-specific respiratory mortality outcomes (i.e., COPD, pneumonia, and LRTI) (Samoli et al., 2014; Janssen et al., 2013). Overall, the results reported in the studies that examine cause-specific respiratory mortality outcomes are generally consistent with the results for all respiratory mortality, but the smaller number of mortality events observed results in unstable estimates with larger uncertainty.

Evidence to further characterize the $PM_{2.5}$-respiratory mortality relationship is also provided by recent epidemiologic studies. Overall, these studies continue to support a relationship between $PM_{2.5}$ and respiratory mortality and provide additional evidence that: gaseous pollutants do not confound the $PM_{2.5}$-respiratory mortality relationship; $PM_{2.5}$ effects on respiratory mortality may not be limited to the first few days after exposure; the magnitude of the association tends to be largest during warmer months; and there is inconsistent evidence that temperature extremes modify associations between short-term $PM_{2.5}$ exposure and respiratory mortality (see Section 5.1.10).

5.1.10 Policy-Relevant Considerations

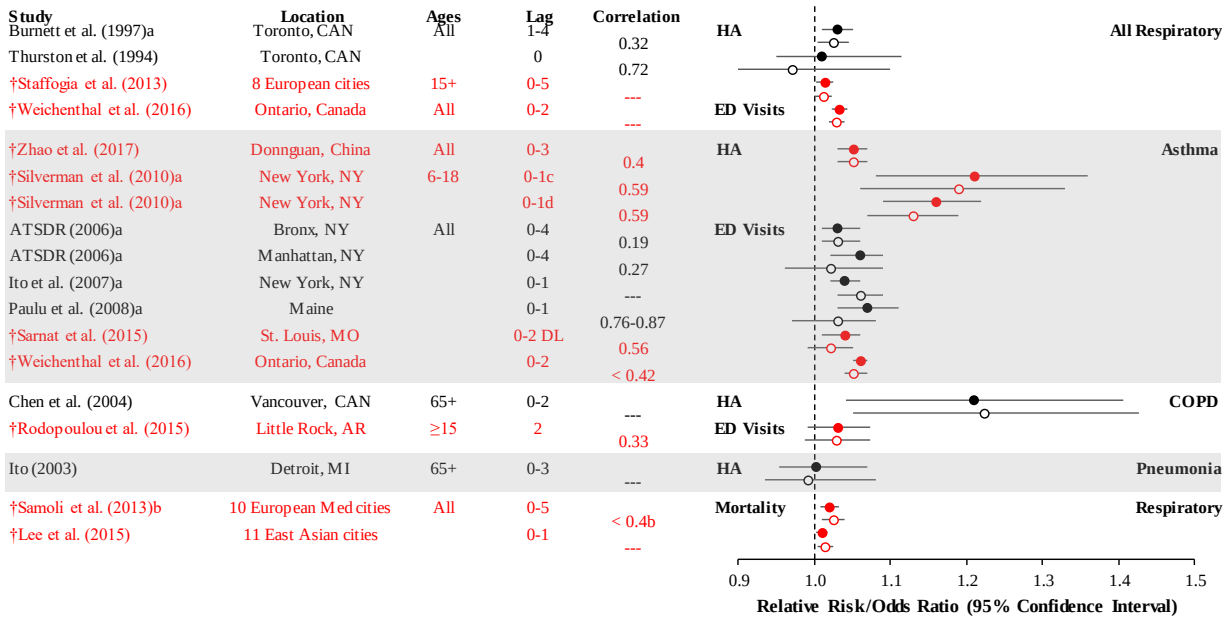
Epidemiologic studies that examined short-term $PM_{2.5}$ exposure and respiratory-related effects often conduct additional analyses to assess whether the associations observed are due to chance, confounding, or other biases. Within this section, evidence is evaluated across epidemiologic studies to further assess the association between short-term $PM_{2.5}$ exposure and respiratory-related effects, focusing specifically on those analyses that address policy-relevant issues: copollutant confounding (Section 5.1.10.1), model specification (Section 0), lag structure (Section 5.1.10.3), the role of season and temperature on $PM_{2.5}$ associations (Section 5.1.10.4), averaging time of $PM_{2.5}$ concentrations (Section 5.1.10.5), and concentration-response (C-R) and threshold analyses (Section 5.1.10.6). The studies that inform these issues are primarily epidemiologic studies that conducted time-series or case-crossover analyses focusing on respiratory-related ED visits and hospital admissions and respiratory mortality. Studies examining additional endpoints, such as subclinical markers of a PM-related respiratory

effect (e.g., lung function, inflammation, etc.), may also examine some of these issues, but are not the focus of this evaluation.

5.1.10.1 Examination of Potential Copollutant Confounding

The potential confounding effect of copollutants is a previously identified source of uncertainty in the examination of the relationship between short-term $PM_{2.5}$ exposure and respiratory effects, and thus requires careful consideration particularly with respect to whether the magnitude and direction of $PM_{2.5}$ risk estimates change in copollutant models. Compared to the evidence available at the completion of the 2009 PM ISA, many recent studies conducted analyses that inform whether the relationship between short-term $PM_{2.5}$ exposures and respiratory-related effects, specifically hospital admissions, ED visits, and respiratory mortality, may be confounded by copollutants. Recent studies have examined the potential for copollutant confounding by evaluating copollutant models that include O_3 (Figure 5-9), NO_2, (Figure 5-10), SO_2 (Figure 5-11), CO (Figure 5-12) and $PM_{10–2.5}$ (Figure 5-13). These recent studies address a previously identified data gap by informing the extent to which effects associated with exposure to $PM_{2.5}$ are independent of coexposures to correlated copollutants. Generally, these studies provide evidence that the association between short-term $PM_{2.5}$ exposures and respiratory health outcomes is robust to the inclusion of copollutants in a statistical model. This evidence provides support for an independent association between $PM_{2.5}$ concentrations and respiratory-related effects.

Building off studies evaluated in the 2009 PM ISA, recent studies that examined the potential confounding effects of O_3 on associations between short-term $PM_{2.5}$ exposure and respiratory-related outcomes continue to report correlations between O_3 and $PM_{2.5}$ ranging from low (<0.4) to high (>0.7). Across the respiratory-related outcomes examined, where positive associations with $PM_{2.5}$ were reported in single-pollutant models, associations were often attenuated in copollutant models, but remained positive. The most extensive evaluation of potential copollutant confounding was for studies focusing on asthma hospital admissions and ED visits, where recent studies report results that are consistent with those observed in studies evaluated in the 2009 PM ISA (Figure 5-9). Additionally, recent evidence provides additional support for positive $PM_{2.5}$ associations with hospital admissions and ED visits for all respiratory diseases as well as initial evidence indicating that $PM_{2.5}$ associations with respiratory mortality are relatively unchanged in copollutant models with O_3. While panel studies infrequently reported results from copollutant models, adverse associations reported across several endpoints were generally persistent, although in some cases attenuated, in copollutant models with O_3. Individual panel study results from copollutant models with O_3 are discussed within the relevant endpoint sections (Section 5.1.2.2, Section 0, and Section 5.1.7.1).

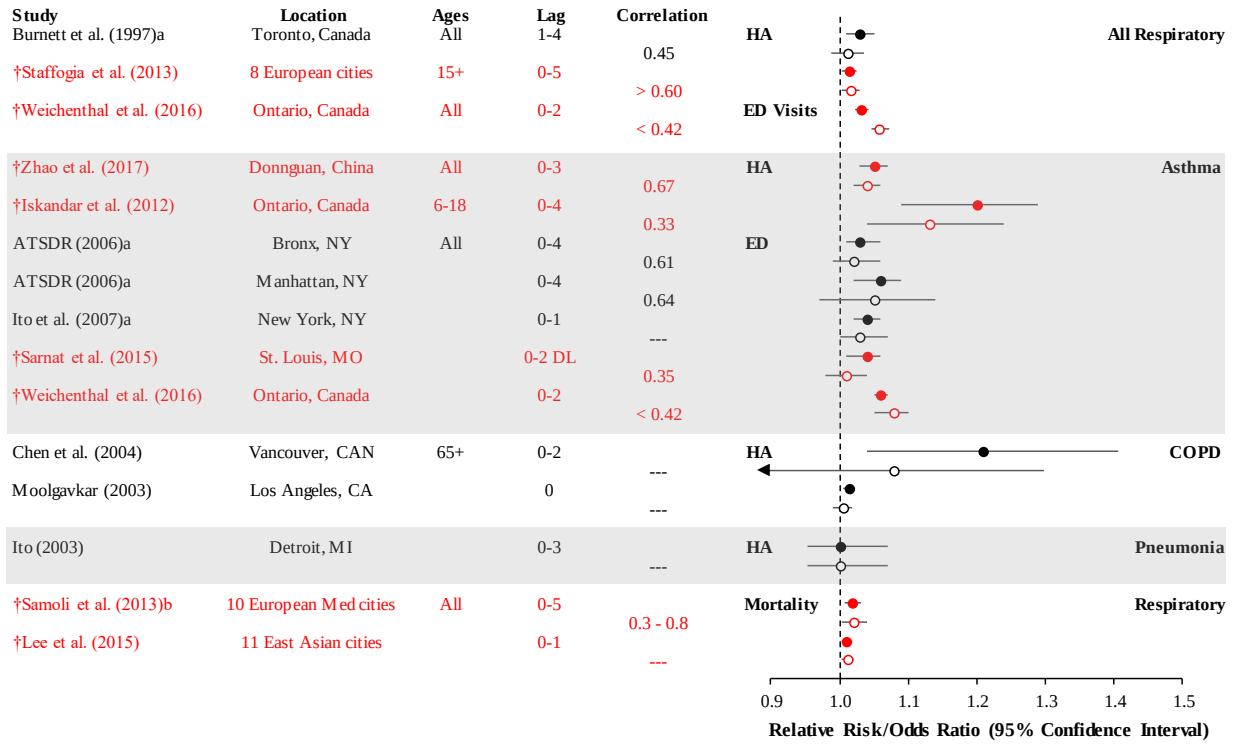


DL = distributed lag model.

Note: †Studies published since the 2009 PM ISA. Black text = U.S. and Canadian studies included in the 2009 PM ISA. a = copollutant analyses for warm season only; b = copollutant analysis only conducted for lag 0−5 days; c = Intensive Care Unit (ICU) admissions; [d] = non-ICU admissions. Corresponding quantitative results are reported in Supplemental Material (U.S. EPA, 2018).

Figure 5-9 Summary of associations for short-term $PM_{2.5}$ exposure and respiratory-related outcomes from copollutant models with ozone (O_3) for a 10 μg/m^3 increase in 24-hour average $PM_{2.5}$ concentrations.

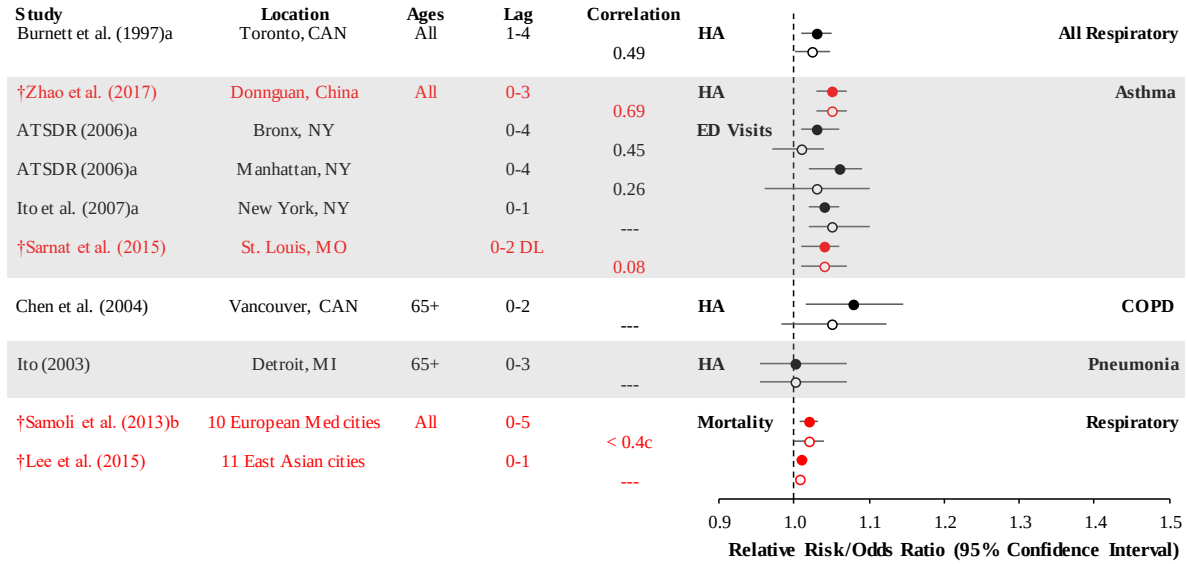
Across studies, $PM_{2.5}$ associations with respiratory-related outcomes remain positive, although in some cases attenuated, in copollutant models with NO_2. Generally, $PM_{2.5}$ was reported to be low to moderately correlated with NO_2 ($r < 0.7$). Similar to the evaluation of copollutant models with O_3, most of the evidence with respect to potential copollutant confounding by NO_2 is from studies examining asthma hospital admissions and ED visits with recent studies supporting the results from studies evaluated in the 2009 PM ISA. Recent studies also build on the initial evidence reported in the 2009 PM ISA that $PM_{2.5}$ associations are robust to control for NO_2 in studies examining hospital admissions and ED visits for all respiratory diseases and provide initial evidence that $PM_{2.5}$ associations with respiratory mortality are also robust (Figure 5-10). While panel studies infrequently reported results from copollutant models, adverse associations reported across several endpoints were persistent, although in some cases attenuated, in copollutant models with NO_2. Individual panel study results from copollutant models with NO_2 are discussed within the relevant endpoint sections (Section 5.1.2.2, Section 0, Section 5.1.2.4, Section 5.1.4.2, Section 5.1.4.4, and Section 5.1.7.1).



Note: †Studies published since the 2009 PM ISA. Black text = U.S. and Canadian studies included in the 2009 PM ISA. a = copollutant analyses for warm season only; b = copollutant analysis only conducted for lag 0−5 days. Corresponding quantitative results are reported in Supplemental Material (U.S. EPA, 2018).

Figure 5-10 Summary of associations for short-term $PM_{2.5}$ exposure and respiratory-related outcomes from copollutant models with NO_2 for a 10 µg/m^3 increase in 24-hour average $PM_{2.5}$ concentrations.

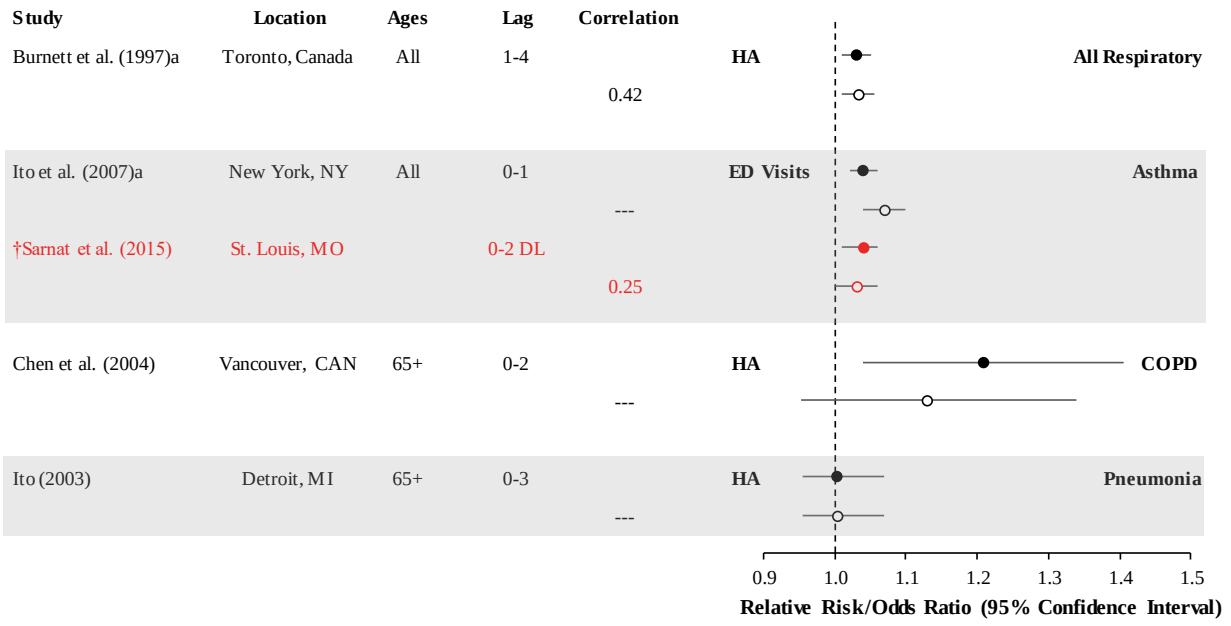
The examination of potential copollutant confounding by SO_2 on the relationship between short-term $PM_{2.5}$ exposure and respiratory-related outcomes is similar to that observed for O_3 and NO_2, with most of the evidence from studies examining asthma hospital admissions and ED visits (Figure 5-11). Across studies, correlations between $PM_{2.5}$ and SO_2 were primarily <0.5. Most of the studies that examined copollutant models with SO_2 were evaluated in the 2009 PM ISA, but recent studies add to the evidence base for asthma hospital admissions and ED visits further demonstrating that associations are relatively unchanged in copollutant models with SO_2, while also providing new evidence for respiratory mortality. While panel studies infrequently reported results from copollutant models, adverse associations reported across several endpoints were generally persistent, although in some cases attenuated, in copollutant models with SO_2. Individual panel study results from copollutant models with SO_2 are discussed within the relevant endpoint sections (Section 0, Section 5.1.2.4, Section 5.1.4.2, Section 5.1.4.4, and Section 5.1.7.1).



Note: †Studies published since the 2009 PM ISA. Black text = U.S. and Canadian studies included in the 2009 PM ISA.
a = copollutant analyses for warm season only; b = copollutant analysis only conducted for lag 0−5 days; c = correlations were <0.4 in all cities except Milan and Turin where it was ~0.6. Corresponding quantitative results are reported in Supplemental Material (U.S. EPA, 2018).

Figure 5-11 Summary of associations for short-term $PM_{2.5}$ exposure and respiratory-related outcomes from copollutant models with sulfur dioxide (SO_2) for a 10 µg/m^3 increase in 24-hour average $PM_{2.5}$ concentrations.

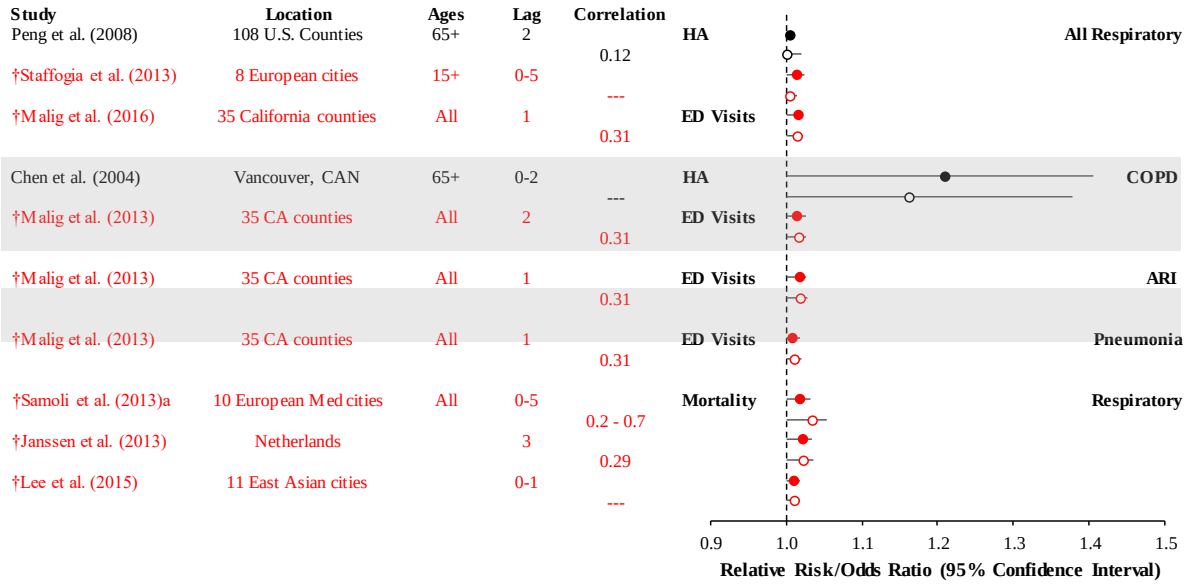
Compared to O_3, NO_2, and SO_2 the assessment of potential copollutant confounding by CO has not been extensively examined in recent studies (Figure 5-12). However, across the studies evaluated in the 2009 PM ISA, along with the recent study conducted by Sarnat et al. (2015) examining asthma ED visits, evidence indicates that in studies that observed positive associations with $PM_{2.5}$, the association was relatively unchanged in copollutant models with CO.



Note: †Studies published since the 2009 PM ISA. Black text = U.S. and Canadian studies included in the 2009 PM ISA.
a = copollutant analyses for warm season only. Corresponding quantitative results are reported in Supplemental Material (U.S. EPA, 2018).

Figure 5-12 Summary of associations for short-term $PM_{2.5}$ exposure and respiratory-related outcomes from copollutant models with carbon monoxide (CO) for a 10 µg/m^3 increase in 24-hour average $PM_{2.5}$ concentrations.

Recent studies also greatly expand upon the examination of potential copollutant confounding by $PM_{10-2.5}$ (Figure 5-13). Across the studies evaluated, correlations between $PM_{2.5}$ and $PM_{10-2.5}$ were primarily low ($r < 0.4$). $PM_{2.5}$ associations for all respiratory-related outcomes are generally unchanged in models that adjust for $PM_{10-2.5}$. However, an uncertainty across studies that examined either single- or copollutant models that include $PM_{10-2.5}$ is the variety of methods employed to estimate $PM_{10-2.5}$ concentrations and the potential measurement error associated with each method (Section 2.5.1.2.3 and Section 3.3.1.1).



Note: †Studies published since the 2009 PM ISA. Black text = U.S. and Canadian studies included in the 2009 PM ISA.
a = copollutant analysis only conducted for lag 0−5. Corresponding quantitative results are reported in Supplemental Material (U.S. EPA, 2018).

Figure 5-13 Summary of associations for short-term $PM_{2.5}$ exposure and respiratory-related outcomes from copollutant models with $PM_{10-2.5}$ for a 10 μg/m³ increase in 24-hour average $PM_{2.5}$ concentrations.

In conclusion, since the 2009 PM ISA, there has been growth in the number of studies that examined potential confounding of the relationship between short-term $PM_{2.5}$ exposure and respiratory-related outcomes by copollutants. These recent studies provide additional evidence supporting that $PM_{2.5}$ associations are relatively unchanged, although in some instances attenuated as well as increased, in copollutant models with gaseous and particle pollutants.

5.1.10.1.1 $PM_{2.5}$ within the Multipollutant Mixture

Although copollutant models are important in assessing potential copollutant confounding, it is well known that collinearity between pollutants can result in unstable estimates and that air masses are not limited to just two pollutants (Dominici et al., 2010). Therefore, in addition to copollutant models, studies that examine multipollutant exposures can provide additional information on the role of $PM_{2.5}$ within the complex air pollution mixture.

Analyses of pollutant mixtures, which use an array of statistical methods and pollutant combinations, for respiratory-related effects have focused on asthma ED visits. These studies indicate

increases in asthma ED visits when ambient concentrations of $PM_{2.5}$ and a copollutant(s) are simultaneously high, but do not clearly show a larger increase than with $PM_{2.5}$ alone. In analyses conducted in Atlanta (Winquist et al., 2014a) and then subsequently for the entire state of Georgia (Xiao et al., 2016), $PM_{2.5}$ was a priori grouped with the other criteria pollutants (i.e., O_3, CO, NO_2, and SO_2) to examine their joint effect on pediatric asthma ED visits. In both studies, $PM_{2.5}$ was associated with pediatric asthma ED visits in single-pollutant models. However, in Xiao et al. (2016) joint effect models were relatively similar to the single-pollutant model, but in Winquist et al. (2014a) the joint effect model results were much larger (quantitative results only presented for warm season, no interaction model) (Table 5-16). Instead of defining air pollution mixtures a priori, other analyses examined whether there were groups of days with similar pollution profiles, specifically days representative of high and low air pollution exposures based on quartiles of $PM_{2.5}$, NO_2, CO, and O_3 concentrations using a classification and regression tree (C&RT) approach. This approach was used to examine associations between high and low air pollution days and asthma in Atlanta, GA; St. Louis, MO; and Dallas, TX. In Atlanta, GA. Gass et al. (2014) reported that RRs with $PM_{2.5}$ were largest in magnitude for days when $PM_{2.5}$ concentrations were in the highest quartile, while NO_2 was in the lowest two quartiles, as well as days when both NO_2 and $PM_{2.5}$ were in higher quartiles. Gass et al. (2015) expanded the analysis of Gass et al. (2014) to include Atlanta, GA; St. Louis, MO; and Dallas, TX. The authors observed that pollution profiles varied across cities resulting in the overall quartiles of pollutant concentrations for a particular mixture sometimes differing from the distribution of concentrations within an individual city. For example, $PM_{2.5}$ concentrations were in the 4th quartile for one city, but the overall mixture across cities showed that $PM_{2.5}$ concentrations were in the 1st quartile. Gass et al. (2015) reported evidence of mixtures with high $PM_{2.5}$ concentrations having the association largest in magnitude, but associations were similar in magnitude in instances when $PM_{2.5}$ concentrations were in the lowest quartile. While the other multipollutant studies focused on examining combinations of pollutants at different parts of the individual pollutant concentration distribution, Toti et al. (2016) in Houston, TX focused on pollutant concentrations on same and successive days that are in the 4th quartile of each pollutant concentration distribution. Across the different combinations, as well as those that included $PM_{2.5}$, the authors reported ORs that were relatively similar in magnitude. In contrast with U.S. cities, the association between asthma ED visits and an air quality health index (AQHI), which combines $PM_{2.5}$, NO_2, and O_3 based on mortality risk, in Windsor, ON, appears to be influenced by either $PM_{2.5}$ or O_3, depending on the lag (Szyszkowicz and Kousha, 2014). The OR for the AQHI was similar to that of O_3 at lag 0 and that of $PM_{2.5}$ at lags 4 and 5 (Table 5-16). Whereas the previous studies evaluated focused on multipollutant mixtures, Weichenthal et al. (2016) examined whether there was evidence of effect modification of the $PM_{2.5}$-asthma ED visit association in 15 Ontario cities. The authors observed that the $PM_{2.5}$ association increased with increasing city-level oxidative potential of $PM_{2.5}$, NO_2, and O_3 combined (Weichenthal et al., 2016).

In summary, the studies that examined multipollutant mixtures that include $PM_{2.5}$ indicate that mixtures encompassing days with high $PM_{2.5}$ concentrations are often those mixtures with the highest risk estimates. Additionally, when comparing single-pollutant $PM_{2.5}$ results with those based on mixtures, the

risk estimate associated with the mixture is relatively similar and, in some cases, larger than that observed for $PM_{2.5}$.

5.1.10.2 Model Specification

An underlying uncertainty in the interpretation of epidemiologic study results is the difference in the magnitude and precision, and sometimes direction, of risk estimates across studies. It has remained difficult to elucidate why there are differences in risk estimates, but it is often thought to reflect the different statistical models used in each study. However, it has also been hypothesized that other factors may also be contributing to these observed differences such as differences in $PM_{2.5}$ composition or demographics between study locations (e.g., Section 11.6.3).

Recent epidemiologic studies have conducted sensitivity analyses to assess whether $PM_{2.5}$ associations with respiratory-related outcomes are dependent on the statistical model employed, in an attempt to reduce potential biases in observed associations. Such sensitivity analyses assess the influence of alternative model specifications, such as increasing degrees of freedom (df) to account for temporal trends, or the inclusion of alternative weather covariates. Collectively, recent studies that examined model specification provide evidence that $PM_{2.5}$ associations are generally robust to increasing the df per year to account for temporal trends, but in some cases attenuation of the association was observed when these additional df were included. Additionally, studies reported that $PM_{2.5}$ associations are relatively unchanged regardless of the weather covariates included in statistical models (i.e., different weather variables or lag days and df specified for the weather variables). Collectively, these studies reduce the uncertainty associated with the differences in the magnitude and direction of risk estimates in epidemiologic studies potentially resulting from the different statistical models employed across studies.

Several studies examined different approaches to control for seasonality or temporal trends by either increasing or decreasing the df/year used in studies of short-term $PM_{2.5}$ exposure and respiratory-related effects. $PM_{2.5}$-associated increases in asthma hospital admissions and ED visits were consistently observed when different df/year were used to account for temporal trends. For example, studies conducted in several U.S. cities reported that $PM_{2.5}$ associations remained robust to alternative

degrees of freedom (2−28 df/year) for temporal trends (Alhanti et al., 2016; Sarnat et al., 2015; Kim et al., 2012; Silverman and Ito, 2010). When examining all respiratory-related hospital admissions and ED visits, an examination of the control for temporal trends was limited to a few studies, all of which were conducted in Europe, (Stafoggia et al., 2013), in eight European cities, and (Lanzinger et al., 2016b), in the UFIREG project. Stafoggia et al. (2013) provided evidence that uniformly applying the same df/year across all cities could underestimate the $PM_{2.5}$ association. This was reflected by comparing results for models where 8 df/year was applied to each city or the df/year applied to each city was selected by minimizing the absolute value of the sum of the partial autocorrelation functions (PACF) to the base model, which employed a three-way interaction between year, month, and day of week to account for temporal trends. The authors reported that using 8 df/year attenuated the association while the PACF approach, which resulted in df/year ranging from 3−9 for each city, resulted in relatively unchanged $PM_{2.5}$ risk estimates. However, Lanzinger et al. (2016b) reported that $PM_{2.5}$ associations were relatively unchanged in models employing 3, 4, or 6 df/year to account for temporal trends.

In addition to conducting sensitivity analyses that examine control for temporal trends, some studies also assessed whether associations between short-term $PM_{2.5}$ exposure and respiratory-related hospital admissions and ED visits were sensitive to alternative weather covariates. Altering the lags (e.g., 0, 2-day average) for temperature and humidity in New Jersey (Gleason et al., 2014), or adjusting for maximum temperature in Atlanta, GA and St. Louis, MO (Alhanti et al., 2016) resulted in $PM_{2.5}$ associations that were relatively unchanged. Stafoggia et al. (2013) also examined the influence of including a longer temperature lag (i.e., 0−6 days) in the model to account for the potential prolonged effects of temperature on respiratory diseases. Replacing the 0−1-day lag temperature covariate with a 0−6-day lag term resulted in a relatively similar effect (lag 0−1: 1.36% [95% CI: 0.23, 2.49]; lag 0−6: 1.48% [95% CI: 0.29, 2.69]).

While most studies examined the influence of model specification on $PM_{2.5}$ associations with respiratory-related effects by focusing specifically on the inclusion of alternative weather covariates in statistical models, a few studies conducted analyses to examine whether there was evidence of model misspecification and potential residual confounding. In studies conducted in Atlanta, GA (Strickland et al., 2010) and St. Louis, MO (Sarnat et al., 2015), model misspecification was evaluated by examining associations with $PM_{2.5}$ concentrations on the day after an asthma ED visit (lag −1 day). In both studies the results of the base model are relatively similar to those reported for lag −1 day (i.e., (Strickland et al., 2010), warm season: RR = 1.05 [95% CI: 1.02, 1.08], lag 0−2, RR = 1.03 [95% CI: 1.00, 1.05], lag −1; (Sarnat et al., 2015), all-year: RR = 1.04 [95% CI: 1.01, 1.06], lag 0−2, RR = 1.02 [95% CI: 0.99, 1.04], lag −1). The smaller association, closer to the null in both studies, indicates that potential confounders of the relationship between short-term $PM_{2.5}$ exposure and asthma ED visits were adequately accounted for in the statistical model.

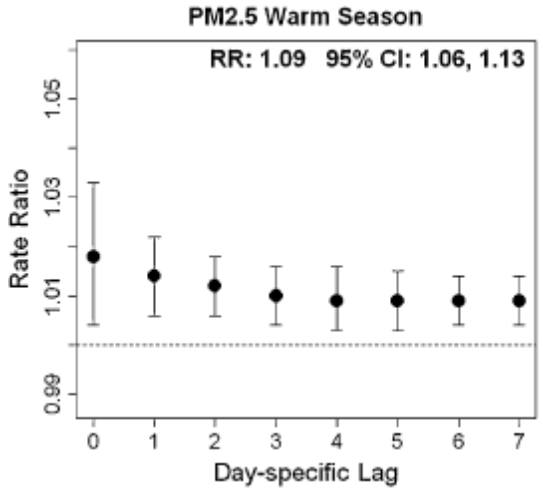
Across studies that examined alternative model specifications, replacing covariates used in the base model to account for the confounding effects of weather did not result in measurable changes in

$PM_{2.5}$ associations for respiratory-related effects. Additionally, there was little evidence that increasing the df/year to account for temporal trends influenced $PM_{2.5}$ associations; however, initial evidence indicates that applying the same df/year across individual cities in a multicity study may contribute to underestimating $PM_{2.5}$ risk estimates.

5.1.10.3 Lag Structure

An examination of associations between short-term $PM_{2.5}$ exposure and respiratory-related effects across different lag days can inform whether $PM_{2.5}$ elicits an immediate, delayed, or prolonged effect on health. As detailed throughout this chapter, evidence from studies that examine respiratory-related hospital admissions and ED visits indicates positive associations across single-day as well as multiday lags ranging from 0 to 4 days. However, to date many studies have not systematically evaluated different lags to examine the timing of effects, specifically whether there is evidence of an immediate (lag 0−1), delayed (lag 2−5), or prolonged (lag 0−5) $PM_{2.5}$ effect. An examination of lag structure in recent studies focusing on asthma, COPD, respiratory infections, and all respiratory-related hospital admissions and ED visits indicates that the strongest association in terms of magnitude and precision is generally within a few days after exposure for each of these outcomes, but there is some evidence demonstrating the potential for a prolonged $PM_{2.5}$ effect.

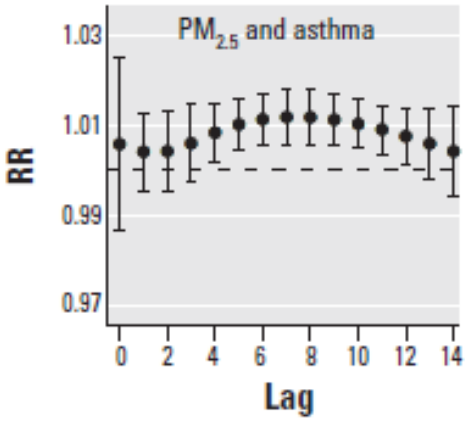
Among children in Atlanta, GA (Strickland et al., 2010) and individuals of all ages in Denver, CO (Kim et al., 2012), the pattern of associations for $PM_{2.5}$-asthma ED visits varied. In Strickland et al. (2010), lag 0 was reported to have the association largest in magnitude, but positive associations persisted across single-day lags of 1 to 7 days (Figure 5-14).



Source: Permission pending, Strickland et al. (2010).

Figure 5-14 Rate ratio and 95% confidence intervals for individual lag days from a constrained cubic polynomial distributed lag model examining associations between short-term $PM_{2.5}$ exposure and pediatric asthma emergency department (ED) visits in Atlanta, GA.

In contrast to the relatively immediate effect observed in Strickland et al. (2010), Kim et al. (2012) reported positive associations across the full range of lags examined (0−14), with the strongest associations, in terms of magnitude and precision, observed at lags 4 to 12 days, indicating a potential delayed response to short-term $PM_{2.5}$ exposure (Figure 5-15). When examining a distributed lag model of 0 to 7 days in Adelaide, Australia, Chen et al. (2016) observed an inconsistent pattern of associations with the strongest associations for asthma hospital admissions occurring at lags 2 and 4 days. When comparing results from multiday averages and distributed lag models, risk estimates were found to be larger in magnitude for the distributed lag model in Atlanta, GA (Strickland et al., 2010) (lag 0−2: RR = 1.05 [95% CI: 1.02, 1.08]; lag 0−7 DL: RR = 1.10 [95% CI: 1.07, 1.14]), but a similar magnitude of an association was observed at shorter and longer distributed lag models in St. Louis, MO (Sarnat et al., 2015) (lag 0−2: 1.04 [95% CI: 1.01, 1.06]; lag 0−4 DL: RR = 1.04 [95% CI: 1.01, 1.08]).



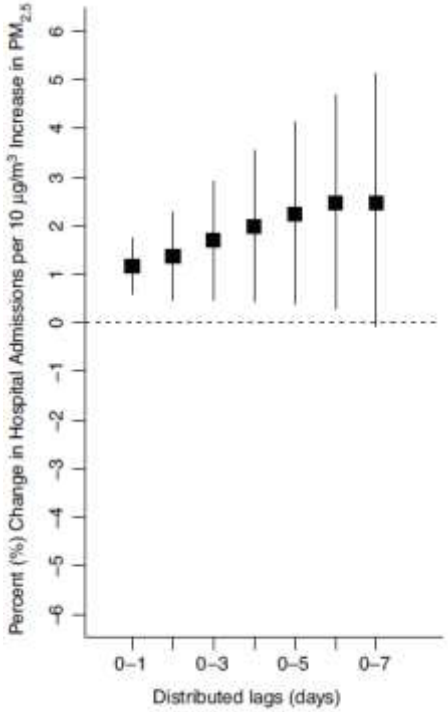
Source: Permission pending, Kim et al. (2012).

Figure 5-15 Relative risk and 95% confidence intervals for individual lag days from a constrained distributed lag model examining associations between short-term $PM_{2.5}$ exposure and asthma hospital admissions in Denver, CO.

Compared to asthma, the assessment of associations across different lags was limited for COPD and respiratory infection. Belleudi et al. (2010) examined both single-day and multiday lags (0 to 6 days, 0−1, 0−2, 0−5, and 0−6) for both COPD and lower respiratory tract infections. For COPD, the authors reported positive associations across a few single-day lags with the strongest association in terms of magnitude and precision observed at lag 0 (1.88% [95% CI: −0.27, 4.09]) and 2 (1.76 [95% CI: −0.18, 3.73]), with no evidence of an association for any of the multiday lags examined. However, for lower respiratory tract infections, positive associations were observed across single-day lags ranging from 1 to 5 days, but the magnitude of the association varied with the largest magnitude at lags 2 (2.82%) and 3 (3.04%). The multiple single-day lags reporting positive associations was further reflected when examining multiday averages, which provide evidence of a prolonged effect of short-term $PM_{2.5}$ exposure on lower respiratory tract infection (lag 0−5: (3.71 [95% CI: −0.57, 8.17]); lag 0−6: (3.62 [95% CI: −0.96, 8.42]).

Associations across different lags were further evaluated in recent studies focusing on all respiratory-related hospital admissions and ED visits. Overall, consistent, positive associations are reported across a range of single-day lags in multiple multicity studies (Bravo et al., 2017; Lanzinger et al., 2016b; Samoli et al., 2016a; Jones et al., 2015; Stafoggia et al., 2013). Some recent studies examined associations over a range of single-day lags through either a traditional single-day lag model or a distributed lag model. For example, Samoli et al. (2016a) and Jones et al. (2015) examined a series of single-day lags and reported positive association that were similar in magnitude across each individual lag, but confidence intervals were wide. In contrast to Samoli et al. (2016a) and Jones et al. (2015), Kim et al. (2012) did not report evidence of an association between short-term $PM_{2.5}$ exposure and

respiratory-related hospital admissions when examining the individual lag days of a 0 to 14 day constrained distributed lag model. However, the results for combinations of respiratory-related diseases differ from those observed for asthma hospital admissions in Kim et al. (2012) where, as previously mentioned, positive associations were observed at lags 4 to 12 days. In single-day lags of 0 to 2 days Bravo et al. (2017) reported a 0.79% increase (95% CI: 0.62, 0.97) at lag 0 in hospital admissions, but no evidence of an association at lags 1 or 2. However, when examining a distributed lag model of 0−7 days, the magnitude of the association increased as lag days increased, but confidence intervals did as well, providing some evidence of a potential prolonged $PM_{2.5}$ effect (Figure 5-16).



Source: Permission pending, Bravo et al. (2017).

Figure 5-16 Percent increase in respiratory-related hospital admissions for a distributed lag model up to 0−7 days for a 10 µg/m³ increase in 24-hour average $PM_{2.5}$ concentrations across 708 U.S. counties.

The results of Bravo et al. (2017) are consistent with both Lanzinger et al. (2016b) and Stafoggia et al. (2013) where positive associations were observed across each of the lags examined with the association with the largest magnitude observed for lag 0−5 in both studies. [(Lanzinger et al., 2016b): 2.8%, lag 0−1; 5.1%, lag 2−5; and 6.0%, lag 0−5; (Stafoggia et al., 2013): 0.49, lag 0−1; 1.1%, lag 2−5; and 1.4%, lag 0−5].

The assessment of associations across different lag structures for short-term $PM_{2.5}$ exposure and respiratory morbidity is further informed by analyses focusing on respiratory mortality. Multicity epidemiologic studies that examined cause-specific mortality in the 2009 PM ISA observed immediate effects with consistent positive associations for respiratory mortality at lags ranging from 0 to 2 days; however, these lags were selected a priori. Lippmann et al. (2013b), within the NPACT study, and Janssen et al. (2013), in a study conducted in the Netherlands, examined $PM_{2.5}$-respiratory mortality associations at single-day lags ranging from 0 to 3 days. While Lippmann et al. (2013b) reported the strongest association at lag 1, Janssen et al. (2013) reported evidence of associations larger in magnitude and with greater precision up to 3 days. Stafoggia et al. (2017), examining single-day lags ranging from 0 to 10 days, provide evidence that potentially supports the pattern of associations observed in both Lippmann et al. (2013b) and Janssen et al. (2013). The authors reported evidence of an immediate effect at lag 1, but also evidence of positive associations similar in magnitude at lags 3, 6, and 7 (quantitative results not presented). However, confidence intervals were wide, complicating the comparison of results across studies.

An examination of multiday lags by Lee et al. (2015) found a similar magnitude of an association across lags ranging from 0−1 to 0−4 days, which is consistent with the results of the studies examining single-day lags. However, Samoli et al. (2013), when examining lags indicative of immediate, delayed, and prolonged effects, reported evidence of an immediate $PM_{2.5}$ effect on respiratory mortality (0.72% [95% CI: −0.11, 1.6]; lag 0−1) that was larger in magnitude at longer lags (lag 2−5: 1.6% [95% CI: 0.62, 2.7]; lag 0−5: 1.9% [95% CI: 0.7, 3.1]). These results were further confirmed when examining single-day lags in a polynomial distributed lag model of 0−7 days, where associations were relatively consistent in magnitude from 0 to 2 days and then steadily increased out to 7 days.

Across the respiratory-related hospital admission and ED visit and mortality studies evaluated that conducted systematic evaluations of $PM_{2.5}$ associations across a range of lags, recent studies further support studies evaluated in the 2009 PM ISA that provided evidence of associations at lags ranging from 0−5 days. Studies of respiratory morbidity, specifically asthma and all respiratory-related hospital admissions and ED visits, along with more limited evidence from studies of COPD and respiratory infection, support that longer $PM_{2.5}$ exposures (i.e., 0−5-day lags) are associated with respiratory-related effects. Studies of respiratory mortality tended to support more immediate $PM_{2.5}$ effects (i.e., lags of 0 to 2 days), but initial evidence of stronger associations, in terms of magnitude and precision, at lags of 0−5 days is consistent with the pattern of associations observed in the hospital admission and ED visit studies.

5.1.10.4 The Role of Season and Temperature on $PM_{2.5}$ Associations

The examination of seasonal differences in $PM_{2.5}$ associations within studies that focus on respiratory-related hospital admissions and ED visits, as well as respiratory mortality, can provide

information that could be used to assess whether specific sources that vary by season are contributing to the $PM_{2.5}$ associations observed in all-year analyses. Additional studies that examine potential modification of $PM_{2.5}$ associations by temperature can further elucidate the impact of season on observed associations. Studies evaluated in the 2009 PM ISA, demonstrated seasonal variability in $PM_{2.5}$ associations with respiratory-related effects with some studies reporting associations in warmer months while others in colder months, which is further supported by recent studies. Fewer recent studies have examined potential modification of $PM_{2.5}$ associations by temperature.

5.1.10.4.1 Season

Recent studies have further examined the role of season on the relationship between short-term $PM_{2.5}$ exposure and respiratory-related effects, with the most extensive analyses focusing on asthma and all respiratory-related hospital admissions and ED visits. In studies of respiratory-related hospital admissions and ED visits, most often the warm season was defined as April−September, particularly for most northern U.S. cities, but in some cases the warm months encompassed May−October, such as for Atlanta, GA. $PM_{2.5}$-associated increases in asthma ED visits were observed in New Jersey in studies restricted to the warm season (Gleason and Fagliano, 2015; Gleason et al., 2014). Seasonal differences in associations are also supported by Malig et al. (2013) in a study of 35 California counties and asthma ED visits, which reported associations larger in magnitude in the warm compared to the cold season, as well as Stafoggia et al. (2013), in a study of eight European cities, which examined whether associations between short-term $PM_{2.5}$ exposure and all respiratory-related hospital admissions in the warm season were larger in magnitude than those observed in the all-year analysis. When restricting the analysis to the warm season (April−September), Stafoggia et al. (2013) reported a larger percent increase in respiratory-related hospital admissions (4.49% [95% CI: 1.72, 7.35]; lag 0−5) compared to the all-year analysis (1.36% [95% CI: 0.23, 2.49]; lag 0−5).

An examination of associations between short-term $PM_{2.5}$ exposure and asthma hospital admissions and ED visits in the cold season in U.S. locations were null except in New York, NY (Silverman and Ito, 2010; Ito et al., 2007). Additionally, (Rodopoulou et al., 2014) in a study examining all respiratory disease and acute respiratory infection ED visits in New Mexico, (Belleudi et al., 2010) in a study conducted in Rome, Italy focusing on respiratory infection ED visits, and (Lanzinger et al., 2016b) in a study of four European cities focusing on all respiratory-related hospital admissions reported evidence of associations larger in magnitude in the cold versus the warm season. The pattern of seasonal associations was also found to differ between two Australian cities, with an association larger in magnitude in the warm season in Sydney (Jalaludin et al., 2008) and in the cold season in Adelaide (Chen et al., 2016).

Additional studies conducted more refined analyses, focusing on all four seasons, to examine potential seasonal differences in $PM_{2.5}$ associations with respiratory-related hospital admissions and ED visits. For studies of asthma hospital admission and ED visit, an examination of $PM_{2.5}$ associations by the

four seasons is limited to Detroit, MI and Seoul, South Korea, but are consistent with each other in showing associations only in the spring (i.e., March−May) (Li et al., 2011 Kim, 2015, 3012210). However, studies focusing on all respiratory-related hospital admissions and ED visits reported a slightly different pattern of associations. Zanobetti et al. (2009), in a study of 26 U.S. counties reported the largest association in the spring (4.34% [95% CI: 2.19, 6.54]; lag 0−1) with the percent increase in respiratory-related hospital admissions ranging from 1.26−1.79% in the other seasons. Jones et al. (2015), in a study of New York state observed a slightly different pattern of associations across the seasons than Zanobetti et al. (2009). Focusing on lag 1, the authors reported associations largest in magnitude in the summer and fall with little evidence of an association in the winter and spring. Bell et al. (2015), in a study of 213 U.S. counties observed stronger associations with respiratory tract infection hospital admissions in spring (0.80% [95% CI: 0.02, 1.58]) and winter (0.40% [95% CI: −0.29, 1.10]), compared to the fall and spring where no evidence of an association was reported. The results from studies examining all four seasons support the results from studies that reported stronger associations during the warm season, but also provide some evidence that the greatest risk of $PM_{2.5}$-related respiratory effects may span into months traditionally defined as representing the cold season.

While studies in the 2009 PM ISA focusing on respiratory morbidity conducted seasonal analyses, studies focusing on mortality were limited to total (nonaccidental) mortality. These studies generally reported larger associations in warmer months (see Section 11.1.6.1) but resulted in uncertainty as to whether the same pattern of associations exists for cause-specific mortality, including respiratory mortality.

Recent multicity studies conducted in the U.S. (Dai et al., 2014; Lippmann et al., 2013a), Europe (Pascal et al., 2014; Samoli et al., 2013), and Asia (Lee et al., 2015) examined whether there was evidence of seasonal differences in the $PM_{2.5}$-respiratory mortality relationship. Within the NPACT study (Lippmann et al., 2013a), the examination of seasonal $PM_{2.5}$ associations resulted in a pattern of associations consistent with what was observed for total mortality (i.e., associations larger in magnitude during the warm season). However, compared to the all-year analysis, there was evidence of positive associations in the warm season across all lags examined with associations similar in magnitude (~0.5% increase) at lags 0, 1, and 3 days. There was also evidence of a positive association with respiratory mortality during the cold season, but only at lag 1 (0.40% [95% CI: −0.34, 1.1]). Dai et al. (2014), in a study of 75 U.S. cities reported results that were generally consistent with Lippmann et al. (2013a), but examined associations across all four seasons. Across seasons, the $PM_{2.5}$-respiratory mortality association was largest in magnitude during the spring (4.0% [95% CI: 2.9, 5.2]; lag 0−1), with positive, but smaller associations across the other seasons ranging from 0.58−1.1%.

Additional studies conducted in Europe report results consistent with those studies conducted in the U.S. In the MED-PARTICLES project, Samoli et al. (2013) examined short-term $PM_{2.5}$ exposure and respiratory mortality at lag 0−5 days and reported associations larger in magnitude in the warm season (6.5% [95% CI: 2.6, 10.5]) compared to the cold (1.7% [95% CI: 0.27, 3.2]). In France, Pascal et al.

(2014) reported similar results, but in an analysis of all four seasons. Associations between short-term $PM_{2.5}$ exposure and respiratory mortality were only positive during the spring and summer seasons, but confidence intervals were wide (quantitative results not presented).

Although the studies that examined U.S. and European cities provide consistent evidence of $PM_{2.5}$-respiratory mortality associations being larger in magnitude during warmer months (i.e., spring and summer), a study conducted in 11 east Asian cities observed a different pattern of associations. Lee et al. (2015) reported that $PM_{2.5}$ associations with respiratory mortality were larger in the cold season (1.3% [95% CI: 0.38, 2.2]) compared to the warm (0.63% [95% CI: −0.21, 1.5]). It is unclear why these results differ from the other studies, but mean $PM_{2.5}$ concentrations and mean temperature tended to be higher across the cities in Lee et al. (2015) compared to the cities in the other studies evaluated in this section.

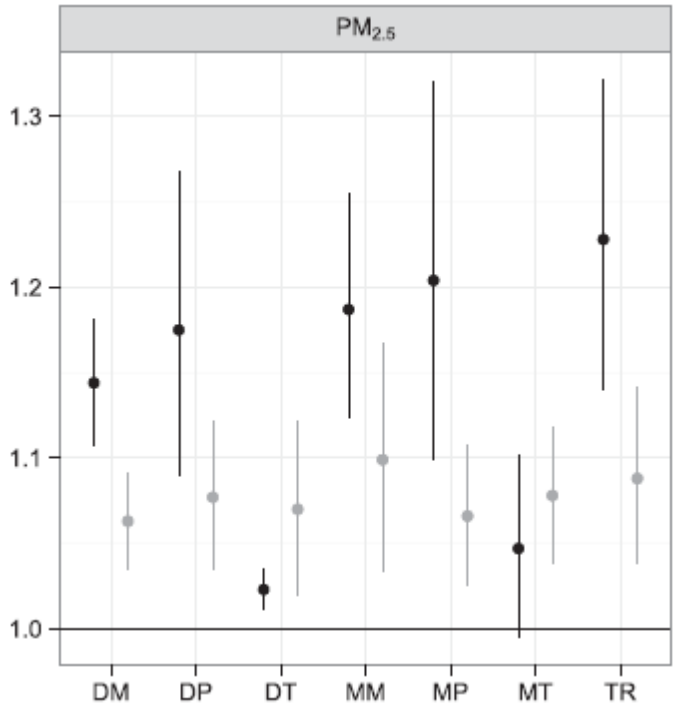
Across the multicity studies that examined seasonal associations, compared to studies of respiratory morbidity, results indicate that associations between short-term $PM_{2.5}$ exposure and respiratory mortality tend to be larger in magnitude during warmer parts of the year (i.e., spring and summer), specifically in locations where mean $PM_{2.5}$ concentrations and temperature are more like those observed in the U.S. These results are supported by studies that conducted more refined examinations of seasonal associations by each of the four seasons and observed associations larger in magnitude in the spring and summer.

In addition to traditional analyses that examine whether $PM_{2.5}$-respiratory-related hospital admission and ED visit associations vary by season; other studies have examined whether specific weather patterns influence associations. Hebbern and Cakmak (2015), in a study conducted in 10 Canadian cities, examined the association between short-term $PM_{2.5}$ exposure and asthma hospital admissions and whether the association was modified by specific synoptic weather patterns. Individual days were grouped into synoptic weather types based on temperature, humidity, and other factors. $PM_{2.5}$ associations with asthma hospital admissions were reported to be largest in magnitude for days classified as moist polar and transitional types and lowest in magnitude for dry tropical and moist tropical days, but interestingly these latter categories had higher $PM_{2.5}$ concentrations. However, when adjusting for aeroallergens, Hebbern and Cakmak (2015) observed that the difference in associations between weather types were absent.

Aeroallergens

While seasonal analyses can inform whether $PM_{2.5}$-asthma hospital admission and ED visit associations are influenced by weather, another factor tangentially related that has a strong seasonal component is aeroallergens. As detailed above, Hebbern and Cakmak (2015) reported that $PM_{2.5}$-asthma hospital admissions varied by synoptic weather pattern, but not when controlling for aeroallergens. However, in the models that controlled for aeroallergens, the RRs across all weather types, although attenuated, remained positive and were relatively similar, ranging from approximately 1.05−1.1 (Figure

5-17). Instead of controlling for the potential confounding effects of aeroallergens, Gleason et al. (2014), in a study conducted in New Jersey, examined whether the $PM_{2.5}$-asthma ED visit association varied across $PM_{2.5}$ quintiles depending on high and low levels of tree, grass, weed, and ragweed pollen. The authors observed no evidence of effect modification across the quintiles for high and low tree and grass pollen levels, and across all quintiles and levels of ragweed except for the combination of high ragweed and the highest quintile of $PM_{2.5}$ concentrations. However, when examining high ragweed pollen levels, as $PM_{2.5}$ concentrations increased there was evidence of effect modification (Table 5-17).



Note: Black circles represent before and grey circles represent after adjustment for aeroallergens.

DM = dry moderate; DP = dry polar; DT = dry tropical; MM = moist moderate; MP = moist polar; MT = moist tropical; TR = transitional weather types.

5.1.10.4.2 Temperature

Instead of conducting traditional seasonal analyses, some recent studies examined whether there was evidence that higher temperatures modified the relationship between short-term $PM_{2.5}$ exposure and asthma hospital admissions and respiratory mortality. Cheng et al. (2015) examined whether specific temperatures modified the $PM_{2.5}$-asthma hospital admission association in Kaohsiung, Taiwan. The authors reported that $PM_{2.5}$ associations were larger in magnitude when analyses were restricted to days with lower temperatures, 13−25°C (RR = 1.10 [95% CI: 1.06, 1.13]) compared to days with higher temperatures (i.e., >25°C: RR = 1.02 [95% CI: 0.98, 1.06]).

Pascal et al. (2014) examined the impact of temperature on the $PM_{2.5}$-respiratory mortality relationship across nine French cities by comparing associations on warm and nonwarm days where warm days were defined as those days where the mean temperature exceed the 97.5th percentile of the mean temperature distribution. Pascal et al. (2014) reported no evidence of an interaction between $PM_{2.5}$ and warm days on respiratory mortality.

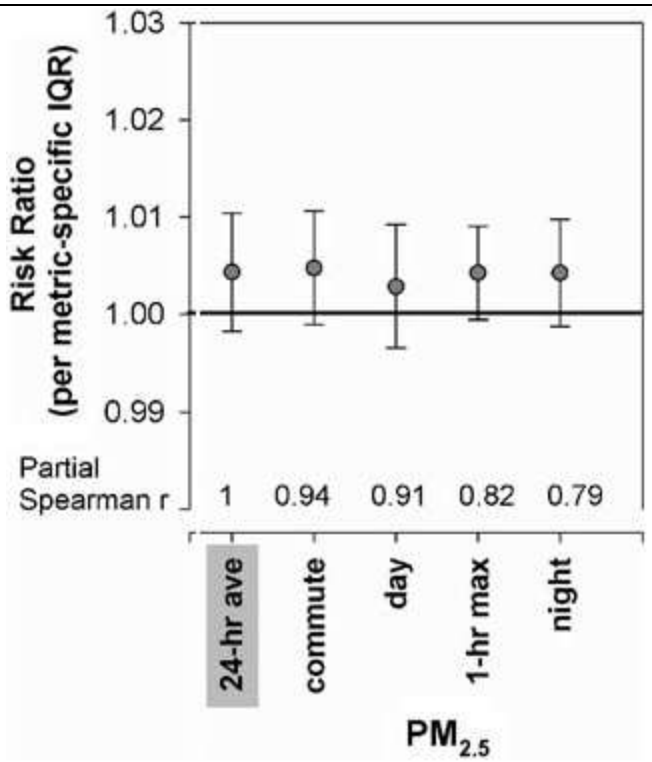
Additional studies conducted in Asia, although at higher mean $PM_{2.5}$ concentrations (i.e., in many cases >20 μg/m^3), also examined whether high temperatures modify the $PM_{2.5}$-respiratory mortality relationship. Li et al. (2015b) examined whether same-day temperature, either higher (>23.5°C) or lower temperatures (<2.6°C), modifies the $PM_{2.5}$-respiratory mortality relationship at lag 0 and 1. At lag 0, there was evidence of an association larger in magnitude at high temperatures (1.7% [95% CI: 0.92, 3.3]) compared to medium (0.76% [95% CI: −0.04, 2.0]), with no evidence of an association at low temperatures. However, at lag 1, the strongest evidence of an association was only for the medium

temperatures (0.80% [95% CI: −0.15, 1.8]). Sun et al. (2015) provides evidence contradictory to the results of Li et al. (2015b). At lag 0−1 days, the authors observed positive associations at high (≥25ºC) and medium temperatures, ranging from 0.26−0.39%, but the magnitude of the association was much smaller than that observed for low temperatures (<22ºC) (1.2% [95% CI: 0.51, 1.8]). Unlike Li et al. (2015b), Sun et al. (2015) did not specifically focus on the tails of the temperature distribution, which complicates the interpretation of the results between the two studies, especially considering the low temperature category in Sun et al. (2015) is relatively similar to the high temperature category in Li et al. (2015b). Overall, the evidence across studies is inconclusive as to whether specific temperature ranges modify the association between short-term $PM_{2.5}$ exposure and respiratory mortality.

5.1.10.5 Averaging Time of $PM_{2.5}$ Concentrations

Collectively, the combination of studies evaluated in the 2009 PM ISA and within this section largely support an association between short-term $PM_{2.5}$ exposures and increases in respiratory-related hospital admissions and ED visits, specifically when using a 24-hour average $PM_{2.5}$ concentration averaging time. To date, very few studies have examined associations with subdaily averaging times for $PM_{2.5}$ concentrations (e.g., 1-hour max), with some evidence indicating associations between ED visits and 1-hour max $PM_{2.5}$ concentrations. Previously, in Bronx, NY, RRs for asthma ED visits were similar in magnitude for 24-hour average and 1-hour max $PM_{2.5}$ concentrations (ATSDR, 2006). The two averaging times were found to be highly correlated (r = 0.78), but the spatiotemporal variability of 1-hour max concentrations was not reported. Similarly, other studies that examined subdaily averaging times have not provided information on the spatiotemporal variability of other exposure metrics, such as 3-hour average or 6-hour average $PM_{2.5}$ concentrations, which were examined in studies conducted in six Canadian cities (Stieb et al., 2009) and Seoul, South Korea (Kim et al., 2015)]. However, in both studies, the authors reported no evidence of an association between 24-hour average $PM_{2.5}$ concentrations and asthma ED visits, nor was there evidence of an association using the subdaily averaging times.

Darrow et al. (2011) systematically examined a series of averaging times to assess whether the 24-hour exposure metric was appropriate. The authors examined several subdaily averaging times (i.e., 1-hour max, commute time average [7−10 a.m. and 6−9 p.m.], daytime average [8 a.m.−7 p.m.], and nighttime average [12−6 a.m.]) in addition to the traditional 24-hour average when examining the relationship between short-term $PM_{2.5}$ exposure and respiratory-related ED visits. The averaging times were found to be highly correlated with one another with r = 0.79−0.94, which is consistent with ATSDR (2006). Across the averaging times examined, the authors reported relatively consistent positive associations of similar magnitude, but confidence intervals were wide (Figure 5-18).



Source: Permission pending, Darrow et al. (2011).

Figure 5-18 Association between short-term $PM_{2.5}$ exposure and respiratory-related emergency department (ED) visits in Atlanta, GA at lag 1 for 24-hour average and subdaily exposure metrics.

While hospital admission and ED visit studies can examine alternative averaging times for the exposure metric if ambient monitoring data is available, panel studies using personal monitors can examine more refined time scales of exposure but are limited to studies of pulmonary inflammation and lung function. A strength of studies of pulmonary inflammation is examination of the hourly lag structure of $PM_{2.5}$ associations. Most (Barraza-Villarreal et al., 2008; Rabinovitch et al., 2006; Mar et al., 2005) but not all (Berhane et al., 2011) results show an increase in inflammation with increases in $PM_{2.5}$ concentration averaged over the preceding 1 to 11 hours. Additional support is provided by associations with mean personal $PM_{1.5}$ exposure in nonhome/school locations (Rabinovitch et al., 2016). Associations also were observed with 1-hour or 8-hour maximum $PM_{2.5}$ that were larger than those for 24-hour average $PM_{2.5}$ (Delfino et al., 2006; Rabinovitch et al., 2006). Maximum concentrations occurred before inflammation was measured. Some results indicate that $PM_{2.5}$ exposure may have a rapid and transient effect on pulmonary inflammation in people with asthma. For Seattle, WA and Riverside and Whittier, CA, distributed lag models show an increase in eNO with the 1-hour average $PM_{2.5}$ concentration up to 5 or 10 hours prior but not with longer lags of 24−48 hours (Delfino et al., 2006; Mar et al., 2005). eNO measured at well-defined intervals after a scripted 2-hour exposure during morning commutes increased

3 hours post-exposure (Mirabelli et al., 2015). Longer lags were not examined, and a similar previous study did not observe any changes up to 22 hours after exposure (McCreanor et al., 2007). It is important to note that most recent studies examined 24-hour or multiday average $PM_{2.5}$, which may explain the inconsistency in associations observed (see section on eNO). However, studies evaluated in the 2009 PM ISA also used 24-hour or multiday average $PM_{2.5}$ concentrations and reported positive associations (Liu et al., 2009; Allen et al., 2008; Delfino et al., 2006).

Additional studies examined subdaily averaging times through 1 to 8-hour scripted outdoor exposures near pollution sources. Epidemiologic studies of scripted outdoor exposures examined $PM_{2.5}$ at high-traffic locations and found inconsistent results with respect to respiratory effects in healthy populations. Among epidemiologic studies of adults commuting by car, bus, or bicycle, working as school crossing guards or traffic police, or spending time in high-traffic areas, $PM_{2.5}$ was associated with increases in pulmonary inflammation (Mirowsky et al., 2015; Zhao et al., 2015; Steenhof et al., 2013) or decreases in lung function (Huang et al., 2016; Shakya et al., 2016; Mirabelli et al., 2015; Weichenthal et al., 2011). Effects were not observed in other studies of pulmonary inflammation (Zuurbier et al., 2011a) or lung function decrements (Matt et al., 2016; Zhao et al., 2015; Zuurbier et al., 2011b; Fan et al., 2008). For $PM_{2.5}$ exposures of 1−8 hours, no distinct pattern of association or effect is observed by exposure duration or concentration. Among epidemiologic studies in the U.S., Canada, and Europe conducted near traffic or a steel plant, 1- to 8-hour average $PM_{2.5}$ concentrations with means 8.1−39 $\mu g/m^3$ were linked to respiratory effects in some studies (Mirabelli et al., 2015; Mirowsky et al., 2015; Dales et al., 2013), but not in others (Strak et al., 2012; Weichenthal et al., 2011). Results are inconsistent at concentrations higher than 39 $\mu g/m^3$ as well, but associations were observed in traffic police, adults exercising outdoors, or adults exposed in a transport hub (Huang et al., 2016; Shakya et al., 2016; Kesavachandran et al., 2015; Zhao et al., 2015) with mean 2- to 8-hour average $PM_{2.5}$ concentrations 53−323 $\mu g/m^3$.

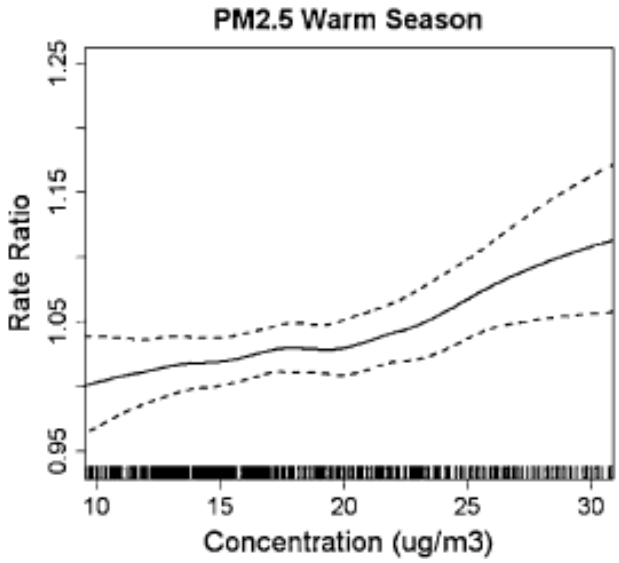
Across the studies evaluated that examined subdaily averaging times and subsequent respiratory effects, the effects tend to be transient. $PM_{2.5}$-associated increases in pulmonary inflammation and oxidative stress (Steenhof et al., 2013; Weichenthal et al., 2011) or decreases in lung function (Mirabelli et al., 2015) often were isolated to immediately or 1 or 2 hours after exposure near traffic, but not 3 to 18 hours after exposure. $PM_{2.5}$ exposure while walking near high-traffic roads and in a forest was associated with eNO 24 hours after exposure (Mirowsky et al., 2015), but lung function decreased only immediately after exposure.

5.1.10.6 Concentration-Response Relationship and Threshold Analyses

At the completion of the 2009 PM ISA, the examination of the PM C-R relationship in epidemiologic studies focused on mortality and cardiovascular outcomes. Recent studies expanded the evaluation of the $PM_{2.5}$ C-R relationship to encompass respiratory-related outcomes, including respiratory-related hospital admissions and ED visits with a focus on examining both the shape of the C-R

curve and whether a threshold exists below which there is no evidence of an effect. Across studies, different analytical methods have been employed to examine the C-R relationship, either explicitly examining the shape of the C-R curve and whether there is evidence of linearity across the full range of $PM_{2.5}$ concentrations, or through cutpoint analyses that examine the risk of a $PM_{2.5}$-related respiratory effect changes within specified ranges of different $PM_{2.5}$ concentrations.

Studies conducted in Atlanta, GA (Strickland et al., 2010), Ontario, Canada (Weichenthal et al., 2016), Dongguan, China (Zhao et al., 2016) and New York, NY (Silverman and Ito, 2010) focused on examining the shape of the $PM_{2.5}$ C-R curve for asthma ED visits or hospital admissions. In Strickland et al. (2010), which focused on pediatric ED visits, a locally weighted scatterplot smoothing (LOESS) C-R analysis provided evidence of a linear C-R relationship for $PM_{2.5}$ in the warm season along the distribution of $PM_{2.5}$ concentrations from the 5th to 95th percentile (Figure 5-19).



Note: Solid line = smoothed concentration-response estimate. Dashed line = twice-standard error estimates.

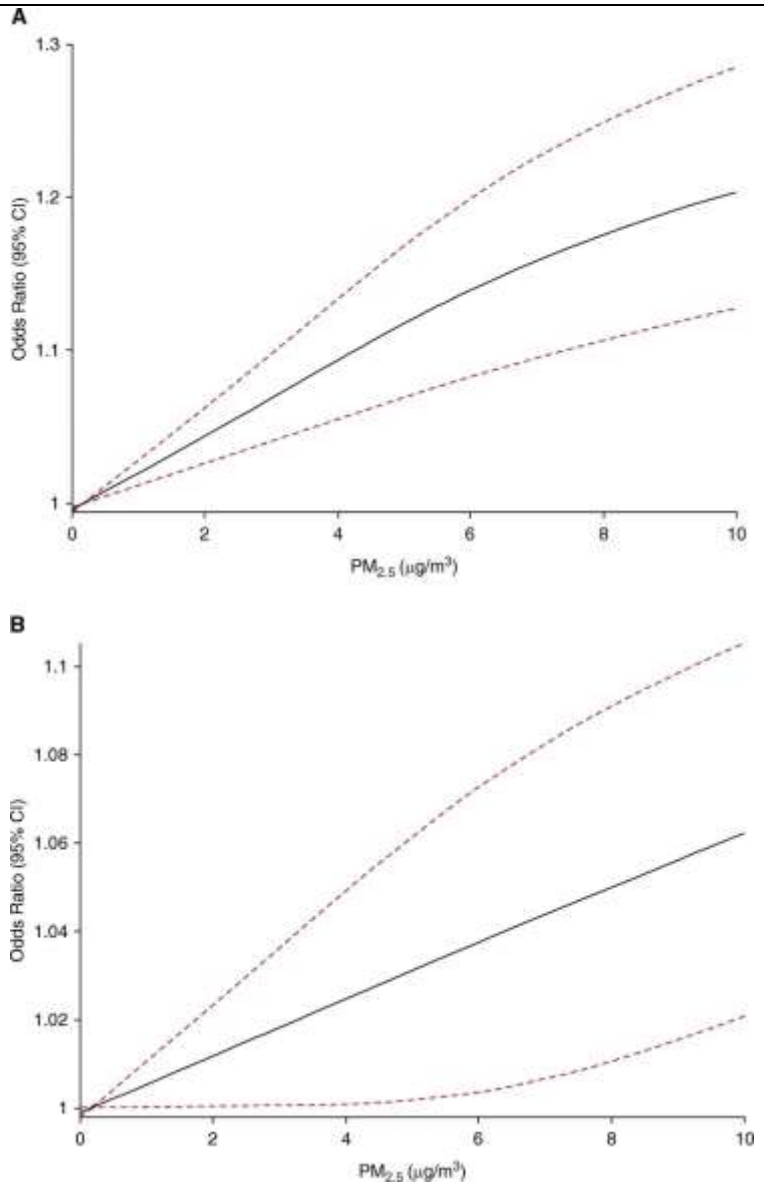
Figure 5-19 Concentration-response for associations between 3-day average (lag 0−2) $PM_{2.5}$ concentrations and emergency department (ED) visits for pediatric asthma at the 5th to 95th percentile of $PM_{2.5}$ concentrations in the Atlanta, GA area during the warm season.

Additionally, Weichenthal et al. (2016) examined the C-R relationship for asthma ED visits among children <9 years of age and all ages in 15 Ontario cities in a case-crossover analysis. The authors examined the C-R curve across the range of $PM_{2.5}$ concentrations representing the 95th percentile of the observed difference in lag 0−2 $PM_{2.5}$ concentrations between case and control days, which represented

concentrations ranging from 0−10 μg/m^3, Weichenthal et al. (2016) reported evidence of a linear relationship for both age ranges, but confidence intervals were larger for the all ages analysis (Panel B of Figure 5-20). Evidence of a linear relationship was also observed by Zhao et al. (2016) at $PM_{2.5}$ concentrations much higher than those examined in the U.S. and Canadian studies. Although the results of Strickland et al. (2010), Weichenthal et al. (2016), and Zhao et al. (2016) are informative for assessing the shape of the C-R curve, the authors did not empirically examine alternatives to linearity.



Note: Solid lines represent point estimates, and dashed lines represent 95% confidence intervals.

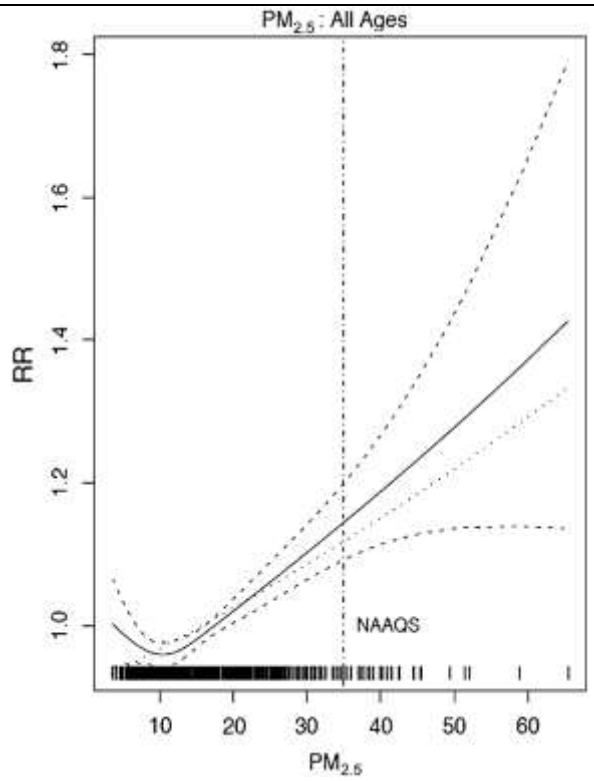
Figure 5-20 Concentration-response curve for lag 0−2-day $PM_{2.5}$ concentrations and asthma emergency department (ED) visits for children (<9 years old) (Panel A) and all ages (Panel B).

Silverman and Ito (2010) assessed whether there was evidence for deviations in linearity for the relationship between short-term $PM_{2.5}$ exposure at lag 0−1 day and asthma hospital admissions by including a smooth function of lag 0−1-day ozone concentrations in the model. When comparing the results from the function including natural splines to account for potential deviations in linearity to a

linear fitted model, the authors observed no evidence that a nonlinear model better represents the C-R relationship (Figure 5-21).



Note: Solid lines = smoothed fitted data, large dashed lines = 95% confidence intervals, short dashed lines = linear fitted data, vertical solid line = current 24-hour average $PM_{2.5}$ NAAQS.

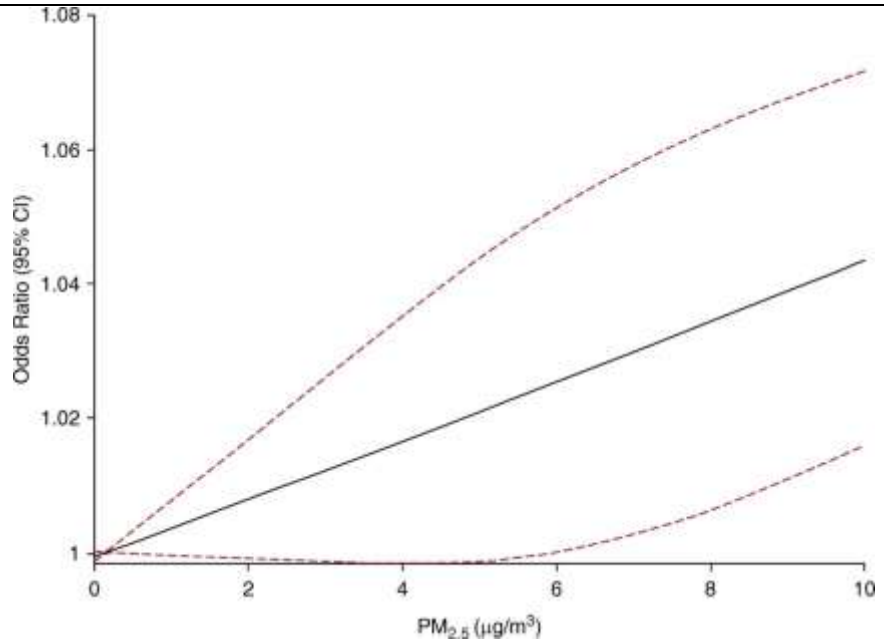
Figure 5-21 Estimated relative risks (RRs) for short-term $PM_{2.5}$ exposure and asthma hospital admissions at lag 0−1 adjusted for ozone at lag 0−1 allowing for a possible nonlinear relationship in New York, NY.

Additional studies focusing on respiratory-related hospital admissions also examined whether there was evidence of linearity and reported results consistent with the studies focusing on asthma hospital admissions and ED visits.

Weichenthal et al. (2016) also examined the C-R relationship for COPD ED visits in 15 cities in Ontario, Canada. Using the same approach to examine the C-R curve for asthma ED visits, in the COPD analysis the authors reported evidence of a linear relationship (Figure 5-23). The C-R analyses conducted by Weichenthal et al. (2016) and Stafoggia et al. (2013) are also supported by Zhao et al. (2016) in a study conducted in Dongguan, China that demonstrated a linear relationship, albeit at $PM_{2.5}$ concentrations much higher than those examined in the U.S. and Canadian studies.



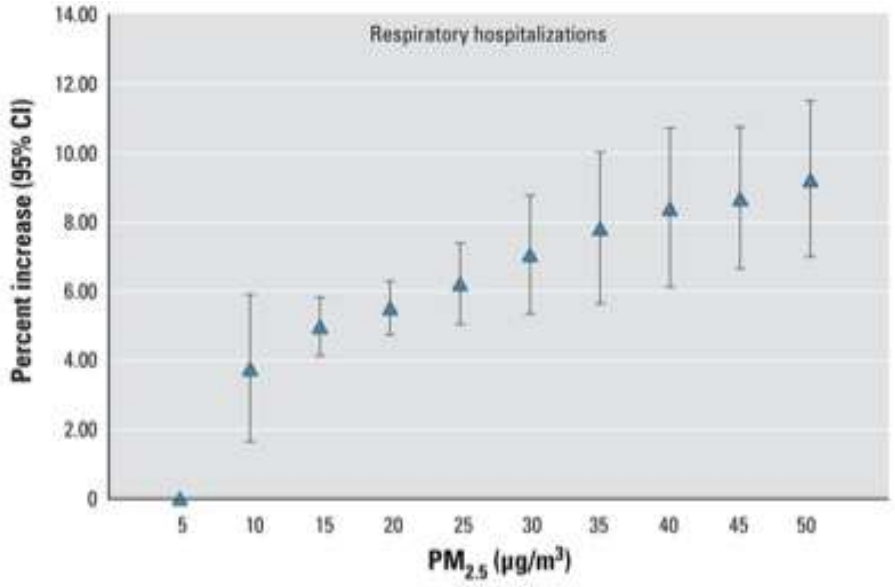
Source: Permission pending, Weichenthal et al. (2016).

Figure 5-22 Concentration-response relationship between 0−2 day mean $PM_{2.5}$ concentrations and chronic obstructive pulmonary disease (COPD) emergency department (ED) visits in Ontario, Canada.

While the studies discussed up to this point have focused specifically on the shape of the C-R curve across the full range of $PM_{2.5}$ concentrations in their respective study locations, other studies focused analyses on specific ranges of $PM_{2.5}$ concentrations to examine whether there is evidence of deviations in linearity. In a study conducted in Detroit, MI, Li et al. (2011) examined whether there is evidence of a nonlinear C-R relationship between air pollutants and pediatric asthma ED visits. Associations with $PM_{2.5}$ were examined in both a time-series and time-stratified, case-crossover study design assuming (1) a linear relationship and (2) a nonlinear relationship starting at 12 $\mu g/m^3$ (i.e., the maximum likelihood estimate within the 10th to 95th percentile concentration where a change in linearity

may occur), which was identified as somewhere in the range of the 35th to 49th percentile of $PM_{2.5}$ concentrations for the time-series and case-crossover analysis, respectively. It is important to note that in the analysis that assumed a nonlinear relationship, the authors did not assume zero risk below the inflection point, which would represent a true threshold. The focus of the analysis by Li et al. (2011) was on identifying whether risk increased above that observed in the linear models at $PM_{2.5}$ concentrations above 12 $\mu g/m^3$. In the analyses assuming linearity, the authors examined single-day lags of 3 and 5 days and multiday lags of 0−2 and 0−4 days. Positive associations were observed for all lags examined and were relatively consistent across models, with the strongest association, in terms of magnitude and precision, for a 0−4-day lag (time series: RR = 1.03 [95% CI: 1.00, 1.07]; case-crossover: OR = 1.04 [95% CI: 1.01, 1.07]). In the models that examined whether there was evidence of nonlinearity, the authors reported larger risk estimates for $PM_{2.5}$ concentrations above 12 $\mu g/m^3$, indicating potential nonlinearity in the $PM_{2.5}$-asthma hospital admissions and ED visit relationship (time series: RR = 1.07 [95% CI: 1.03, 1.11); case-crossover: OR = 1.06 (95% CI: 1.03, 1.09].

Instead of examining the association between short-term $PM_{2.5}$ exposure and asthma hospital admissions and between short-term $PM_{2.5}$ exposure and ED visits at one point along the distribution of $PM_{2.5}$ concentrations as was done by Li et al. (2011), Strickland et al. (2010), in Atlanta, GA, Gleason et al. (2014), in New Jersey, and Stafoggia et al. (2013) in eight European cities examined whether the associations varied across defined cutpoints along the distribution of $PM_{2.5}$ concentrations. Both studies provide some evidence indicating potential nonlinearity in the C-R relationship. In a quintile analysis of lag 0−2-day $PM_{2.5}$ concentrations, Strickland et al. (2010) examined whether risk estimates increased across the quintiles in both the warm and cold season when compared to the 1st quintile (i.e., <10 $\mu g/m^3$). Results were null across all quintiles for the cold season except the highest quintile (i.e., 23.8 ≤ 65.8) (RR = 1.05 [95% CI: 0.99, 1.11]). However, in the warm season, there was evidence of an increase in the magnitude of the association from the 3rd to 5th quintiles, ranging from 1.01−1.05, although confidence intervals were wide. Gleason et al. (2014) which also focused on lag 0−2 $PM_{2.5}$ concentrations, similarly reported a positive association for the highest quintile (i.e., 16.9−47.2 $\mu g/m^3$) (OR = 1.04 [95% CI: 0.98, 1.10]). However, the authors observed no evidence of an association for $PM_{2.5}$ concentrations in the range of the 3rd and 4th quintiles (i.e., 8.5−16.8 $\mu g/m^3$), but reported the association largest in magnitude for the 2nd quintile (i.e., 6.1−8.5 $\mu g/m^3$) (OR = 1.06 [95% CI: 1.01, 1.12]). Instead of focusing on quintiles, Stafoggia et al. (2013) examined associations between short-term $PM_{2.5}$ exposure and respiratory-related hospital admissions across various concentration ranges relative to 5 $\mu g/m^3$. The authors first combined results across each individual city by incorporating a natural spline with two equally spaced knots and then applying a metasmoothing approach to develop a combined result across the cities. As demonstrated in Figure 5-23, Stafoggia et al. (2013) report positive associations across each of the cut-points evaluated indicating no evidence of a threshold.



Source: Permission pending, Stafoggia et al. (2013).

Figure 5-23 Cut-point analysis examining the association between short-term $PM_{2.5}$ exposure and respiratory-related hospital admissions, lag 0−5, relative to 5 µg/m³.

Across the studies that examined the shape of the C-R curve, there is some evidence for a linear relationship for short-term $PM_{2.5}$ exposure and both respiratory disease and asthma hospital admissions and ED visits. However, complicating the interpretation of these results is both the lack of thorough empirical evaluations of alternatives to linearity as well as the results from cutpoint analyses that provide some potential indication for nonlinearity in the relationship between short-term $PM_{2.5}$ exposure and respiratory disease and asthma hospital admission and ED visits.

5.1.11 $PM_{2.5}$ Components and Sources and Respiratory Effects

While many PM components are associated with a range of health effects, the 2009 PM ISA concluded that there was "not yet sufficient evidence to allow differentiation of those [components] or sources that more closely related to specific health outcomes" compared to $PM_{2.5}$ mass (U.S. EPA, 2009). For respiratory effects, studies available at the completion of the 2009 PM ISA that examined PM components were few, and the overall evidence linking increases in respiratory effects with short-term exposure to $PM_{2.5}$ components and sources was less consistent than for other health outcomes (i.e., cardiovascular disease and mortality). However, there was some evidence of positive associations between respiratory ED visits and decrements in lung function with sulfate. In addition, several PM sources (i.e., crustal/soil/road dust and traffic) were associated with increased respiratory symptoms in

children with asthma and decreased PEF in adults with asthma. Generally, studies that evaluated individual PM components with respiratory morbidity and mortality observed inconsistent results, with limited evidence from a few studies that evaluated several metals (i.e., Cu, Pb, Zn) as well as OC were associated with respiratory health effects.

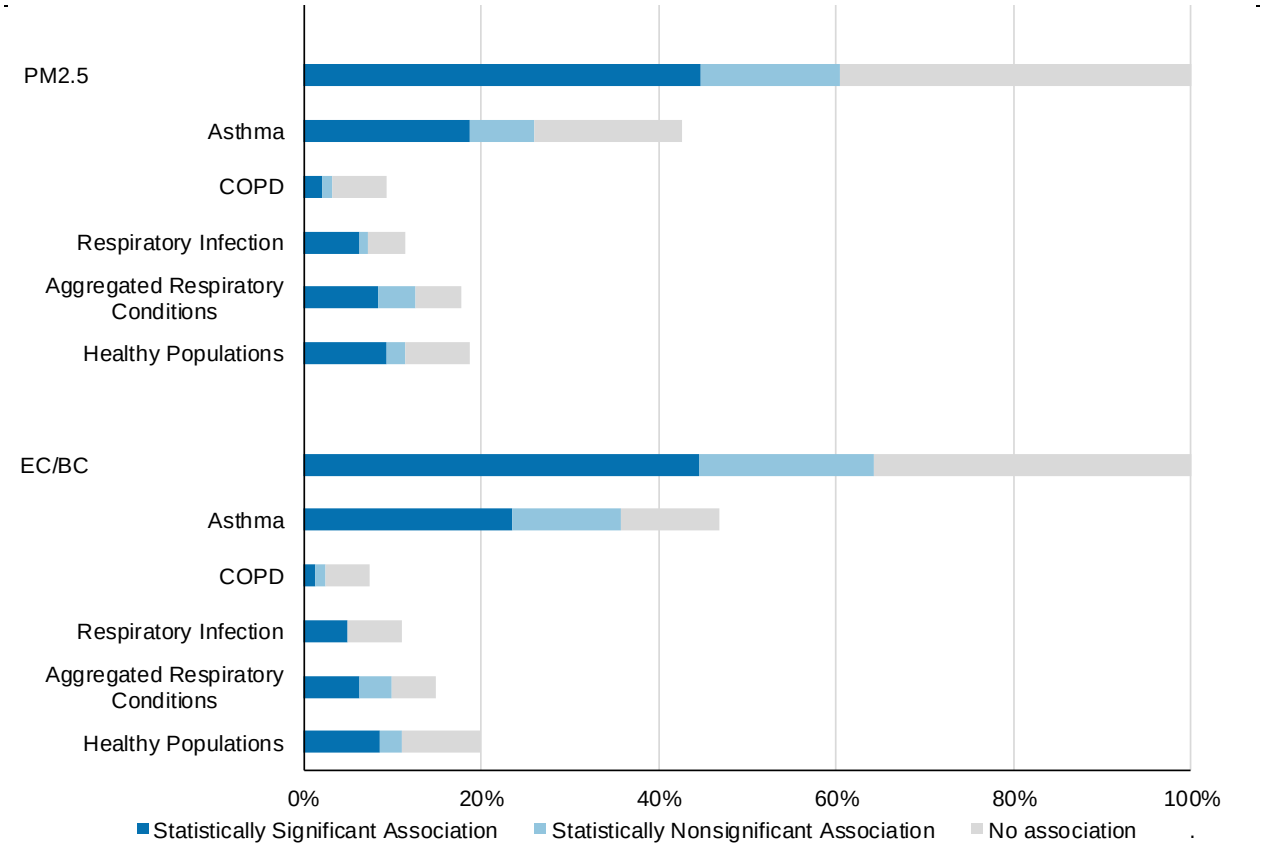
To provide a thorough and consistent evaluation of the evidence with respect to whether a component(s) or source(s) are more strongly related to respiratory effects than $PM_{2.5}$ mass, the evidence is organized by component or source and discussed in the context of associations with $PM_{2.5}$ mass. Additionally, the evidence for components and sources is evaluated in the context of broad health outcome categories, allowing for an integration of evidence related to specific outcomes (e.g., asthma exacerbation). The examination of the relationship between $PM_{2.5}$ components and respiratory effects can generally be divided into two types of analyses: (1) those that examine whether specific components modify the $PM_{2.5}$-respiratory effects association, or (2) those that examine whether an individual component is associated with respiratory effects and potentially a better indicator of PM toxicity compared to PM mass. Although approach 1 is considered one of the techniques used to assess component toxicity as detailed in Mostofsky et al. (2012) these studies are often used to examine heterogeneity in $PM_{2.5}$-respiratory effect risk estimates. As a result, the focus of this section is on population-level epidemiologic studies using those techniques that fall under approach 2, which includes assessing $PM_{2.5}$ component effect by: component concentration; component proportion; component concentration adjusted for $PM_{2.5}$ mass; component residual; or $PM_{2.5}$ residual (Mostofsky et al., 2012).

This section summarizes the evidence evaluating associations between individual components or sources and asthma exacerbation, respiratory infection, or respiratory effects in healthy populations in the context of associations between those respiratory effects and $PM_{2.5}$ mass. EC/BC was the component most often evaluated in studies of respiratory morbidity, and asthma exacerbations were the respiratory effect most commonly examined. Generally, some studies report positive associations between some components and sources and various respiratory health outcomes, though the consistency and coherence of this evidence varies across components and sources. For example, recent studies examined exposure to the EC/BC component of $PM_{2.5}$ and observed consistent associations with indicators of asthma exacerbation in children, though the associations were similar to those observed with $PM_{2.5}$ exposure. Expanded results for NO_3^- and $PM_{2.5}$ from road dust are inconsistent across the array of respiratory outcomes as is new information on PAHs and oxidative potential of $PM_{2.5}$. Overall, associations with respiratory effects are not more clearly linked to a specific PM component or source compared with $PM_{2.5}$ total mass, and within-study comparisons do not show a consistent difference in association between $PM_{2.5}$ and a particular component or source. The evidence for $PM_{2.5}$ components and sources are detailed below.

5.1.11.1 Elemental and Black Carbon

A large body of recent studies consistently links short-term increases in EC/BC concentration with respiratory effects, with the most studies examining asthma-related effects in children. Studies that observed positive associations between exposure to EC/BC and asthma-related effects in children also observed similar associations with $PM_{2.5}$ mass (Figure 5-24). For EC/BC, results are coherent among asthma ED visits, asthma symptoms, and pulmonary inflammation in populations with asthma. However, like trends observed for $PM_{2.5}$ mass, EC/BC associations with lung function are inconsistent. Neither EC/BC nor $PM_{2.5}$ is consistently associated with COPD exacerbation, and the evidence for EC/BC associations with respiratory infection, aggregated respiratory conditions, or respiratory effects in healthy populations is limited and inconsistent. Within most (Sarnat et al., 2015; Winquist et al., 2014b; Kim et al., 2012) but not all (Xiao et al., 2016) U.S. studies, EC was associated with effects related to asthma but not COPD or respiratory infection. Across respiratory effects, there is generally no difference in the pattern or consistency of associations between EC/BC and $PM_{2.5}$ (Figure 5-24).

Most studies associated respiratory effects with both $PM_{2.5}$ and EC/BC, though some showed associations with only one or the other. Many results point to similar magnitude of association for EC/BC and $PM_{2.5}$, often presented per IQR increase in concentration. Some studies estimated larger effects for EC/BC; others estimated larger effects for $PM_{2.5}$. Respiratory effects were associated with EC/BC in cities across regions of the U.S.; no pattern in the presence of an association for EC/BC or the magnitude relative to $PM_{2.5}$ is discerned by geographic location. In the nationwide U.S. Medicare population, EC was not associated with hospital admissions for all respiratory diseases combined (Levy et al., 2012). These results add 2 years to those of Peng et al. (2009a) (2000−2008 vs. 2000−2006), who reported an association with EC. The recent analysis by Levy et al. (2012) indicated the likelihood of greater risk for EC than $PM_{2.5}$ in the East. For locations showing similar magnitude associations for EC/BC and $PM_{2.5}$, correlations ranged 0.23−0.83. Across these studies, no pattern is observed for EC/BC by its correlation with $PM_{2.5}$. Most studies were conducted across seasons, so a pattern of association for EC by season in not discernable. Where stratified by season, EC/BC and $PM_{2.5}$ associations were similar in the same season. Warm season associations with asthma ED visits are indicated in Atlanta, GA and St. Louis, MO (Winquist et al., 2014b; Strickland et al., 2010), and cold season associations with pneumonia hospital admissions are indicated in Boston, MA (Zanobetti and Schwartz, 2006).



BC = black carbon, EC = elemental carbon, $PM_{2.5}$ = particulate matter with nominal mean aerodynamic diameter ≤2.5 µm.

Note: Colored bars indicate the proportion of those studies observing statistically significant positive associations, positive associations, null associations, negative associations, and statistically significant negative associations.

Figure 5-24 Associations for $PM_{2.5}$ total mass and elemental or black carbon with respiratory effects by outcome group.

Potential measurement error is an important consideration in drawing inferences from associations observed with EC/BC and in in comparing the effects relative to $PM_{2.5}$. Consistent with the contribution of local motor vehicle emissions to EC/BC and regional sources to $PM_{2.5}$, some studies indicated greater spatiotemporal variability in concentrations of EC/BC than $PM_{2.5}$. Both BC and $PM_{2.5}$ were highly correlated between two schools in Ciudad Juarez, Mexico (r = 0.85 for BC, r = 0.93 for $PM_{2.5}$) (Sarnat et al., 2012) but not between schools in El Paso, TX, where the correlation was moderate for BC and high for $PM_{2.5}$ ($_r$ = 0.60 for BC, $_r$ = 0.89 for $PM_{2.5}$) (Greenwald et al., 2013; Zora et al., 2013). In New York, NY, correlations between BC and $PM_{2.5}$ were moderate, and varied across schools ($_r$ = 0.47−0.68) (Patel et al., 2010). For these schools that varied in proximity to or intensity of traffic, the school-based EC/BC and $PM_{2.5}$ may have had more comparable exposure error than measurements at

central site monitors. Across studies, concentrations of EC/BC measured at schools were associated with larger increases in symptoms and pulmonary inflammation and larger decreases in lung function among children with asthma (Greenwald et al., 2013; Patel et al., 2013; Zora et al., 2013; Sarnat et al., 2012; Spira-Cohen et al., 2011; Patel et al., 2010).

The associations for respiratory effects and EC or $PM_{2.5}$ measured from personal exposures likely have comparable exposure error. Total personal EC concentrations, but not $PM_{2.5}$ concentrations, were associated with asthma-related effects among children in New York, NY (Spira-Cohen et al., 2011), whereas the opposite was observed for children in Los Angeles, CA (Delfino et al., 2008). One explanation could be variation in sources, for example, indoor exposures. EC and $PM_{2.5}$ were more highly correlated for ambient (r = 0.51) than personal measurements (r = 0.22, 0.43). Personal EC was weakly correlated with school EC in New York, NY (r = 0.27) and uncorrelated with central site EC in Los Angeles, CA (r = −0.01). The relative impact of personal ambient $PM_{2.5}$ and EC exposures also varied for adults (mostly healthy populations) exposed for 2−5 hour in high- and low-traffic locations. Some studies estimated larger effects for $PM_{2.5}$, and correlations with EC/BC were low (r = 0.29, 0.39) (Kubesch et al., 2015; Mirabelli et al., 2015; Mirowsky et al., 2015). Other studies estimated similar effects for EC/BC and $PM_{2.5}$ (Huang et al., 2016; Steenhof et al., 2013; Strak et al., 2012; Zuurbier et al., 2011b).

Associations with asthma-related hospital admissions and ED visits are generally the same for EC/BC and $PM_{2.5}$ measured at central site monitors. Effect estimates were similar per IQR increases in EC and $PM_{2.5}$ during 1993−2001 (Strickland et al., 2011; Strickland et al., 2010) but stronger for $PM_{2.5}$ in later years (2002−2010) (Strickland et al., 2014). For both EC and $PM_{2.5}$, similar effects were estimated when assigning exposure using concentrations at a monitor in the city center and those averaged across monitors by weighting by population density. The representativeness of EC and $PM_{2.5}$ metrics is supported by high correlations between exposure assessment methods (r = 0.96 for $PM_{2.5}$, 0.80 for EC) and the high density of asthma ED visits in the city center. There are greater uncertainties in comparisons in St. Louis, MO showing larger or similar increases in asthma ED visits for $PM_{2.5}$ than EC/BC when a single monitor was used (Sarnat et al., 2015; Winquist et al., 2014b). EC concentrations were spatiotemporally variable relative to $PM_{2.5}$ (median intersite r = 0.88 for $PM_{2.5}$ and 0.47 for EC).

Recent statistical analyses support an association for EC/BC independent of $PM_{2.5}$. Robust associations for EC are observed after adjusting for the non-EC portion of $PM_{2.5}$, which made up 96% total mass (Sarnat et al., 2012) or adjusting for the residuals from a model regressing EC with $PM_{2.5}$ (Basagaña et al., 2015). The latter also showed an association for $PM_{2.5}$. In copollutant models, associations for EC/BC persist when adjusted for $PM_{2.5}$, but associations for $PM_{2.5}$ adjusted for EC/BC were attenuated in some cases (Samoli et al., 2016c; Lin et al., 2011). A role for EC in modifying $PM_{2.5}$ effects is unclear based on contrasting results in the Medicare population. The $PM_{2.5}$ association with aggregated respiratory-related hospital admissions or ED visits increased as the EC fraction of long-term average $PM_{2.5}$ increased when assessed in 106 U.S. counties for 2000−2005 (Bell et al., 2009b) but was unaffected when assessed in 26 cities for 2000−2003 (Zanobetti et al., 2009). Across the 26 cities, EC

comprised 2−14% of total $PM_{2.5}$ mass. Other studies showed no consistent difference in association between EC and $PM_{2.5}$ in locations where EC made up 4−8% of $PM_{2.5}$ (Basagaña et al., 2015; Sarnat et al., 2015; Bell et al., 2014; Winquist et al., 2014b; Spira-Cohen et al., 2011; Peng et al., 2009a). Whether EC/BC has an effect independent of traffic-related copollutants is still uncertain. Correlations were high with UFP (r = 0.84−0.86) and wide-ranging with NO_2 or NO_X (r = 0.36−0.76). In copollutant models examined only with NO_2 or NO_X, associations for personal ambient EC were robust in some cases (Strak et al., 2012) but attenuated in others (Steenhof et al., 2013; McCreanor et al., 2007). Among children in New York, NY, associations for total personal EC were robust to adjustment for school NO_2 (Spira-Cohen et al., 2011), but potential differential measurement error limits inferences from the results. A similar uncertainty applies to results for asthma ED visits in Georgia not indicating synergistic interactions for EC with the highly correlated NO_2, CO, and OC (Xiao et al., 2016). The fused-CMAQ model's predictive capacity of EC, CO, and OC concentrations was mediocre (cross-validation R^2 = 0.53−0.54).

Overall, there is generally no difference in the pattern or consistency of associations between EC/BC and $PM_{2.5}$ across respiratory effects. A large body of recent studies that consistently observed positive associations between exposure to EC/BC and respiratory effects also observed similar associations with $PM_{2.5}$ mass. These results continue to support the conclusion in the 2009 PM ISA that there is "not yet sufficient evidence to allow differentiation of those [components] or sources that more closely related to specific health outcomes" compared to $PM_{2.5}$ mass (U.S. EPA, 2009).

5.1.11.2 Organic Carbon

In contrast with studies characterized in the 2009 PM ISA, recent studies consistently report a positive association of OC with asthma-related hospital admissions, ED visits, symptoms, and pulmonary inflammation but not lung function decrements. Recent results from a limited number of studies demonstrate consistent positive associations between OC exposure and aggregated respiratory-related diseases but not COPD exacerbation, respiratory infection, or respiratory effects in healthy population. Across these studies, the consistency and magnitude of respiratory effect associations are generally similar for OC and $PM_{2.5}$, and these studies report moderate to high correlations between OC and $PM_{2.5}$ (r = 0.51−0.87) (Krall et al., 2016; Xiao et al., 2016; Basagaña et al., 2015; Jones et al., 2015; Sarnat et al., 2015; Kim et al., 2012) and a large contribution of OC to total $PM_{2.5}$ mass [Section 2.5.1.1.6 and 11 and 21% in (Jones et al., 2015; Sarnat et al., 2015)]. In exception to most results, a recent analysis of the U.S. Medicare population indicates greater risk of hospital admission for respiratory infection for OC than $PM_{2.5}$ (Levy et al., 2012).

Like $PM_{2.5}$, OC was associated with respiratory effects among people of all ages or children in locations across U.S. regions. During 2000−2008, OC was linked to hospital admissions for respiratory infection in 98 eastern but not 21 western U.S. counties (Levy et al., 2012). Risk estimates for $PM_{2.5}$ with

hospital admissions for COPD plus respiratory infection during 2000−2003 did not vary by the long-term average OC to $PM_{2.5}$ ratio, which ranged 0.10 to 0.99 across 26 cities and four seasons (Zanobetti et al., 2009). Both OC and $PM_{2.5}$ show associations in the cold and warm season, but few seasonal analyses were conducted. Except for pneumonia, associations for OC and $PM_{2.5}$ are larger in the warm season in U.S. locations (Jones et al., 2015; Winquist et al., 2014b; Strickland et al., 2010).

The lack of clear differences in associations between OC and $PM_{2.5}$ is observed across exposure assessment methods, including concentrations at central site monitors in Atlanta, GA where OC and $PM_{2.5}$ similarly showed spatiotemporal homogeneity (r = 0.96 for $PM_{2.5}$, 0.89 for OC between a monitor in the city center and a population-weighted average) (Strickland et al., 2011) and St. Louis, MO where OC was more variable than $PM_{2.5}$ (median intersite r = 0.43 for OC, 0.88 for $PM_{2.5}$) (Sarnat et al., 2015). Results did not consistently differ between OC and $PM_{2.5}$ for weakly correlated (r = 0.26) total personal exposures of children with asthma (Delfino et al., 2008; Delfino et al., 2006) and moderately to highly correlated (r = 0.40−0.79) personal ambient exposures of adults during 2 or 5 hours spent in high- or varying-traffic locations (Mirabelli et al., 2015; Mirowsky et al., 2015; Strak et al., 2012). In addition to the uncertainty of associations of OC that are independent of the effects of $PM_{2.5}$ mass, it is also unclear if the association for OC with respiratory effects is independent of moderately correlated NO_2 or EC/BC (r = 0.44−0.51 with NO_2, 0.53−0.64 with EC) given that no studies examined confounding.

5.1.11.3 Secondary $PM_{2.5}$—Sulfate, Nitrate, Ammonium

Several recent studies add to the limited body of evidence in the 2009 PM ISA for associations of SO_4^{2-} and asthma exacerbation, and several recent studies contribute evidence to characterize the associations between NO_3^-, and ammonium (NH_4^+) and respiratory effects (Figure 5-25). Evidence for effects on asthma exacerbation are generally more consistent than associations for other respiratory outcomes. In most locations, results are similar between $PM_{2.5}$ and SO_4^{2-} or NH_4^+ in direction and magnitude of association. In the U.S., Europe, and Asia, there was consistent evidence of positive associations for SO_4^{2-}, NH_4^+, and NO_3^- (Wang and Lin, 2016; Jones et al., 2015; Steenhof et al., 2013; Kim et al., 2012; Atkinson et al., 2010). However, in some instances, associations were observed with NO_3^- but not SO_4^{2-} (Ostro et al., 2016; Mann et al., 2010), or associations were observed with SO_4^{2-} but not NO_3^- (Sarnat et al., 2015; Darrow et al., 2014; Strickland et al., 2014). Analyses of the U.S. Medicare population did not report consistently positive associations for SO_4^{2-} or NO_3^- across respiratory effects. For 2000−2008, hospital admissions for respiratory infection were not associated with SO_4^{2-} or NO_3^- in the east or west (Levy et al., 2012). For 2000−2006, hospital admissions for respiratory infection and COPD combined were associated with SO_4^{2-} not NO_3^- (Peng et al., 2009a).

For U.S. locations, associations for SO_4^{2-}, NO_3^-, and NH_4^+ tends to follow their relation to total $PM_{2.5}$ mass. Where associations were observed for SO_4^{2-} but not NO_3^-, $PM_{2.5}$ was highly correlated with SO_4^{2-} (r = 0.74−0.81) not NO_3^- (r = 0.02−0.45) (Sarnat et al., 2015; Darrow et al., 2014; Strickland et al.,

2014; Peng et al., 2009a). The converse was observed in California (r for $PM_{2.5}$ = 0.9 with NO_3^- and <0.5 with SO_4^{2-}) (Ostro et al., 2009). Where associations were observed with SO_4^{2-} and NO_3^-, both were highly correlated with $PM_{2.5}$ (r = 0.68−0.97 for SO_4^{2-}, 0.51−0.82 for NO_3^-) (Wang and Lin, 2016; Jones et al., 2015; Kim et al., 2012; Atkinson et al., 2010). The few available seasonal analyses show higher concentrations of SO_4^{2-} and NH_4^+ in the warm season and of NO_3^- in the cold season.

Analyses of effect measure modification also do not clearly show that SO_4^{2-}, NO_3^-, or NH_4^+ influences $PM_{2.5}$-associated respiratory effects. Consistent with previous findings (Bell et al., 2009b), recent results in the Medicare population show no clear difference in $PM_{2.5}$-associated respiratory hospital admissions by the ratio of SO_4^{2-}, NO_3^-, or NH_4^+ to $PM_{2.5}$ in New York State (Jones et al., 2015) and low probability that risk for SO_4^{2-} or NO_3^- is greater than that for $PM_{2.5}$ in the U.S. overall (Levy et al., 2012). An independent association for SO_4^{2-} is not clearly indicated with adjustment for the non-SO_4^{2-} portion of $PM_{2.5}$ in St. Louis, MO (Sarnat et al., 2015) or residuals from a model regressing $PM_{2.5}$ on SO_4^{2-} concentrations in Europe (Basagaña et al., 2015). In California, the association for NO_3^- was robust to adjustment for a factor of traffic-related $PM_{2.5}$ components (Ostro et al., 2016).

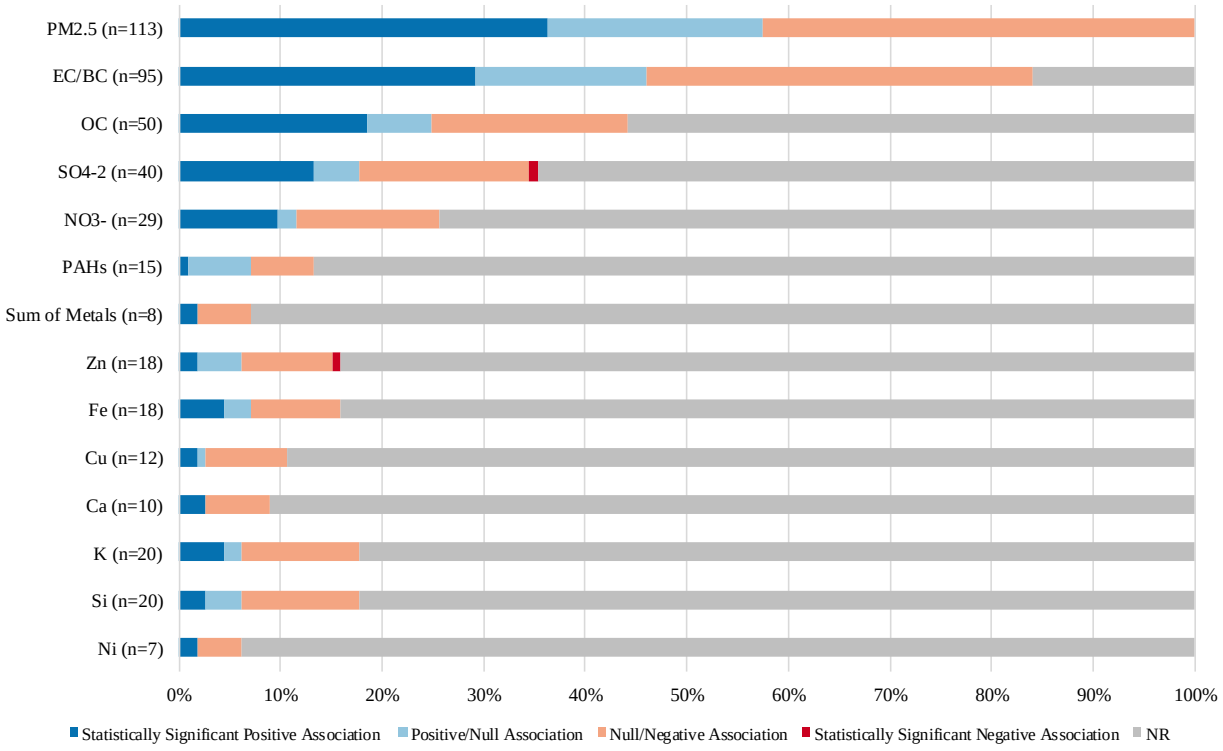
5.1.11.4 Metals

Compared with $PM_{2.5}$ mass, short-term exposures to metal components of $PM_{2.5}$ are inconsistently associated with respiratory effects (Figure 5-25). In the expanded body of recent studies, relatively few observed associations with a metal that differed substantially from the association with $PM_{2.5}$ mass (Ferreira et al., 2016; Bell et al., 2014; Strak et al., 2012; Hong et al., 2010). Most studies that included a metal component of $PM_{2.5}$ observed an association with some metal, and studies that examined numerous metals observed an association with multiple metals. However, findings are inconsistent for any individual metal or the sum of metals. Fe, Zn, Cu, Ca, K, and Si are most studied, and many associations are positive for Fe or Zn with indicators of asthma exacerbation (Prieto-Parra et al., 2017; Mirabelli et al., 2015; Hong et al., 2010; Sinclair et al., 2010; Gent et al., 2009; Ostro et al., 2009). Results are mostly null for Al, Mn, Pb, As, Se, Br, Ti, and V, but associations for V tend to be similar to those for Ni (Basagaña et al., 2015; Bell et al., 2014).

Neither the percentage contribution metals make to $PM_{2.5}$ mass nor the correlation between metal and $PM_{2.5}$ mass concentrations affected the pattern of associations between metal components and respiratory effects. Where metals comprised less than 1% of $PM_{2.5}$, associations with respiratory effects were observed in Bell et al. (2014), but not Sarnat et al. (2015). The range of correlations between metals and $PM_{2.5}$ (r = 0.25−0.63) did not clearly differ between studies that observed (Krall et al., 2016; Basagaña et al., 2015; Ostro et al., 2009) and did not observe (Basagaña et al., 2015; Sarnat et al., 2015) positive associations with metals. Few seasonal analyses were conducted to assess a pattern of association. Previous U.S.-wide analyses indicate that the $PM_{2.5}$ association with respiratory hospital admissions varies across cities depending on the percentage of Na, Ca, Ni or V (Bell et al., 2009b;

Zanobetti et al., 2009), with (Bell et al., 2009b) indicating effect modification by Ni or V only when New York, NY counties were included. Recent studies confirm a positive association with Ni and V in the Northeast (i.e., Connecticut and Massachusetts) (Bell et al., 2014; Gent et al., 2009).

Ambient concentrations of metals can be spatiotemporally more heterogeneous than $PM_{2.5}$ total mass. In St. Louis, MO, $PM_{2.5}$ but not metals were associated with asthma ED visits, and Fe, Cu, and Zn were variable across monitors (median r = 0.54 for Fe, 0.03 for Cu and Zn) (Sarnat et al., 2015). Exposure measurement error could contribute to inconsistent findings for metals. However, personal Fe exposures while driving in a car or in locations with varying traffic levels were inconsistently associated with lung function decrements or increases in pulmonary inflammation (Mirabelli et al., 2015; Strak et al., 2012).



BC = black carbon, Ca = calcium, Cu = copper, EC = elemental carbon, Fe = iron, K = potassium, N = the number of studies evaluating $PM_{2.5}$ mass or components, Ni = nickel, NO_3^- = nitrate, OC = organic carbon, PAH = polycyclic aromatic hydrocarbon, $PM_{2.5}$ = particulate matter with nominal mean aerodynamic diameter ≤2.5 µm, Si = silicon, SO_4^{2-} = sulfate, Zn = zinc.

Note: Colored bars indicate the proportion of those studies observing statistically significant positive associations, positive associations, null associations, negative associations, and statistically significant negative associations.

Figure 5-25 Distribution of associations for all respiratory effects and short-term $PM_{2.5}$ mass and $PM_{2.5}$ components exposure.

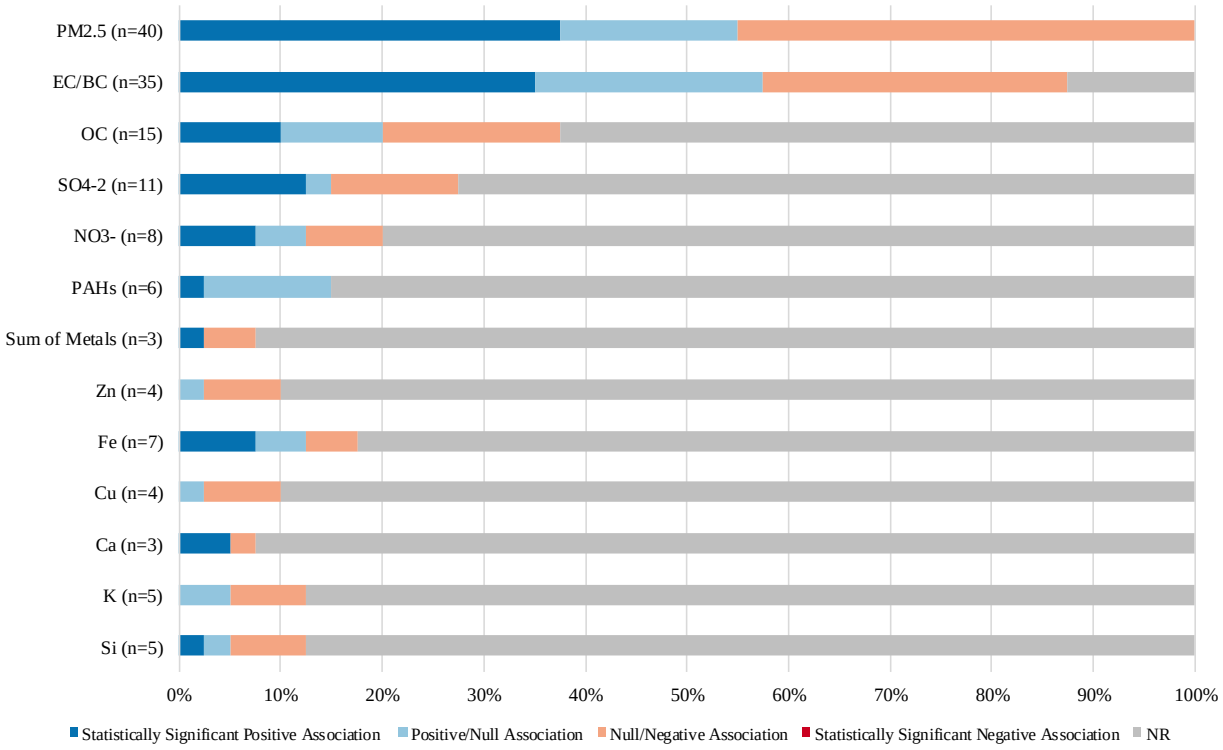
5.1.11.5 Other $PM_{2.5}$ components

Information from a limited number of recent studies links respiratory effects with oxidative potential of $PM_{2.5}$ and chlorine but is inconsistent for polycyclic aromatic hydrocarbons, alkanes, hopanes, and endotoxin. Information is available from a few studies and locations for each of these $PM_{2.5}$ components and for a variety of respiratory effects, with few studies evaluating the same combination of $PM_{2.5}$ component and respiratory effect [e.g., Maikawa et al. (2016); Mirabelli et al. (2015); Sarnat et al. (2015); (Delfino et al., 2013)]. Notably, for the studies examining oxidative potential of $PM_{2.5}$, associations were not observed with total $PM_{2.5}$ mass. Associations for polycyclic aromatic hydrocarbons and alkanes were linked to sources such as traffic or petroleum industries, and associations for endotoxin were linked to farm exposures.

5.1.11.6 Sources of $PM_{2.5}$

A limited number of studies included in the 2009 PM ISA examined associations between respiratory effects and sources of $PM_{2.5}$ (e.g., crustal, soil, road dust, traffic). Several recent studies apportioned $PM_{2.5}$ components into source factors and provide some evidence linking $PM_{2.5}$ from traffic to asthma exacerbation and $PM_{2.5}$ from biomass burning to asthma exacerbation and respiratory infection (Figure 5-25 and Figure 5-26). These respiratory effects also are consistently associated with short-term $PM_{2.5}$ exposures during wildfires. Evidence is inconsistent for $PM_{2.5}$ from dust or soil, and as examined in few studies, oil, salt, long-range transport, and local industry. Results do not appear to depend on the contribution or correlation of a source to $PM_{2.5}$ mass. For example, associations were observed with biomass-related $PM_{2.5}$ comprising 2.8 to 15.8% of mass and showing correlations with $PM_{2.5}$ mass from 0.24 to 0.84. In contrast, long-range transport contributed 30−57% to $PM_{2.5}$ mass. Further, studies that examined numerous sources tended to observe associations with $PM_{2.5}$ with combustion-related activities, specifically traffic and biomass. Some U.S., Canadian, and European studies observed respiratory effects in association with source-specific $PM_{2.5}$ but not with $PM_{2.5}$ mass (Brand et al., 2016; Bell et al., 2014; Alessandrini et al., 2013; Gent et al., 2009), but findings overall are more consistent for $PM_{2.5}$ mass. No clear difference in associations between total $PM_{2.5}$ mass or source-specific $PM_{2.5}$ and respiratory effects is indicated across studies during wildfire and nonwildfire study periods (Kollanus et al., 2016; Salimi et al., 2016; Delfino et al., 2009).

Respiratory effects were associated with $PM_{2.5}$ from motor vehicles or biomass in various U.S. regions, including a study of Atlanta, GA; Birmingham, AL; Dallas, TX; and St. Louis, MO, where $PM_{2.5}$ components were apportioned into similar factors (Krall et al., 2016). Examination of wildfire-related $PM_{2.5}$ mostly focused on the western U.S., including an analysis of 561 counties (Liu et al., 2017), but also included a study focusing on a peat fire in North Carolina (Rappold et al., 2012). No distinct seasonal pattern is discerned for associations with source-specific $PM_{2.5}$, but many wildfires occur during the warm season.



BC = Black carbon, Ca = calcium, Cu = copper, EC = elemental carbon, Fe = iron, K = potassium, N = the number of studies evaluating $PM_{2.5}$ mass or components, NO_3^- = nitrate, OC = organic carbon, PAH = polycyclic aromatic hydrocarbon, $PM_{2.5}$ = particulate matter with nominal mean aerodynamic diameter ≤2.5 µm, Si = silicon, SO_4^{2-} = sulfate, Zn = zinc.

Note: Colored bars indicate the proportion of those studies observing statistically significant positive associations, positive associations, null associations, and negative associations.

Figure 5-26 Associations for asthma exacerbations with $PM_{2.5}$ mass and components.

The results for source-specific $PM_{2.5}$ do not always agree with those for the components that make up the source factors. Respiratory effects are inconsistently associated with dust- or soil-related $PM_{2.5}$, Si, Ca, and Al as well as with salt-related $PM_{2.5}$, Na, and Cl (Section 5.1.11.4). In northeastern U.S. locations, associations were observed with Ni or V but not oil-related $PM_{2.5}$ (Bell et al., 2014; Gent et al., 2009). Similarly, associations are observed with SO_4^{2-} or NO_3^- but inconsistently for factors representing long-range transported $PM_{2.5}$. In New Mexico, no association was observed for $PM_{2.5}$ or for air masses identified as originating from regions in the western U.S. (Rodopoulou et al., 2014). Results agree better for motor vehicle-related $PM_{2.5}$, as evidence also links asthma-related effects to EC (Section 5.1.11.1), OC (Section 5.1.11.2), Zn, and Fe (Section 5.1.11.4), which comprised most motor vehicle source factors. A few studies observed associations with EC/BC or OC but not motor vehicle-related $PM_{2.5}$ (Krall et al., 2016; Bell et al., 2014). The influence of total $PM_{2.5}$ mass or EC/BC does not clearly depend on proximity to traffic. With scripted exposures near roadways, $PM_{2.5}$ and EC/BC are inconsistently associated with

respiratory effects in healthy populations (Section 5.1.7). However, similar inconsistency is observed for children with asthma attending school near major roads (Greenwald et al., 2013; Sarnat et al., 2012). For biomass-related $PM_{2.5}$, results for asthma-related effects tend to correspond with K or OC within studies, but across studies, consistency is observed for OC (Section 5.1.11.2) not K (Section 5.1.11.4).

5.1.11.7 Summary

Generally, some studies report positive associations between some components and sources and various respiratory health outcomes, though the consistency and coherence of this evidence varies across components and sources. Overall, associations with respiratory effects are not more clearly linked to a particular PM component or source compared with $PM_{2.5}$ total mass, and within-study comparisons do not show a consistent difference in association between $PM_{2.5}$ and a specific component or source (Figure 5-25). The majority of studies evaluating $PM_{2.5}$ components examined associations with asthma exacerbation, and these results are presented in Figure 5-26. Some recent studies did not observe increased respiratory effects with $PM_{2.5}$ mass, but did with PM components and sources, typically EC/BC (Section 5.1.11.1) and metals (Section 5.1.11.4). However, in most cases, associations were observed with $PM_{2.5}$ as well as components or sources.

5.1.12 Summary and Causality Determination

The 2009 PM ISA (U.S. EPA, 2009) concluded that a "causal relationship is likely to exist" between short-term $PM_{2.5}$ exposure and respiratory effects (U.S. EPA, 2009).[56] This conclusion was based mainly on epidemiologic evidence demonstrating associations between short-term $PM_{2.5}$ exposure and various respiratory effects. There was more limited evidence from controlled human exposure and animal toxicological studies, which provided coherence and biological plausibility for a subset of epidemiologic findings. Epidemiologic evidence was consistent for COPD exacerbation, respiratory infection, and respiratory mortality and inconsistent for asthma-related hospital admissions and ED visits. However, associations between short-term $PM_{2.5}$ exposure and increased respiratory symptoms and decreases in lung function were observed in children with asthma. Evidence supporting an independent effect of $PM_{2.5}$ on the respiratory system was provided by animal toxicological studies of $PM_{2.5}$ CAPs, which demonstrated changes in some pulmonary function parameters, as well as inflammation, oxidative stress, injury, enhanced allergic responses, and reduced host defenses. Many of these effects have been implicated in the pathophysiology for asthma exacerbation, COPD exacerbation, or respiratory infection. In the few controlled human exposure studies conducted in individuals with asthma or COPD, $PM_{2.5}$ exposure mostly had no effect on respiratory symptoms, lung function, or pulmonary inflammation.

[56] As detailed in the Preface, risk estimates are for a 10 $\mu g/m^3$ increase in 24-hour average $PM_{2.5}$ concentrations unless otherwise noted.

Short-term $PM_{2.5}$ exposure was not clearly related to respiratory effects in healthy people. For many endpoints the recent epidemiologic evidence is expanded compared with evidence available in the 2009 PM ISA. However, recent controlled human exposure and animal toxicological studies are limited in number. While there are more analyses of potential copollutant confounding indicating that associations are robust to the inclusion of gaseous pollutants, uncertainties remain due to the limited experimental evidence supporting an independent $PM_{2.5}$ effect from controlled human exposure and toxicological studies. The evidence for the relationship between short-term exposure to $PM_{2.5}$ and respiratory effects is summarized in Table 5-18, using the framework for causality determinations described in the Preamble to the ISAs (U.S. EPA, 2015).

For asthma exacerbation, the key epidemiologic evidence consists of hospital admissions and ED visits. Recent studies strengthen the relationship between asthma exacerbation in children and short-term $PM_{2.5}$ exposure, while, in adults, the relationship continues to be inconsistent. Exposure measurement error related to uncharacterized spatial variability tends to be lower in $PM_{2.5}$ mass concentration compared with other size fractions and species (Section 3.4.2.2). Copollutant models are examined in recent studies of children and people of all ages and add evidence of robust $PM_{2.5}$ associations after adjustment for gaseous copollutants or pollen. Recent studies continue to indicate $PM_{2.5}$-related increases in asthma symptoms and medication use in children, with less consistent evidence for lung function decrements and pulmonary inflammation. In adults, asthma studies with personal 2-hour ambient $PM_{2.5}$ exposures on or near a high-traffic road were associated with lung function decrements. While controlled human exposure studies find little evidence for altered lung function and pulmonary inflammation, animal toxicological studies show enhancement of allergic inflammation, other allergic responses, and airway remodeling in animal models of allergic airway disease. These results provide coherence with and biological plausibility for epidemiologic findings of allergic asthma, the most common phenotype in children. Overall, several well-conducted epidemiologic studies with total personal, residential outdoor, and school outdoor $PM_{2.5}$ measurements show associations with asthma-related effects.

Table 5-18 Summary of evidence for a likely to be causal relationship between short-term $PM_{2.5}$ exposure and respiratory effects.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{2.5}$ Concentrations Associated with Effects[c]
Asthma exacerbation			
Consistent epidemiologic evidence from multiple, high-quality studies at relevant $PM_{2.5}$ concentrations	Increases in asthma-related hospital admissions and ED visits in children, and all ages combined in studies conducted in the U.S. and Canada.	Section 5.1.2.1.1 Section 5.1.2.1.2	7.9−12.9 µg/m^3 7.1−19.2 µg/m^3
Epidemiologic evidence from copollutant models provides some support for an independent $PM_{2.5}$ association	Expanded examination of potential copollutant confounding for asthma-related hospital admissions and ED visits in recent studies, with evidence that associations remain robust in models with gaseous pollutants. No studies provide copollutant model results with $PM_{10-2.5}$. When reported, correlations with gaseous copollutants were primarily in the low to moderate range (r < 0.7).	Section 5.1.10.1	
Coherence in epidemiologic studies across the continuum of effects	Panel studies in children with asthma provide support for asthma exacerbation in children with consistent associations for respiratory symptoms and medication use, and lung function decrements. Less consistent evidence for pulmonary inflammation.	Section 5.1.2.2 Section 0 Section 5.1.2.4	
Lack of evidence from controlled human exposure studies	In adults with asthma, most measures of lung function are unaffected. There is a lack of evidence for pulmonary inflammation.	Section 0 Section 0 Urch et al. (2010)	64 µg/m^3
Some evidence from toxicological studies at relevant concentrations	Most studies show enhancement of allergic inflammation, other allergic responses, or airway remodeling in animal model of allergic airway disease.	Section 5.1.2.4.2 Harkema et al. (2009) Wagner et al. (2012)	356−596 µg/m^3
Biological plausibility	Evidence from animal toxicological studies provides biological plausibility for epidemiologic findings for exacerbation of allergic asthma, the most common asthma phenotype in children.		

Table 5-18 (Continued): Summary of evidence for a likely to be causal relationship between short term $PM_{2.5}$ exposure and respiratory effects.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{2.5}$ Concentrations Associated with Effects[c]
Exacerbation of COPD			
Consistent epidemiologic evidence from multiple, high-quality studies at relevant $PM_{2.5}$ concentrations	Increases in COPD-related hospital admissions and ED visits in studies conducted in the U.S. and Canada.	Section 5.1.4.1.1 Section 5.1.4.1.2	7.7−18.0 µg/m^3 7.1−19.2 µg/m^3
Epidemiologic evidence from a limited number of copollutant models provide some support for an independent $PM_{2.5}$ association	Limited examination of potential copollutant confounding for COPD-related hospital admissions and ED visits, with evidence that associations remain robust in models with gaseous pollutants. Limited information is available regarding models with $PM_{10-2.5}$. When reported, correlations with gaseous copollutants were primarily in the low to moderate range ($r < 0.7$).	Section 5.1.10.1	
Some coherence in epidemiologic studies across the continuum of effects	Panel studies in adults with COPD provide support for COPD exacerbation with consistent evidence of increased eNO in response to short-term $PM_{2.5}$ exposure. Less consistent evidence for respiratory symptoms and lung function.	Section 5.1.4.2 Section 5.1.4.3 Section 5.1.4.4	
Limited evidence from a controlled human exposure study and animal toxicological studies at relevant concentrations	Lung injury, inflammation and decrements in lung function are observed.	Section 5.1.4.3 Section 5.1.4.4	171−1,200 µg/m^3
Biological plausibility	Evidence from animal toxicological studies provides biological plausibility for epidemiologic findings for COPD.		
Respiratory mortality			
Consistent epidemiologic evidence from multiple, high quality studies at relevant $PM_{2.5}$ concentrations	Consistent evidence of increases in mortality in response to short-term $PM_{2.5}$ exposure in multicity studies in the U.S. and Canada. Evidence of immediate effects (lag 0 to 1 days), and some recent evidence of prolonged effects (lags >2 days).	Section 5.1.9	7.9−19.9 µg/m^3
Epidemiologic evidence from a limited number of copollutant models provide some support for an independent $PM_{2.5}$ association	Potential copollutant confounding is examined in a limited number of studies with some evidence that associations remain robust in models with gaseous pollutants and $PM_{10-2.5}$. [b]Describes the key evidence and references, supporting or contradicting, contributing most heavily to causality determination and, where applicable, to uncertainties or inconsistencies. References to earlier sections indicate where full body of evidence is described.

[c]Describes the $PM_{2.5}$ concentrations with which the evidence is substantiated.

Epidemiologic evidence is also expanded for COPD-related hospital admissions and ED visits. The 2009 PM ISA described consistent associations in most of those studies conducted in the U.S. or Canada. Additional U.S. analyses of the Medicare population provide supporting evidence, as do many multicity U.S. and Canadian studies. However, many studies of single cities do not indicate associations. Although recent studies add inconsistent findings, the overall evidence links recent COPD hospital admission and ED visits to short-term $PM_{2.5}$ exposures. A common uncertainty across the studies is the lack of examination of copollutants to assess the potential for confounding and compare to previous findings showing attenuation of the $PM_{2.5}$ associations with adjustment for NO_2. However, recent observations of $PM_{2.5}$-related increases in COPD symptoms, medication use, pulmonary inflammation, and decreases in lung function in epidemiologic studies support and add coherence for the hospital admission and ED visits studies. Results of controlled human exposure and animal toxicological studies show decrements in lung function, pulmonary inflammation, and lung injury, providing coherence with and biological plausibility for epidemiologic findings.

Studies evaluated in the 2009 PM ISA (U.S. EPA, 2009) consistently observed associations between $PM_{2.5}$ concentrations and hospital admissions or ED visits for respiratory infections, which often encompassed multiple individual respiratory infections, but not for pneumonia alone. Recent studies expand findings but are not consistent with the results of older studies since the respiratory infection-related outcomes examined were heterogeneous. Many studies of respiratory infection did not examine any copollutants, making it unclear whether $PM_{2.5}$ associations are independent of copollutants. Results from an animal toxicological study demonstrate biological plausibility by showing altered host defense and greater susceptibility to bacterial infection as a result of short-term $PM_{2.5}$ exposure.

Studies of combined respiratory-related hospital admissions and ED visits examine groups of specific diseases or examine all respiratory-related diseases. Associations are seen in children, people of all ages, and older adults from single-city studies and in people of all ages in multicity studies. Studies of respiratory mortality also report associations in single and multicity studies, although confidence intervals are sometimes wide, as reflected by the small percentage of deaths that are due to respiratory mortality (~9%) (NHLBI, 2017). Potential copollutant confounding is examined in a few studies of aggregated respiratory condition and respiratory mortality and while there is some evidence indicating that associations remain robust in models with gaseous pollutants or $PM_{10-2.5}$, uncertainty remains.

In epidemiologic studies in healthy populations, changes in lung function and pulmonary inflammation are observed, but changes tend to be transient and copollutant confounding is inadequately examined. Controlled human exposure and animal toxicological studies provide evidence for lung function decrements and pulmonary inflammation, as well as for pulmonary injury, oxidative stress, morphologic changes, and allergic sensitization. However, effects were not observed in every study.

The strongest evidence of an effect of short-term $PM_{2.5}$ exposure on respiratory effects is provided by epidemiologic studies of asthma and COPD exacerbation. While animal toxicological studies provide biological plausibility for these findings, some uncertainty remains with respect to the independence of $PM_{2.5}$ effects. **Overall, the collective evidence is sufficient to conclude that a causal relationship is likely to exist between short-term $PM_{2.5}$ exposure and respiratory effects.**

5.2 Long-Term Exposure $PM_{2.5}$ Exposure and Respiratory Effects

The 2009 PM ISA concluded that a causal relationship is likely to exist between long-term $PM_{2.5}$ exposure and respiratory effects (U.S. EPA, 2009).[57] This conclusion was based mainly on epidemiologic evidence demonstrating associations between long-term $PM_{2.5}$ exposure and changes in lung function or lung function growth rate in children. Biological plausibility was provided by a single animal toxicological study involving pre- and post-natal exposure to $PM_{2.5}$ CAPs which found impaired lung development. Epidemiologic evidence for associations between long-term $PM_{2.5}$ exposure and other respiratory outcomes such as the development of asthma, the development of allergic disease, the development of COPD, respiratory infection, and the severity of disease was limited, both in the number of studies available and the consistency of the results. In an animal toxicological study, long-term exposure to $PM_{2.5}$ CAPs also led to morphological changes in nasal airways of healthy animals. Additional animal toxicological studies involved exposure to mixtures, such as motor vehicle exhaust and woodsmoke, and effects were not attributed to the particulate or gaseous components of the mixture.

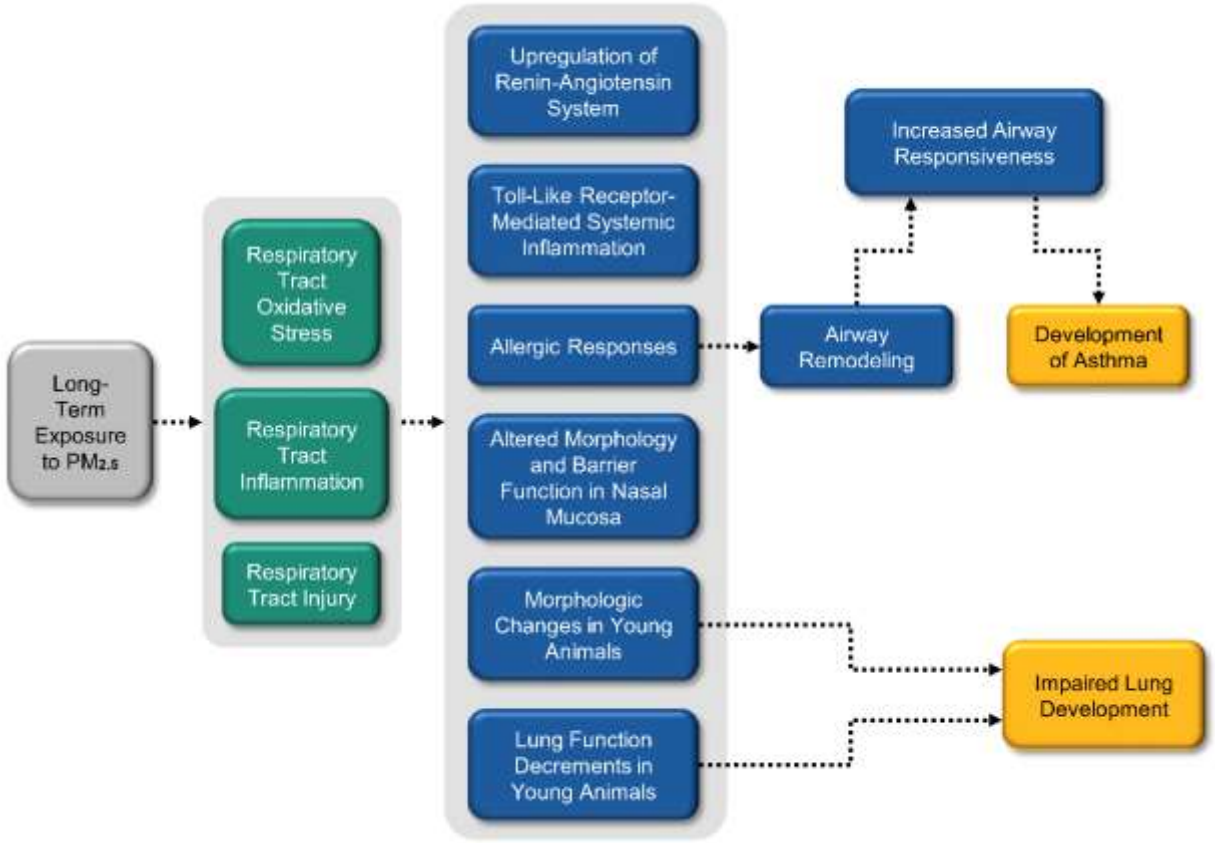
[57] As detailed in the Preface, risk estimates are for a 5 $\mu g/m^3$ increase in annual $PM_{2.5}$ concentrations unless otherwise noted.

Recent evidence continues to link long-term exposure to $PM_{2.5}$ and reduced lung development in children and supports $PM_{2.5}$-related acceleration of lung function decline in adults (Section 5.2.2). The recent body of literature enhances the limited evidence base, providing further evidence that long-term exposure to $PM_{2.5}$ is associated with asthma development in children (Section 5.2.3) and COPD development in adults (Section 5.2.5). Epidemiologic evidence for the development of allergic disease (Section 5.2.4), respiratory infection (Section 5.2.6), and severity of disease (Section 5.2.7) is inconsistent. Recent animal toxicological studies provide evidence for respiratory effects in healthy populations (Section 5.2.8) and animal models of cardiovascular disease (Section 5.2.9), including pulmonary oxidative stress and inflammation. Studies focusing on the nasal airways find inflammation and morphologic changes (Section 5.2.8). The epidemiologic literature provides evidence for respiratory mortality in relationship to long-term $PM_{2.5}$ exposure (Section 5.2.10) and examines the relationship between the decline in $PM_{2.5}$ levels and metrics of respiratory health (Section 5.2.11). Findings that improved respiratory health in children are linked to decreased $PM_{2.5}$ concentrations add to the evidence base linking long-term $PM_{2.5}$ exposure and respiratory effects. However, uncertainty with respect to copollutant confounding remains.

5.2.1 Biological Plausibility

This section describes biological pathways that potentially underlie respiratory health effects resulting from long-term exposure to $PM_{2.5}$. Figure 5-27 graphically depicts the proposed pathways as a continuum of upstream events, connected by arrows, that lead to downstream events observed in epidemiologic studies. This discussion of "how" long-term exposure to $PM_{2.5}$ may lead to respiratory health effects contributes to an understanding of the biological plausibility of epidemiologic results evaluated later in Section 0.

Once $PM_{2.5}$ deposits in the respiratory tract, it may be retained, cleared, or solubilized (see CHAPTER 4). Insoluble and soluble components of $PM_{2.5}$ may interact with respiratory tract cells, such as epithelial cells, inflammatory cells, and sensory nerve cells. One way in which this may occur is through reduction-oxidative (redox) reactions. As discussed in Section 2.3.3, PM may generate reactive oxygen species (ROS) and this capacity is termed "oxidative potential." Furthermore, respiratory tract cells may respond to the presence of PM by generating ROS. Further discussion of these redox reactions, which may contribute to oxidative stress, is found in Section 5.1.1 of the 2009 PM ISA (U.S. EPA, 2009). In addition, insoluble particles may translocate to the interstitial space beneath the respiratory epithelium and accumulate in the lymph nodes (see CHAPTER 4). Immune system responses due to the presence of particles in the interstitial space may contribute to respiratory health effects.



Note: The boxes above represent the effects for which there is experimental or epidemiologic evidence, whereas the dotted arrows indicate a proposed relationship between those effects. Shading around multiple boxes denotes relationships between groups of upstream and downstream effects. Progression of effects is depicted from left to right and color-coded (gray, exposure; green, initial event; blue, intermediate event; orange, apical event). Here, apical events generally reflect results of epidemiologic studies, which often observe effects at the population level. Epidemiologic evidence may also contribute to upstream boxes. When there are gaps in the evidence, there are complementary gaps in the figure and the accompanying text below.

Figure 5-27 Potential biological pathways for respiratory effects following long-term $PM_{2.5}$ exposure.

Evidence that long-term exposure to $PM_{2.5}$ may affect the respiratory tract generally informs one proposed pathway (Figure 5-27). It begins with injury, oxidative stress, and inflammation in the respiratory tract, as demonstrated by animal toxicological studies. These responses, which are difficult to disentangle, were also observed in some studies of short-term exposure to $PM_{2.5}$ (Figure 5-1). Persistent or intermittent exposure to $PM_{2.5}$ over months to years may lead to cumulative or chronic effects, including the development of asthma or impaired lung development, as measured by decrements in lung function growth.

Inhalation of CAPs resulted in the upregulation of the renin-angiotensin system (RAS), as indicated by an increase in mRNA and protein levels of angiotensin receptor Type 1, in rodent lung tissue

(Aztatzi-Aguilar et al., 2015). Angiotensin receptor Type 1 mediates the effects of angiotensin II, which is a potent vasoconstrictor and mediator in the vasculature. This response was accompanied by upregulation of heme oxygenase-1, an antioxidant enzyme induced in response to oxidative stress. Whether upregulation of the RAS was mediated by inflammation or oxidative stress is not clear. The SNS and the RAS are known to interact in a positive feedback fashion (Section 8.1.2) with important ramifications in the cardiovascular system. But, there is no evidence that long-term exposure to $PM_{2.5}$ leads to activation of sensory nerves or to modulation of ANS responses, as was observed in the case of short-term exposure to $PM_{2.5}$ (Figure 5-1). Thus, there is no evidence to support a relationship between activation of sensory nerves and changes in the RAS following long-term exposure to $PM_{2.5}$.

Some animal toxicological studies shed light on specific types of inflammation such as Th1 and Th2 innate immunity. Long-term inhalation of CAPs increased levels of oxidized phospholipids in the BALF (Deiuliis et al., 2012; Kampfrath et al., 2011). Specific macrophage and T-cell subtypes were also increased in lung tissue. These results are consistent with the known role of oxidized phospholipids in activating the Toll-like Receptor (TLR4) system. The TLR4 system stimulates macrophages to release cytokines that recruit and activate T cells. This response is a proinflammatory Th1 innate immune response capable of transmitting cell signals to the systemic circulation, leading to systemic inflammation (see Section 6.2.1). Th2 innate immune responses were also demonstrated following inhalation of $PM_{2.5}$. Long-term exposure to diesel exhaust particles (DEPs) resulted in increased levels of Th2 cytokines in BALF (Kim et al., 2016a). This response was accompanied by methacholine-induced changes in enhanced pause (Penh), which may indicate an increase in airway responsiveness. These changes are consistent with the development of an allergic asthmatic phenotype and possibly underlie epidemiologic findings linking exposure to $PM_{2.5}$ and the development of asthma (Section 5.2.3).

Other animal toxicological studies focused on respiratory responses in a specific region (e.g., the nose) or in the context of a specific disease state (e.g., cardiovascular disease) or lifestage (e.g., young animals). Oxidative stress, injury, inflammation, and morphologic changes were demonstrated in nasal mucosa following long-term exposure to $PM_{2.5}$ (Guo et al., 2017);(Guo et al., 2017; Ramanathan et al., 2017). Findings of increased malondialdehyde, cytokines, numbers of eosinophils and neutrophils, markers of eosinophil and neutrophil activation, as well as nasal epithelial necrosis, increased septal thickness, and sinonasal epithelial cell barrier dysfunction were reported. Inflammatory responses, such as upregulation of cytokine mRNA and monocytic infiltration in the lung, were found in two animal models of cardiovascular disease following CAPs exposure (Ying et al., 2015; Xu et al., 2012). Experimental studies in young animals exposed to $PM_{2.5}$ also demonstrated oxidative stress-related changes in lungs following pre- and post-natal exposures (Song et al., 2017) and secretory changes in nasal mucosa following neonatal exposure (Pires-Neto et al., 2006). Further, inhalation of CAPs in the pre- and post-natal period resulted in decreased lung function (i.e., decreased inspiratory and expiratory volumes) and altered lung morphology (i.e., decreased alveolar surface to volume ratio) (Mauad et al., 2008). These changes reflect impaired lung development likely due to incomplete alveolarization and the enlargement

of air spaces as a result of exposure to $PM_{2.5}$. They provide plausibility for decrements in lung function growth seen in epidemiologic studies (Section 5.2.2).

As described here, there is one main pathway, with many branches, by which long-term exposure to $PM_{2.5}$ could lead to respiratory health effects. It involves respiratory tract injury, inflammation, and oxidative stress as initial events. There is evidence of Th1 and Th2 innate immune system activation. The latter response, indicating the development of an allergic phenotype, may lead to increases in airway responsiveness, which are linked to the development of asthma. Inflammatory changes in the upper respiratory tract (i.e., the nose) of adult animals likely triggered the observed morphologic changes and barrier dysfunction. Respiratory tract inflammation may also lead to morphologic changes and lung function decrements in young animals, which are linked to impaired lung development. The multibranched pathway described here provides biological plausibility for epidemiologic evidence of respiratory health effects and will be used to inform a causality determination, which is discussed later in the chapter (Section 5.2.13).

In addition, evidence for Type 1 innate immune system activation in the respiratory tract provides a link to systemic inflammation resulting from long-term exposure to $PM_{2.5}$ (Section 6.2.1). This pathway may contribute to extrapulmonary effects following inhalation of $PM_{2.5}$.

5.2.2 Lung Function and Development

In the 2009 PM ISA (U.S. EPA, 2009), the strongest evidence for a relationship between long-term $PM_{2.5}$ exposure and respiratory effects was provided by epidemiologic studies examining lung function or lung function growth rate in children. Changes in lung function over time in children are indicative of lung development. In adults, lung function measurements may provide an indicator of declining lung function over time. Epidemiologic evidence supported an association between long-term $PM_{2.5}$ exposure and reduced lung development in children in different cohorts and locations. An animal toxicological study provided support for the epidemiologic evidence since pre- and post-natal exposure to ambient levels of urban particles was found to impair mouse lung development. Recent studies provide further support demonstrating a relationship between long-term exposure to $PM_{2.5}$ and reduced lung development in children as well as the possible acceleration of lung function decline in adults.

5.2.2.1 Lung Development

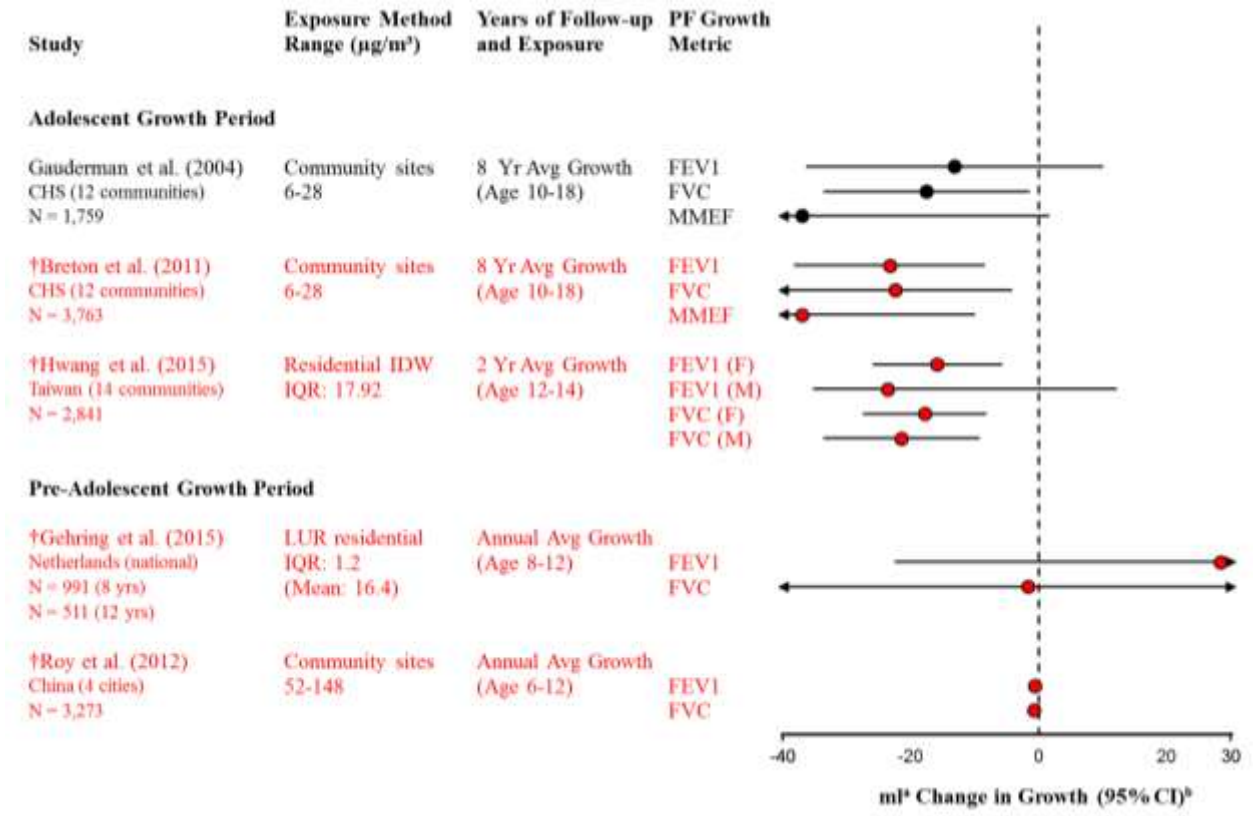
Lung development occurs from the fetal period through early adulthood, comprising a long window of potential vulnerability to environmental stressors, such as PM (Stanojevic et al., 2008; Zeman and Bennett, 2006; Thurlbeck, 1982). Lung function measures capture the cumulative effects of pulmonary growth, damage, and repair (Wang et al., 1993). As such, measures of lung function are

effective indicators of pulmonary health, and changes in lung function over time are indicative of lung development.

5.2.2.1.1 Epidemiologic Studies

Epidemiologic studies evaluated in the 2009 PM ISA (U.S. EPA, 2009) indicated that long-term exposure to $PM_{2.5}$ is associated with decrements in lung development in schoolchildren. Key evidence informing the relationship came from analyses of the Children's Health Study (CHS), a prospective cohort study of children in 12 southern California communities. Two studies of this cohort that were reviewed in the 2004 PM AQCD (U.S. EPA, 2009) observed decrements in annual pulmonary growth rates for all of the examined lung function measures (FVC, FEV_1, MMEF, and FEF_{75}) in relation to long-term in $PM_{2.5}$ exposure (Gauderman et al., 2002; Gauderman et al., 2000). Gauderman et al. (2000) examined lung function growth over a 4-year period for three age cohorts within CHS, including 4th graders, 7th graders, and 10th graders. The authors consistently reported the strongest associations, in magnitude and precision, in 4th graders and the weakest associations in 10th graders for all lung development metrics. A study reviewed in the 2009 PM ISA expanded on the previous CHS analyses, following children for 8 years (Gauderman et al., 2004). Gauderman et al. (2004) reported that PM-related deficits in average lung development between ages 10 and 18 years resulted in clinically important deficits in attained lung function at age 18 (Gauderman et al., 2004).

Recent data from studies based in the U.S. and Asia continue to provide evidence for $PM_{2.5}$-related decrements in lung development in children (Figure 5-28). The focus of this section is on longitudinal epidemiologic studies conducted in cohorts in diverse locations with a wide range of ambient $PM_{2.5}$ concentrations. Study-specific details, air quality characteristics, and select results from these studies are highlighted in Table 5-19. The CHS is further evaluated in recent studies that provide supporting evidence in multiple cohorts recruited in 1993 and 1996 and followed through 2007 (Gauderman et al., 2015; Breton et al., 2011). Recent results from the CHS not only corroborate previous results, but they also indicate improvements in lung development in association with declining $PM_{2.5}$ concentrations (Gauderman et al., 2015) (Section 5.2.11). Results from the CHS indicate that long-term $PM_{2.5}$ exposure may impact lung development during adolescence (age 10−18 years), a period of rapid, nonlinear growth (Wang et al., 1993). Associations during adolescence also are supported in a multicity cohort in Taiwan (Hwang et al., 2015). However, mean $PM_{2.5}$ concentrations in this study were notably higher than those in the CHS studies. As examined in a limited number of recent studies, evidence is less clear for effects during the linear growth period of preadolescence. $PM_{2.5}$ was associated with reduced lung development in a cohort in China that included children ages 6−12 years at baseline (Roy et al., 2012). However, no association was observed between $PM_{2.5}$ and lung development in the PIAMA cohort between ages 8 and 12 years (Gehring et al., 2015a). Information on critical periods of exposure is limited, as most studies examined concurrent exposure. In the PIAMA cohort, lung development was not associated with $PM_{2.5}$ exposure estimated for the concurrent period or birth year (Gehring et al., 2015a).



CHS = Children's Health Study, CI = confidence interval, F = female, FEV_1 = forced expiratory volume in 1 second, FVC = forced vital capacity, IDW = inverse distance weighting, IQR = interquartile range, LUR = land use regression, M = male, MMEF = maximum midexpiratory flow.

[a]FEV_1 and FVC are measured in ml, MMEF is measured in ml/s.

[b]Effect estimates are standardized to a 5 µg/m^3 increase in $PM_{2.5}$.

1

Copollutant Confounding and Other Sources of Uncertainty

Due to a limited number of studies that examined potential copollutant confounding, uncertainty remains in distinguishing an independent effect of long-term $PM_{2.5}$ exposure on lung development. In the only study to report results from copollutant models, Hwang et al. (2015) observed that $PM_{2.5}$-associated decrements in lung development persisted in copollutant models that included NO_2 or CO. NO_2 and CO were weakly correlated with $PM_{2.5}$ (r = 0.25 and 0.03, respectively). Other studies that reported copollutant correlations observed moderate to high correlations for most pollutants (NO_2: r = 0.73−0.87, SO_2: r = 0.69, O_3: r = 0.33−0.39; Table 5-19).

Because results for lung development are based on changes in lung function measured over time, loss to follow up and the method of lung function assessment could be additional sources of error or bias. However, neither is indicated to have systematically influenced the evidence for $PM_{2.5}$ associations. As detailed in Table 5-19, attrition of 10% or less was reported in some studies (Hwang et al., 2015; Breton et al., 2011). Others reported higher loss to follow-up (Gauderman et al., 2015; Gehring et al., 2015a; Roy et al., 2012), but reported similar characteristics between participants and nonparticipants, or no relation between participation and either baseline lung function or exposure to air pollution. Additionally, in a study that had changes in the device used to measure lung function, $PM_{2.5}$ associations were robust to adjustment for a factor representing the difference between devices (Gauderman et al., 2015).

Finally, the CHS studies in this section rely on exposure estimates from single fixed-site monitors within each community, which may result in misclassification of exposure. However, analyses of some individual CHS communities show low-to-moderate spatial heterogeneity of ambient $PM_{2.5}$ concentrations. In Long Beach, CA, $PM_{2.5}$ concentrations were moderately to highly correlated (r = 0.67−0.91) across four sites within 6.4 km of each other, including two schools attended by CHS cohort subjects (Krudysz et al., 2008). In Riverside, CA, $PM_{2.5}$ concentrations at a fixed-site monitor explained 96% of the variance in concentrations outside the homes of children with asthma (Ducret-Stich et al., 2012). Further, an analysis of multiple CHS communities described monitoring sites in some but not all communities as well representing the range of residential and school outdoor $PM_{2.5}$ concentrations of subjects. Thus, long-term concentrations measured at fixed-site monitors are unlikely to introduce major exposure measurement error.

5.2.2.1.2 Animal Toxicological Studies

The 2009 PM ISA evaluated studies that examined lung development. These studies involved early life exposure to ambient levels of urban particles in Sao Paulo, Brazil (Mauad et al., 2008; Pires-Neto et al., 2006). Urban air PM mainly consisted of $PM_{2.5}$, but it also contained some PM_{10}; other ambient pollutants were also present. Control mice were exposed to filtered urban air, which contained greatly reduced concentrations of PM. Mauad et al. (2008) found decreased inspiratory and expiratory

volumes in mice exposed both pre- and postnatally compared to control animals. Alveolar surface to volume ratio was also decreased in animals exposed during both the pre- and post-natal periods. No changes in lung function or morphology were observed in animals exposed only prenatally or only postnatally. These results reflect altered lung development resulting from $PM_{2.5}$ exposure. Pires-Neto et al. (2006) found secretory changes in the nasal cavity of neonatal mice exposed for 5 months to urban PM from Sao Paulo Brazil. Specifically, production of acidic mucosubstances was increased, potentially representing impaired respiratory defense mechanisms. Interpretation of effects due to long-term urban air exposure is complicated by the presence of $PM_{10-2.5}$. Recently, Song et al. (2017) demonstrated changes in lung molecular clock gene expression resulting from pre- and post-natal exposure of rats to ambient levels of urban particles in Beijing, China. Control rats were exposed to filtered urban air, which contained greatly reduced concentrations of PM. In addition, altered lung morphology and oxidative stress were observed in rat pups and in pregnant rats. These findings are discussed in Section 9.3.3.

5.2.2.2 Lung Function

The relationship between long-term $PM_{2.5}$ exposure and lung function in children and in adults was examined in numerous epidemiologic studies.

5.2.2.2.1 Children

In addition to lung development, a number of studies examine the effects of long-term $PM_{2.5}$ exposure in relation to attained pulmonary function at a given point in time. Epidemiologic studies reviewed in the 2009 PM ISA (U.S. EPA, 2009) indicated that long-term exposure to $PM_{2.5}$ is associated with decrements in attained lung function in children. Notably, in the CHS analysis described in Section 5.2.2.1.1, Gauderman et al. (2004) observed that 18-year-olds had increased risk of clinically low FEV_1 measurements at age 18 in communities with higher $PM_{2.5}$ concentrations. However, unlike the results reported for lung development, the attained lung function estimates did not include adjustment for potential confounders, introducing uncertainty into the interpretation of the results. European birth cohort studies also generally reported evidence of an effect on lung function metrics when examining long-term $PM_{2.5}$ exposure (Oftedal et al., 2008; Schikowski et al., 2005; Ackermann-Liebrich et al., 1997), but results were not entirely consistent (Gotschi et al., 2008). None of the lung function studies reviewed in the 2009 PM ISA examined copollutant models. Recent studies available for review add to the existing evidence supporting an association between long-term exposure to $PM_{2.5}$ and decreased lung function in children. These studies examine a variety of exposure periods, exposure methods, cohorts, locations, and exposure levels. Additionally, a limited number of copollutant models indicate that the observed $PM_{2.5}$ effect may be independent of NO_2, CO, and O_3 exposures. Study-specific details, air quality characteristics, and select results from these studies are presented in Table 5-20.

Table 5-20 Associations of $PM_{2.5}$ with lung function in children and adults.

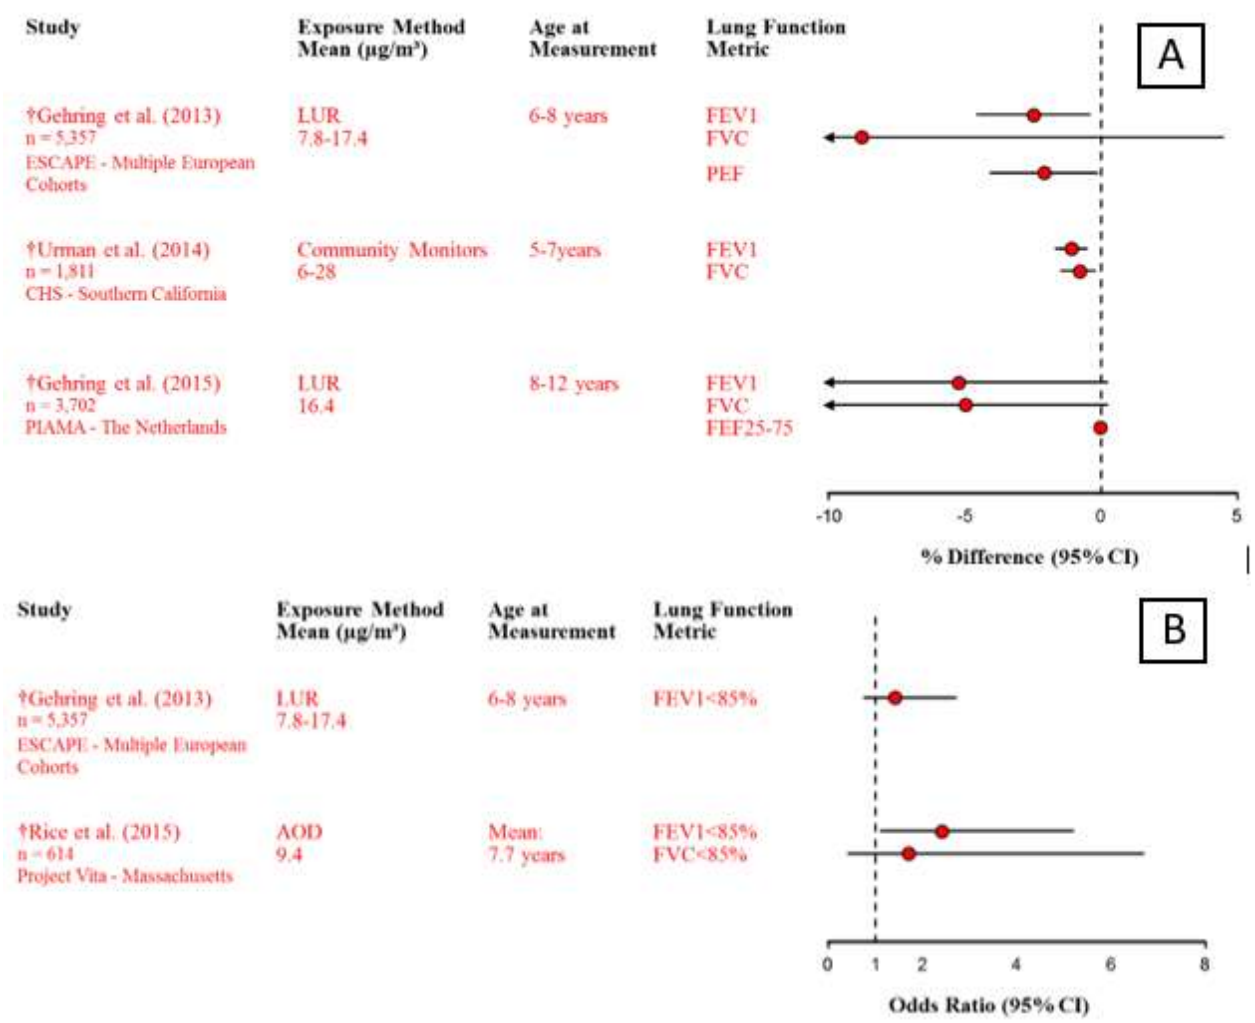
†Studies published since the 2009 PM ISA.

Recently reviewed studies provide consistent evidence that long-term exposure to $PM_{2.5}$ is associated with decreased lung function in children (Figure 5-29 and Table 5-20). Like the results from Gauderman et al. (2004), a small prebirth cohort study in Massachusetts (Rice et al., 2015b) and an ESCAPE analysis of multiple European cohorts Gehring et al. (2013) observed increased odds of clinically low FEV_1 and FVC measurements in relation to long-term $PM_{2.5}$ exposure. Associations between $PM_{2.5}$ and lung function were also observed as a measure of percent difference or absolute change in spirometry measures in the aforementioned studies (Rice et al., 2015b; Gehring et al., 2013), the CHS cohort (Urman et al., 2014), and the PIAMA cohort (Gehring et al., 2015a; Wang et al., 2015b).

The reviewed studies used an array of exposure assessment methods to produce long-term $PM_{2.5}$ estimates, including LUR models, dispersion models, hybrid models incorporating AOD observation data with land use variables, and fixed-site monitors. Associations were evident across the various exposure assignment techniques. Wang et al. (2015b) directly compared results from dispersion- and land-use regression (LUR)-modeled $PM_{2.5}$ estimates in relation to lung function metrics. The authors observed $PM_{2.5}$-related decreases in FEV_1 and FVC for both exposure assessment techniques, but noted larger but less precise (i.e., wider 95% CIs) decreases for LUR-modeled increases in $PM_{2.5}$ (quantitative results not provided; results presented graphically). These results suggest robust evidence of an association despite differences in exposure measurement error across exposure assessment methods.

Most of the reviewed studies focused on lung function in 6 to 8-year-old children. Obtaining valid spirometric lung function data is sometimes not possible in younger children. Alternatively, interrupter resistance (Rint) is a reliable technique to assess airway resistance in preschool aged children. In the PIAMA cohort, Eenhuizen et al. (2013) reported increases in Rint consistent with long-term $PM_{2.5}$ exposure estimated outside participants' birth addresses. Higher Rint was associated with lower FEV_1 levels at age 8, suggesting that Rint may be a predictor of later lung function.

A few studies examined varying windows of exposure to assess periods of potential sensitivity to PM exposure. Rice et al. (2015b) incorporated satellite-derived aerosol optical depth (AOD) observations into a land use regression model to estimate participants' exposure to ambient $PM_{2.5}$ in the first year of life, in the year prior to lung function testing, and averaged over their lifetime. The observed associations across lung function metrics were consistently stronger in magnitude, but not always precision, for $PM_{2.5}$ concentrations estimated in the year prior to examination. A similar finding was reported in the European study of cohorts for air pollution effects (ESCAPE) project analysis. Gehring et al. (2013) noted higher effect estimates for FEV_1 in relation to a 5 $\mu g/m^3$ increase in outdoor $PM_{2.5}$ concentrations estimated at current residence at the time of lung function measurement (−2.49% difference [95% CI: −4.57, −0.36]) compared to exposure assigned at the participants' birth address (−1.22% [95% CI: −3.30, 0.80]). Notably, the ESCAPE project and the prevention and incidence of asthma and mite allergy (PIAMA) cohort, discussed with regards to exposure windows in Section 5.2.3.1, use LUR models to estimate exposure after follow-up. The LUR was constructed for the cohort's current age and adjusted based on the year of lung function testing. The ratio of $PM_{2.5}$ concentration at a fixed-site monitor in the year of birth and during the year of lung function testing was used to extrapolate concentrations back to birth year at the birth residential location for each participant. Hence, changes in spatial variability between birth and the year of lung function testing were not captured. Despite the resulting uncertainty, the potentially enhanced lung-function sensitivity to $PM_{2.5}$ exposures closer to lung function examination may explain why the CHS analysis by Urman et al. (2014), which implemented a surrogate for lifetime-exposure, observed a smaller effect estimate than studies that used current address or previous year $PM_{2.5}$ estimates (Table 5-20).



AOD = aerosol optical depth, CHS = Children's Health Study, CI = confidence interval, FEF_{25-75} = forced expiratory flow at 25−75% of the pulmonary volume, FEV_1 = forced expiratory volume in 1 second, FVC = forced vital capacity, LUR = land use regression.

Note: †Studies published since the 2009 PM ISA. Panel A depicts percent difference in lung function metrics. Panel B depicts odds of lung function metrics below normal levels (85% predicted). Red text/circles = studies published since the completion of the 2009 PM ISA. Effect estimates are standardized to a 5 µg/m^3 increase in $PM_{2.5}$. Corresponding quantitative results and study details are reported in Table 5-20.

Figure 5-29 Long-term exposure to $PM_{2.5}$ and lung function in children.

Copollutant Confounding

Several studies of pulmonary function in children provide information on potential copollutant confounding through the evaluation of two-pollutant models. These studies add to the strength of the evidence by establishing a $PM_{2.5}$ relationship with observed lung function decrements that is generally unchanged in models with other pollutants [quantitative results presented in Supplemental Material (U.S. EPA, 2018)]. $PM_{2.5}$ correlations with NO_2 ranged from 0.25 to 0.75, across studies. In studies that reported higher correlations (r = 0.75), associations between $PM_{2.5}$ and lung decrements were attenuated

but still negative in copollutant models adjusting for NO_2 (Wang et al., 2015b; Gehring et al., 2013). Meanwhile, in studies with low $PM_{2.5}$-NO_2 correlations (r = 0.25−0.33), associations were relatively unchanged in copollutant models (Chen et al., 2015a; Hwang et al., 2015). Hwang et al. (2015) and Chen et al. (2015a) also reported declines in lung function that persisted in copollutant models adjusting for CO, O_3, and SO_2. However, these studies of school-children in Taiwan lack generalizability given $PM_{2.5}$ concentrations that are much higher than studies in North America and Europe.

5.2.2.2.2 Adults

Lung function generally peaks in adults around the age of 25, and then slowly declines throughout adulthood (Götschi et al., 2008). In addition to studies of lung function in children, some studies have investigated whether long-term $PM_{2.5}$ exposure accelerates the rate of decline in lung function as adults age. A limited number of studies reviewed in the 2009 PM ISA (U.S. EPA, 2009) observed contrasting evidence of an association between long-term exposure to $PM_{2.5}$ and lung function in adults. A longitudinal study of adults from 10 European countries found that annual $PM_{2.5}$ concentrations were not associated with lung function decrements measured from two spirometry tests taken approximately 10 years apart (Götschi et al., 2008). However, $PM_{2.5}$ exposures were estimated at the end of the study period, which may have introduced bias if the pattern of spatial variability of $PM_{2.5}$ concentrations did not remain constant across cities over the 10-year study period. In contrast, cross-sectional studies reported associations between annual average $PM_{2.5}$ and mean lung function (Schikowski et al., 2005; Ackermann-Liebrich et al., 1997). A limited number of recent longitudinal and cross-sectional studies in the U.S. and Europe have reported more consistent evidence that $PM_{2.5}$ is associated with decreased lung function parameters in adults. As with past studies, lung function in these cohorts was assessed either as a measure of lung function decline over time or cross-sectionally as a single measure in time. These cross-sectional measurements are generally less informative than longitudinal studies because they do not establish a temporal relationship between the exposure and outcome of interest. Study-specific details, air quality characteristics, and select results from these studies are presented in Table 5-20.

The Framingham Heart Study examined the association between long-term exposure to $PM_{2.5}$ and longitudinal decline in lung function over a 15-year period (Rice et al., 2015a). Rice et al. (2015a) reported a 5.25 ml/year (95% CI: 0.5, 10.5) faster rate of decline in FEV_1 and a 5 ml/year (95% CI: −0.25, 10.25) faster decline in FVC per 5 μg/m^3 increase in annual average $PM_{2.5}$ concentrations in the index year. The authors also observed $PM_{2.5}$ associations with cross-sectional FEV_1 and FVC measures but did not observe evidence of associations with FEV_1/FVC in longitudinal or cross-sectional analyses. In an ESCAPE project analysis of five European cohorts, Adam et al. (2015) also reported evidence of an association between long-term exposure to $PM_{2.5}$ and lung function in adults. Lung function measurements taken approximately 10 years apart indicated that long-term $PM_{2.5}$ exposure was associated with an accelerated decrease in FVC (−1.37 ml/year [95% CI: −4.04, 1.29]), but not FEV_1 (−0.14 ml,

95% CI [−2.26, 1.98]). However, similar to Götschi et al. (2008), discussed above, $PM_{2.5}$ was estimated (2008−2011) after the two spirometry tests were conducted (1985−2010). $PM_{2.5}$ was also negatively associated with cross-sectional FEV_1 and FVC levels measured during the second exam (Adam et al., 2015). Supporting evidence of a longitudinal association between $PM_{2.5}$ concentrations and lung function in adults, Boogaard et al. (2013) examined traffic policy-related reductions in air pollution and found improvements in lung function associated with declining $PM_{2.5}$ concentrations (Section 5.2.11).

In the Multi-Ethnic Study of Atherosclerosis (MESA), the association between long-term exposure to $PM_{2.5}$ and lung function was examined cross-sectionally (Adar et al., 2015). $PM_{2.5}$ was estimated using area-specific prediction models based on pollution measurements at the community or residential level in a subset of participants (MESA Air), which were incorporated with local geographic, meteorological, and emission data into a hierarchical spatiotemporal model to predict long-term exposure outside of participants' homes. $PM_{2.5}$ levels 1 year prior to baseline exam and 20-year average exposures were estimated and both were negatively associated with FEV_1 and FVC and with higher odds of airflow limitation. Similar to the Framingham Heart Study (Rice et al., 2015a), the authors found null associations between long-term exposure to $PM_{2.5}$ and FEV_1/FVC (Adar et al., 2015).

5.2.2.3 Summary of Lung Function and Development

In summary, recent epidemiologic studies enhance the evidence that was available in the 2009 PM ISA (U.S. EPA, 2009) suggesting that long-term exposure to $PM_{2.5}$ is associated with impaired lung function and lung function growth in children. Notably, extended CHS analyses continue to report $PM_{2.5}$-related decrements in lung development during the adolescent growth period. These updated analyses comprise additional cohorts with differing demographics and indicate that declining $PM_{2.5}$ concentrations are associated with improvements in lung development. Studies of attained lung function in children provide consistent evidence supporting the association observed with lung development. The strength of the epidemiology evidence was in the variety of exposure methods, study locations, and exposure levels for which associations were present. Additionally, a limited number of copollutant models indicate that the observed $PM_{2.5}$ effect may be independent of NO_2, CO, and O_3. The available evidence also indicates that $PM_{2.5}$ concentrations estimated proximate to lung function examination are most strongly associated with measures of attained lung function. These findings are supported by an animal toxicological study that demonstrated impaired lung development, as measured by decrements in lung function and changes in alveolar structure, as a result of pre- and post-natal exposure to $PM_{2.5}$. In a limited number of studies, altered nasal morphology and evidence of respiratory tract inflammation and oxidative stress were found in animals exposed to $PM_{2.5}$ during early lifestages.

While the 2009 PM ISA (U.S. EPA, 2009) noted inconsistent evidence of an association between long-term exposure to $PM_{2.5}$ and lung function in adults, more recent large prospective cohort studies have consistently observed $PM_{2.5}$-related accelerations of lung function decline in adults. This finding is

corroborated by evidence of lung function improvement in areas with declining $PM_{2.5}$ concentrations. Studies of lung function in adults have not adequately examined potential copollutant confounding.

5.2.3 Development of Asthma

Asthma is described by the National Heart, Lung, and Blood Institute as a chronic inflammatory disease of the airways that develops over time (NHLBI NAEPP, 2007). Pulmonary inflammation can increase airway responsiveness and induce airway remodeling, resulting in bronchoconstriction (bronchial smooth muscle contraction), and in turn, episodes of shortness of breath, coughing, wheezing, and chest tightness. When the pathophysiology of asthma advances in its development to the stage where the symptoms lead people to seek medical treatment, a diagnosis of asthma can result. A potential outcome of asthma development is that the pattern of reduced growth in lung function seen in early childhood persists into adulthood (McGeachie et al., 2016), potentially resulting in alterations to lung structure as adults (Donohue et al., 2013). In this section, asthma in children is discussed first, followed by asthma in adults, and subclinical effects underlying asthma development, such as pulmonary inflammation and increased airway responsiveness. While the evidence-base remains limited for subclinical effects and asthma in adults, recent studies of asthma in children supplement the limited number of studies reviewed in the 2009 PM ISA (U.S. EPA, 2009), and provide evidence of an association between long-term $PM_{2.5}$ exposure and asthma development in children.

5.2.3.1 Asthma in Children

Epidemiologic studies evaluated in the 2009 PM ISA (U.S. EPA, 2009) that examined asthma development in children were limited in number. In a birth cohort study in the Netherlands, early-life $PM_{2.5}$ exposure was associated with doctor-diagnosed asthma at age 4 years (Brauer et al., 2007). In the southern California Children's Health Study (CHS), $PM_{2.5}$ was examined in relation to the association between lung function and asthma incidence. The protective association between lung function and new onset asthma observed in the overall population was not present in high $PM_{2.5}$ communities (Islam et al., 2007).

The recent body of literature enhances the limited evidence base, providing further evidence that long-term exposure to $PM_{2.5}$ is associated with asthma development in children. The strongest evidence supporting the relationship between long-term exposure to $PM_{2.5}$ and childhood asthma comes from a number of recent prospective and retrospective cohort studies conducted in North America and Europe. Longitudinal epidemiologic studies, which follow subjects over time, can better characterize the temporal sequence between $PM_{2.5}$ exposures and the incidence of asthma by ascertaining the first record of a physician diagnosis. In this regard, longitudinal studies distinguish between asthma onset and asthma exacerbation. Study-specific details, air quality characteristics, and select results from these studies,

discussed throughout this section, are highlighted in Table 5-21. In the majority of studies, asthma incidence was ascertained through validated questionnaires that asked parents about the child ever having a physician diagnosis of asthma at baseline, and, at each follow-up, questions about a diagnosis of asthma in the intervening period. In other studies, asthma was assessed by pediatric allergist evaluation (Carlsten et al., 2011) and primary care physician diagnosis or hospitalization due to asthma (Tétreault et al., 2016a; Clark et al., 2010).

Most recent asthma incidence studies focus on birth year as the period of potentially heightened sensitivity to $PM_{2.5}$ exposure and examine asthma incidence across varying follow-up times. The association between birth-year $PM_{2.5}$ exposure and diagnosis of asthma at age 7 was examined in a birth cohort of children at high-risk for asthma (n = 186) in Vancouver, Canada (Carlsten et al., 2011). The smaller sample size compared to other recent studies is balanced by using a high-risk cohort, which results in a higher proportion of cases compared to general population studies. Despite low mean outdoor $PM_{2.5}$ concentrations at birth residences (5.6 $\mu g/m^3$), Carlsten et al. (2011) observed that $PM_{2.5}$ was associated with increased odds of asthma diagnosis (OR: 4.0 [95% CI: 1.4, 11.5). In a larger study with relatively low mean $PM_{2.5}$ concentrations (9.9 $\mu g/m^3$; max: 14.9), Tétreault et al. (2016a) reported a positive and precise association between $PM_{2.5}$ and onset of asthma in an administrative cohort study of over 1 million children (HR: 1.23 [95% CI: 1.21 to 1.24]). The observed HR was robust to sensitivity analyses examining the impact of time-varying $PM_{2.5}$ concentrations and more rigorous case definitions for children under 5. Other studies conducted at higher $PM_{2.5}$ concentrations also reported generally positive associations between $PM_{2.5}$ and asthma incidence (Figure 5-30). A pooled retrospective case-control analysis of minority children provided an exception to the generally consistent evidence of an association (Nishimura et al., 2013). However, the study had low statistical power due to missing $PM_{2.5}$ concentration measurements for some regions.

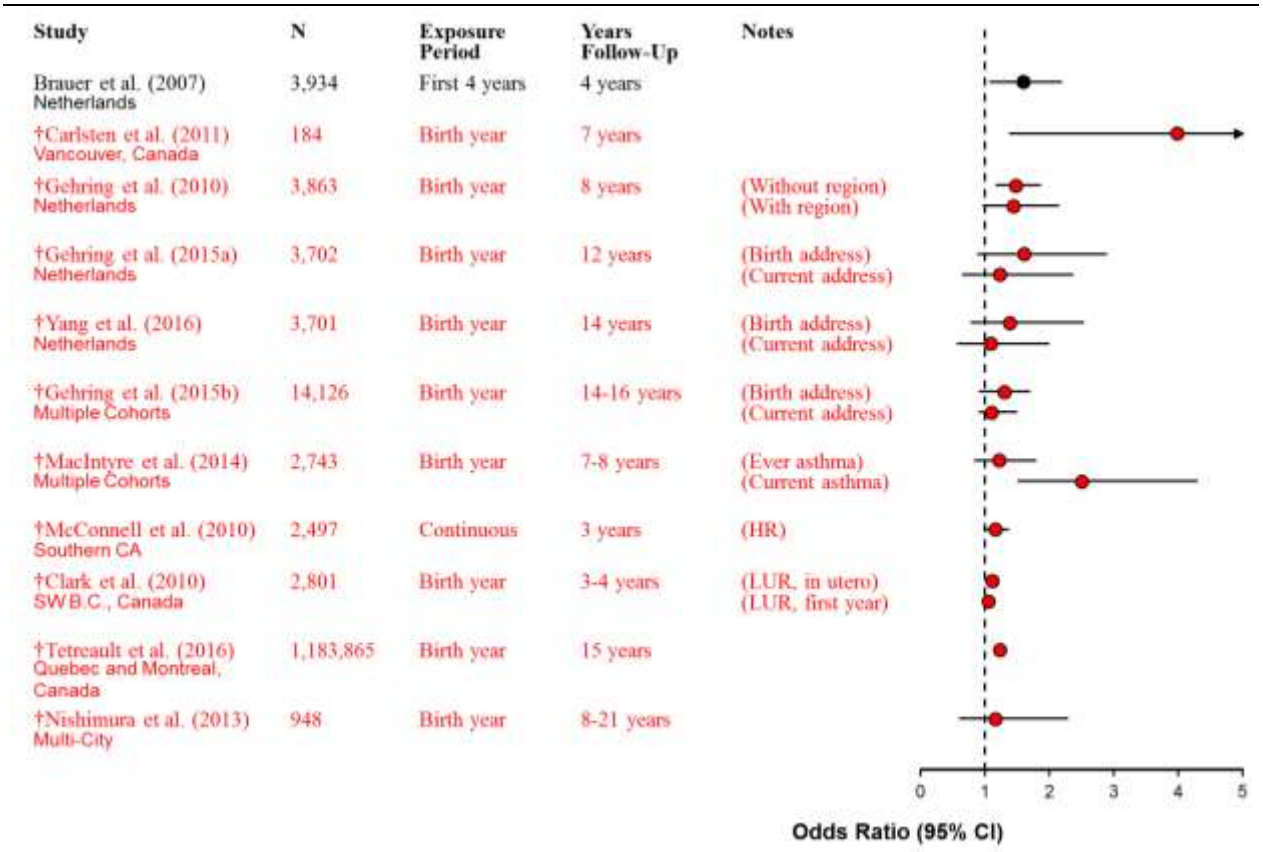
†Studies published since the 2009 PM ISA.

A number of studies examined alternate exposure windows to assess other periods of potential sensitivity to PM exposure in the development of asthma. Two studies of the PIAMA cohort in the Netherlands (Yang et al., 2016; Gehring et al., 2015a), and one pooled analysis of four European birth cohorts (Gehring et al., 2015b), observed that asthma incidence was associated with $PM_{2.5}$ concentrations outside birth residences, and reported attenuated but still positive associations with $PM_{2.5}$ concentrations at the address of the participant at the time of follow-up (quantitative results presented in Table 5-21). As

discussed in Section 5.2.2.2.1, exposure was modeled after follow-up for all of these cohorts, such that exposure estimates are representative of spatially relative concentrations. An earlier PIAMA study stratified by participants who had and had not moved from their birth address (movers vs. nonmovers) and observed associations between $PM_{2.5}$ and incident asthma that were slightly stronger in magnitude in nonmovers (OR: 1.6 [95% CI: 1.1, 2.3]) than movers (OR: 1.3 [95% CI: 0.97, 1.8]) (Gehring et al., 2010). While the difference in ORs is not large, the stratified results may suggest continued sensitivity to $PM_{2.5}$ exposure later in life. In a nested case-control study in British Columbia, Clark et al. (2010) examined asthma incidence at ages 3−4 years in association with $PM_{2.5}$ concentrations in both the prenatal period and first year of life. The authors reported similar asthma-$PM_{2.5}$ associations for prenatal and first year of life exposures estimated by LUR (OR [95% CI]: 1.1 [1.0, 1.2] and 1.1 [0.95, 1.2] for prenatal and first year $PM_{2.5}$ averages, respectively).



CI = confidence interval, HR = hazard ratio, LUR = land use regression.

Note: †Studies published since the 2009 PM ISA. Black text/circles = studies evaluated in the 2009 PM ISA. Red text/circles = studies published since the completion of the 2009 PM ISA. Odds ratios are standardized to an increment of 5 µg/m^3. Corresponding quantitative results and study details are reported in Table 5-21.

Figure 5-30 Long-term exposure to $PM_{2.5}$ and asthma incidence in children.

Recent studies of asthma prevalence generally provide supporting evidence for an association with $PM_{2.5}$ (Hasunuma et al., 2014 Macintyre, 2014, 2230511, Gehring, 2015, 3070314; Mölter et al., 2014), though some did not (Fuertes et al., 2013b; Akinbami et al., 2010). Supporting evidence was also reported in studies examining $PM_{2.5}$ and wheeze, a common symptom of asthma. Repeated wheeze in 2-year-olds was prospectively studied in a pregnancy cohort of women (n = 708) receiving care at Brigham & Women's Hospital in Boston (Chiu et al., 2014). Prenatal $PM_{2.5}$ exposure, estimated using a hybrid model incorporating AOD observations with land use predictors to yield residence-specific ambient $PM_{2.5}$ concentration estimates, was associated with increased odds of repeated wheeze at age 2 (OR: 2.0 [95% CI: 1.2, 3.4] for above median vs. below median $PM_{2.5}$ concentrations). In the larger PIAMA cohort study detailed in Table 5-21, Gehring et al. (2010) observed increased odds of parental-reported prevalent wheeze during the first 8 years of life associated with long-term $PM_{2.5}$ concentration (OR: 1.3 [95% CI: 1.1, 1.6]).

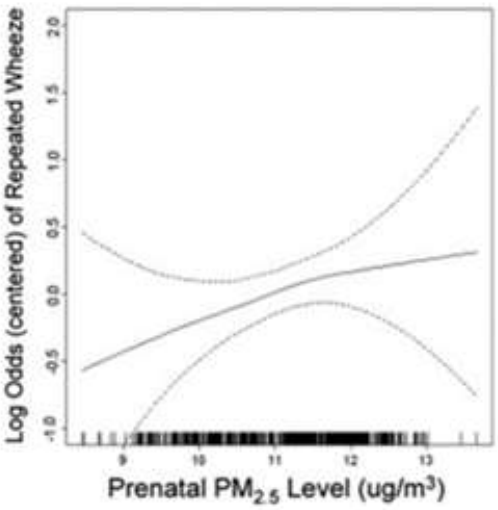
5.2.3.1.1 Copollutant Confounding

Most of the reviewed studies of asthma incidence in children did not present results from copollutant models. This may be the result of consistently high correlations reported between $PM_{2.5}$ and other pollutants across studies (Table 5-21), which reduces the reliability of copollutant models. MacIntyre et al. (2014a) observed a weak correlation between $PM_{2.5}$ and NO_2 (r = 0.23) in a pooled analysis of four birth cohorts. The association observed between birth-year $PM_{2.5}$ exposure and having a current asthma diagnosis (OR [95% CI]: 2.5 [1.5, 4.3]) remained after adjustment for NO_2 in a copollutant model (4.5 [1.4, 14.2]). However, given the lack of additional studies, uncertainties remain regarding whether the association between $PM_{2.5}$ and asthma incidence in children is independent of coexposure to other pollutants.

5.2.3.1.2 Concentration-Response Relationship

The shape of the C-R relationship between asthma incidence in children and long-term exposure to $PM_{2.5}$ was examined in (Tétreault et al., 2016a). To examine whether there is evidence of linearity in the relationship restricted cubic splines with three knots were included in the model. For $PM_{2.5}$, as well as O_3 and NO_2, nonlinear models did not result in better fits than the linear models for both exposures outside the home address at birth and for time-varying exposures during the follow-up period. Carlsten et al. (2011) examined the $PM_{2.5}$-asthma incidence association across exposure quartiles and reported monotonically increasing risk. However, this analysis stratified an already small sample size, resulting in wide CIs for each quartile estimate of risk. A C-R relationship was also evaluated in a study of childhood wheeze. Chiu et al. (2014) used penalized spline models to assess the nature of the relationship between prenatal $PM_{2.5}$ exposure and repeated wheeze. As depicted in Figure 5-31, the C-R relationship was approximately linear with some evidence of a less steep relationship at the higher exposure levels, albeit

with high uncertainty due to limited data at higher exposures. Confidence in the shape of the curve, as indicated by the dotted lines surrounding the spline curve, is highest from about 10 to 12 µg/m^3, where most of the observations occur. None of the evaluated studies provide a thorough empirical evaluation of alternatives to linearity, limiting the conclusions that can be drawn with respect to the shape of the C-R relationship.



Solid lines depict the penalized spline curve, and dotted lines indicate the 95% confidence bounds.

5.2.3.2 Asthma in Adults

No studies of long-term $PM_{2.5}$ exposure and asthma in adults were discussed in the 2009 PM ISA (U.S. EPA, 2009). Since then, a number of recent studies have examined incidence and prevalence of asthma and wheeze in adults in several cohorts. Contrary to the recent evidence supporting the presence of an association in children, the results for adult populations have been largely inconsistent. Study-specific details, including study locations, cohort descriptions, air quality characteristics, and select results from these studies, are highlighted in Table 5-22. A forest plot of the effect estimates, depicting the heterogeneity of results across studies, is presented in Figure 5-32.

Figure 5-32 Asthma and wheeze incidence and prevalence in adults in relation to long-term $PM_{2.5}$ exposure.

A limited number of studies on incident asthma in adults reported inconsistent evidence of an association. In a large prospective cohort study of women across the U.S., asthma incidence was associated 1-year average $PM_{2.5}$ concentrations at the beginning of follow-up (OR: 1.3 [95% CI: 0.99, 1.7]) (Young et al., 2014). Cases were defined by self-reporting of all three of the following conditions: asthma diagnosis by a doctor, use of asthma medication, and presence of asthma symptoms. In support of the association seen with incident asthma, Young et al. (2014) also reported an increase in wheeze incidence associated with long-term exposure to $PM_{2.5}$. In contrast, the ESCAPE study, an analysis of six

European cohorts, did not observe an association between long-term $PM_{2.5}$ concentrations and asthma onset in adults (Jacquemin et al., 2015). The finding was unchanged in a sensitivity analysis aimed at reducing exposure measurement error by restricting the analysis to cities with better LUR model validation. Similarly, in a large cohort study of chronic disease prevalence in women living in Ontario, Canada, To et al. (2015) also reported a null association. However, because $PM_{2.5}$ concentrations were estimated from satellite observations of AOD taken in the middle of the study period, asthma cases were restricted to the years after exposure estimates were available, which reduced the case number and power of the study. Utilizing the entire study population, To et al. (2015) did observe an association between long-term $PM_{2.5}$ exposure and asthma prevalence.

In addition to the To et al. (2015) study, there were a few other studies that examined asthma prevalence in adults. These studies were of cross-sectional design and the results, similar to studies of asthma incidence, were also inconsistent. While a health survey-based study of adults in Wisconsin reported evidence of a large increase in odds of asthma prevalence in association with annual average $PM_{2.5}$ concentration in the previous year (OR [95% CI]: 3.58 [2.36, 5.43]), the authors did not observe an association with prevalent wheeze (Schultz et al., 2017). In contrast, cross-sectional analyses of a longitudinal cohort (Rice et al., 2015a) and a national health survey (Nachman and Parker, 2012) observed null associations between long-term exposure to $PM_{2.5}$ and asthma prevalence in adults.

5.2.3.3 Subclinical Effects Underlying Development of Asthma

Subclinical effects underlying the development of asthma, including airway inflammation and airway hyperresponsiveness, have been examined in both epidemiologic studies and animal toxicological studies. The 2009 PM ISA (U.S. EPA, 2009) reported a cross-sectional analysis of school children in Windsor, Ontario that observed an increase in airway inflammation (eNO) corresponding to an increase in annual $PM_{2.5}$ concentrations (Dales et al., 2008). Also reviewed in the 2009 PM ISA were several studies that reported subclinical effects underlying the development of asthma following long-term exposure to DE or woodsmoke. However, these studies did not distinguish between effects due to gases or particles in the mixture.

5.2.3.3.1 Epidemiologic Studies

Recently, a longitudinal study of the CHS cohort reported that, in models adjusted for short-term $PM_{2.5}$ exposure, annual $PM_{2.5}$ concentrations were associated with a 10.3 ppb (95% CI: 3.0, 17.6) increase in FeNO (Berhane et al., 2014). Results from a prior CHS analysis (Bastain et al., 2011) showed that elevated eNO was associated with increased risk of new onset asthma. However, potential copollutant confounding was not examined in either study. Thus, there are a limited number of epidemiologic studies

providing evidence for subclinical effects underlying the development of asthma in association with long-term exposure to $PM_{2.5}$.

5.2.3.3.2 Animal Toxicological Study

Recently, a study evaluating the effects of $PM_{2.5}$ on the development of asthma has become available. Kim et al. (2016a) exposed BALB/c mice to nebulized DEPs for 4, 8, and 12 weeks and found increased BALF levels of the Th2 cytokines IL-5 (8 and 12 weeks) and IL-13 (4 and 12 weeks) ($p < 0.05$). Since these mice were naïve and not sensitized or challenged with allergens, this result provides evidence that $PM_{2.5}$ can induce an immune phenotype in the absence of an allergen. In addition, airway responsiveness to methacholine was assessed using whole-body plethysmography to measure Penh. Methacholine is a muscarinic receptor agonist that elicits bronchoconstriction and is used to evaluate airway hyperresponsiveness, a hallmark of asthma. DEP exposure resulted in increased Penh at all three-time points studied ($p < 0.01$). As discussed in Section 5.1.2.3.3, there is uncertainty associated with the use of Penh for the determination of airway responsiveness. Additional study details are found in Table 5-23.

Table 5-23 Study-specific details from an animal toxicological study of long-term $PM_{2.5}$ exposure and subclinical effects underlying development of asthma.

Study/Study Population	Pollutant	Exposure	Endpoints
Kim et al. (2016a) Species: Mouse Strain: BALB/c Sex: Female Age/Weight: 5−6 weeks	DEP nebulized Particle size: Mean diameter 0.4 µm before nebulization and 1−5 µm after nebulization Control: Saline solution	Dose/Concentration: 0.1 and 3 mg/m^3 DEP or saline (Only results from 0.1 mg/m^3 reported here) Duration: 1 h/day, 5 days/week for 4, 8, and 12 weeks Time to analysis: 1 day after last exposure	Penh- methacholine challenge BALF cells BALF cytokines Histochemistry • Masson trichome staining of lung

DEP = diesel exhaust particles; Penh = enhanced pause.

5.2.4 Development of Allergic Disease

The 2009 PM ISA (U.S. EPA, 2009) reviewed a limited number of epidemiologic studies examining a range of allergic indicators that found a mix of positive and null associations with long-term exposure to $PM_{2.5}$. While a number of studies reported $PM_{2.5}$ associations with hay fever/allergic rhinitis, indoor and outdoor allergic sensitization, and/or eczema, there was comparable evidence of null

associations across the same endpoints within the reviewed studies. Most studies examining allergic endpoints assessed prevalence outcomes cross-sectionally. In addition to a lack of prospective studies on allergic disease incidence, none of the studies reviewed in the 2009 PM ISA used copollutant models to evaluate the independent effect of $PM_{2.5}$. Studies published since the completion of the 2009 PM ISA encompass two main indicators of allergic disease: hay fever/allergic rhinitis diagnosis and allergic sensitization. In addition, a single recent animal toxicological study provided evidence that long-term $PM_{2.5}$ exposure can promote the development of a Th2 phenotype (see Section 5.2.3.3.2).

Allergic sensitization, measured by detectable allergen-specific IgE levels, was examined in the recent evidence base. A pooled analysis of five European birth cohorts reported that annual average $PM_{2.5}$ concentrations outside participants' birth addresses were associated with higher odds of sensitization to any common allergen at ages 4 and 8 (Gruzieva et al., 2014). However, the association was driven by results from the PIAMA cohort in the Netherlands (Gehring et al., 2010), whereas analyses of other cohorts included in the pooled analysis, such as the LISA and GINI cohorts (Fuertes et al., 2013b), did not observe associations. The PIAMA cohort study observed associations with $PM_{2.5}$ concentrations outside birth addresses that were larger in magnitude compared to current addresses, but also reported associations that were larger in magnitude among nonmovers compared to movers (Gehring et al., 2010). As discussed in Section 5.2.3 on asthma development, early life exposure may be important to allergic sensitization, but the critical exposure window may continue into later childhood. In a 2005−2006 NHANES study comprising a nationally representative sample of the U.S. population, Weir et al. (2013) found that annual average $PM_{2.5}$ concentration was associated with increased odds of sensitization to indoor allergens for exposure assigned from monitors within 20 miles of the participants' home address (OR: 1.27 [95% CI: 1.12, 1.45]) and using geocoded CMAQ $PM_{2.5}$ concentration estimates (OR: 1.26 [95% CI: 1.16, 1.38]). Associations with sensitization to food allergens were positive but imprecise, while sensitization to outdoor allergens were not related to annual average $PM_{2.5}$ concentrations. Although copollutant models were not examined, $PM_{2.5}$ was weakly correlated with NO_2 and O_3.

Other recent studies examined parental and self-reported hay fever/allergic rhinitis and rhino conjunctivitis in children and adults. A few studies of the PIAMA cohort reported that $PM_{2.5}$ assigned at birth address was not associated with increased odds of hay fever (Gehring et al., 2010) or rhino conjunctivitis incidence (Gehring et al., 2015b) in children. However, an association of $PM_{2.5}$ with hay fever was present in children who did not move during follow-up (OR [95% CI]: 1.43 [1.01, 2.04]). The lack of an association in the overall population may have been due to exposure measurement error for children who moved, as evident in the association amongst nonmovers. In contrast to Gehring et al. (2010), a pooled analysis of six Canadian and European cohorts (CAPPS, SAGE, PIAMA, BAMSE, and GINI/LISA), reported that birth-year $PM_{2.5}$ was associated with a 37% increase in odds of allergic rhinitis at age 7−8 (95% CI: 1, 86%) (Fuertes et al., 2013a). Wang et al. (2015a) also observed a positive association between parental-reported allergic rhinitis and cumulative long-term $PM_{2.5}$ exposure in a cohort of kindergarteners living within 10 km of an air quality monitoring station. In a cross-sectional study of adults in Wisconsin, Schultz et al. (2017) observed no evidence of a linear association between

annual $PM_{2.5}$ concentrations and subjects who self-reported a physician diagnosis of allergies or hay fever (OR: 1.06 [95% CI: 0.74, 1.53]). However, the authors reported increased odds of allergies or hay fever for participants in the second (9.32−10.20 µg/m^3; OR: 1.38 [95% CI: 1.03, 1.76]) and third (10.21−10.85 µg/m^3; OR: 1.33 [95% CI: 1.00, 1.76]) quartiles of PM exposure compared to those in the first (6.59−9.31 µg/m^3), suggesting a potential nonlinear association.

In summary, recent studies evaluated associations between long-term exposure to $PM_{2.5}$ and various allergic outcomes in a mix of large representative cohort and cross-sectional survey studies. While recent evidence includes more longitudinal study designs, there are no studies that evaluate copollutant models. Despite this limitation, there is generally consistent evidence of an association between long-term $PM_{2.5}$ exposure and allergic sensitization in single pollutant models. However, as seen in Weir et al. (2013) and studies reviewed in the 2009 PM ISA (U.S. EPA, 2009), consistent associations with specific allergens have not emerged. The findings for allergic rhinitis were inconsistent, although a limited number of studies that aimed to reduce exposure measurement error, either by restricting distance between study participants and monitors or by excluding participants who moved, did observe associations. Overall, evidence indicates an association between long-term exposure to $PM_{2.5}$ and at least some manifestations of allergic disease. Limited evidence from a single animal toxicological study showing that long-term exposure to DEP promotes the development of an allergic phenotype supports for epidemiologic findings of allergic responses.

5.2.5 Development of Chronic Obstructive Pulmonary Disease (COPD)

There were no epidemiologic studies examining the association between long-term exposure to $PM_{2.5}$ and COPD available for inclusion in the 2009 PM ISA (U.S. EPA, 2009). An animal toxicological study provided evidence for the development of emphysema, a form of COPD, following long-term exposure to woodsmoke, but did not distinguish between effects due to gases or particles in the mixture. Several recent epidemiologic studies examined COPD as an outcome using medical records data, lung function measures, and imaging data obtained in cohorts and cross-sectional studies based in North America and Europe. Studies also examined specific forms of COPD, including emphysema, marked by destruction of the alveolar region of the lungs, and chronic bronchitis, or long-term inflammation of the bronchial tubes. These studies are discussed below. There are no recent animal toxicological studies examining long-term exposure to $PM_{2.5}$ and COPD.

Recent large cohort studies examined the association between long-term $PM_{2.5}$ and COPD development. In a study of COPD incidence in the U.K., a dispersion model was used to assign annual-average $PM_{2.5}$ exposure to nearest postcode centroid for each patient (Atkinson et al., 2015). The authors reported that $PM_{2.5}$ was associated with higher odds of first COPD hospitalization (OR [95% CI]: 1.14 [0.96, 1.36]), but not for COPD diagnosis from a general practitioner (0.98 [0.84, 1.16]). Hospital admissions records may represent more severe cases of COPD, which may explain the difference in effect

estimates. The COPD hospitalization results persisted in two-pollutant models with SO_2, NO_2 and O_3 ($r < 0.5$ for all pollutants). Similarly, 5-year average $PM_{2.5}$ was associated with an increase, with wide confidence intervals, in the risk of hospitalization due to COPD (RR [95% CI]: 1.06 [0.93, 1.20]) in a large population-based cohort in metropolitan Vancouver (Gan et al., 2013). The study was limited to participants who had no previous record of COPD diagnosis, but hospitalization records were analyzed only for a few years prior. Thus, the hospitalization could reflect exacerbation of a previously diagnosed disease, rather than COPD onset. In a large cohort study of chronic disease prevalence in women living in Ontario, Canada, To et al. (2015) assigned $PM_{2.5}$ exposure at a postal code level using satellite-based AOD observation data. The authors reported that the incidence and prevalence of COPD were associated with 8-year average $PM_{2.5}$ concentrations. Contrasting evidence was observed in an ESCAPE Project pooled analysis of four European cohorts (Schikowski et al., 2014). COPD was defined using prebronchodilator FEV_1/FVC below the lower limit of normal (LLN) and the Global Initiative for Chronic Obstructive Lung Disease (GOLD) definition (FEV_1/FVC <0.70). Annual $PM_{2.5}$ concentrations, estimated by LUR, were not associated with incidence (OR [95% CI]: 1.06 [0.73, 1.53]) or prevalence (OR [95% CI]: 0.95 [0.47, 1.9]) of COPD defined by LLN. Similar estimates were obtained using the GOLD definition of COPD.

A limited number of studies examined specific forms of COPD, including emphysema and chronic bronchitis. As discussed in the 2009 PM ISA (U.S. EPA, 2009), McConnell et al. (2003) reported associations between annual and 4-year average $PM_{2.5}$ and bronchitic symptoms in a prospective study of children in 12 CHS communities. A recent pooled analysis of five European cohorts also examined chronic bronchitis in relation to $PM_{2.5}$ (Cai et al., 2014). Annual average $PM_{2.5}$ concentrations were not associated with chronic bronchitis in the overall population (OR [95% CI]: 0.90 [0.74, 1.09]), but was associated with chronic bronchitis in a subanalysis of nonsmokers (OR [95% CI]: 1.28 [0.95, 1.72]). A U.S. cross-sectional study using data from the National Health Interview Survey (NHIS) also observed an association between $PM_{2.5}$ concentrations in the past year and the odds of chronic bronchitis (OR [95% CI]: 1.08 [0.94, 1.24]) (Nachman and Parker, 2012). The association between emphysema and exposure to $PM_{2.5}$ was examined cross-sectionally in the MESA study (Adar et al., 2015). PM concentrations 1 year prior to baseline exam and 20-year average exposures were estimated. Percent emphysema, determined from CT scans, was positively associated with both 1-year average and 20-year average $PM_{2.5}$. However, these results were driven by lower mean percent emphysema in one city (St. Paul) with the lowest $PM_{2.5}$ concentrations, and the associations were no longer positive after adjustment for study site, or in analyses excluding St. Paul.

Recent studies provide some evidence that long-term $PM_{2.5}$ exposure may be associated with development of COPD in adults, but uncertainties remain. Notably, studies of COPD hospitalization may reflect exacerbation of previously diagnosed disease rather than disease onset. Additionally, hospitalizations may represent severe cases of COPD and may not account for the potential effect of short-term exposures leading to these acute events. There is also a lack of available studies that examine potential copollutant confounding. However, one study observed that $PM_{2.5}$ was associated with first-time

COPD hospitalization independent of gaseous pollutants (Atkinson et al., 2015). Overall, a limited number of studies also provide evidence of an association between long-term exposure to $PM_{2.5}$ and chronic bronchitis, a specific form of COPD.

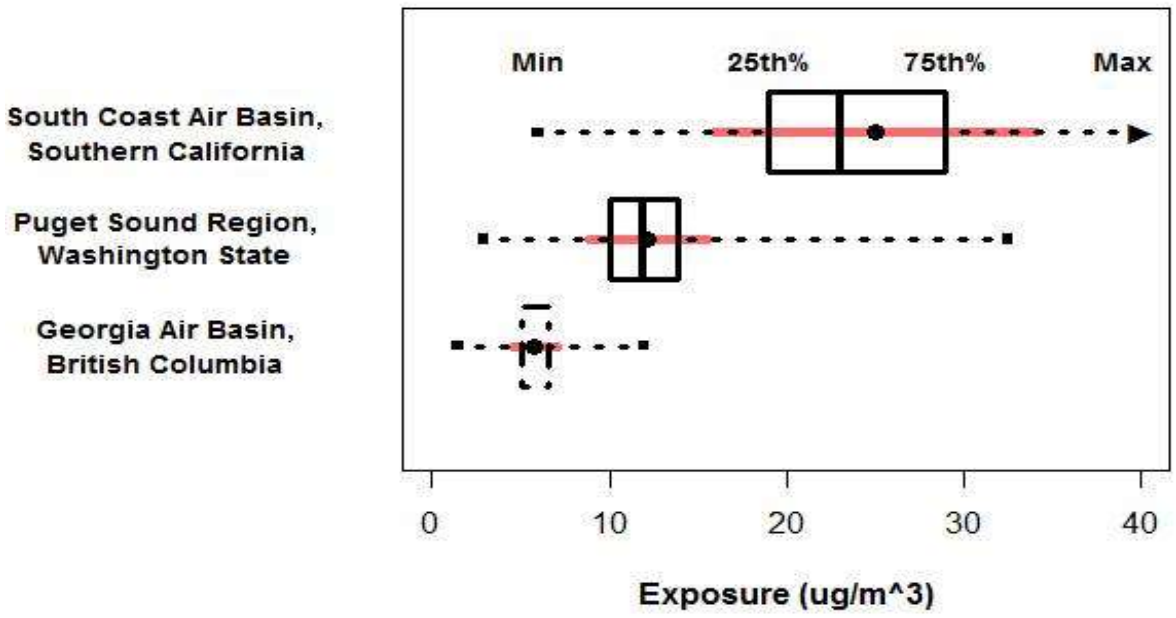
5.2.6 Respiratory Infection

In the 2009 PM ISA (U.S. EPA, 2009), results from epidemiologic studies indicated an association between PM and respiratory infection. However, this association was largely evident in studies of short-term PM exposure, as only one study examined the relationship between long-term exposure to $PM_{2.5}$ and respiratory infection. Several animal toxicological studies examined the effects of long-term exposure to DE on host defense. While evidence for altered host defense was found, these studies did not distinguish between effects due to gases or particles in the DE mixture. Recent epidemiologic studies in North America and Europe have examined the associations between long-term exposure to $PM_{2.5}$ and infant bronchiolitis, pneumonia, croup, and otitis media. There are no recent animal toxicological studies of long-term $PM_{2.5}$ exposure and host defense.

The association between infant bronchiolitis and long-term $PM_{2.5}$ exposure was examined in three large cohorts (Karr et al., 2009b; Karr et al., 2009a; Karr et al., 2007). A prominent respiratory infection in infancy, bronchiolitis is primarily caused by the respiratory syncytial virus (RSV), and results in inflammation of the bronchioles. As discussed in the 2009 PM ISA (U.S. EPA, 2009), Karr et al. (2009b) examined infant bronchiolitis hospitalization in a birth registry cohort in the Puget Sound region of Washington. Two similar studies, which were not reviewed in the 2009 PM ISA, also examined infant bronchiolitis in the Georgia Air Basin of British Columbia (Karr et al., 2009a) and the South Coast Air Basin of California (Karr et al., 2007). Each nested case-control study examined cumulative lifetime exposure to $PM_{2.5}$ in relation to bronchiolitis incidence in the first year of life. The results were inconsistent across studies.

Karr et al. (2009b) assigned lifetime average $PM_{2.5}$ from the closest fixed-site monitor within 20 km of subjects' residential postal code. The authors reported that $PM_{2.5}$ concentrations were associated with RSV bronchiolitis, but not all bronchiolitis, which includes bronchiolitis due to other infectious agents. However, in a model examining effect modification, Karr et al. (2009b) reported an association with all bronchiolitis for infants living within 5 km of a fixed-site monitor. The restricted analysis may have reduced exposure measurement error, as infants spend most of their time in or near their homes (Wiley et al., 1991). Karr et al. (2007) did not exclude maternal-infant pairs based on distance to monitor but reported that 90% of study participants lived within 17.7 km of a monitor. The authors observed a 4% increase in the odds of bronchiolitis hospitalization in the first year of life in relation to cumulative lifetime $PM_{2.5}$ exposure (95% CI: 2, 7%). The association with $PM_{2.5}$ was robust to the inclusion of O_3 in a copollutant model (4% [95% CI: 1.03 to 1.15]; $r = -0.24$). In contrast to evidence observed in Washington (Karr et al., 2009b) and California (Karr et al., 2007), Karr et al. (2009a) reported null

associations between lifetime $PM_{2.5}$ exposure and infant bronchiolitis in British Columbia. The analysis included infants living within 10 km of a monitor and modeled exposure concentrations using an LUR model to produce similar results. A comparison of the $PM_{2.5}$ distributions across the three studies shows that mean concentration and variance are smallest in British Columbia (Figure 5-33). The narrow exposure range, resulting in limited variability in $PM_{2.5}$ concentrations, may have contributed to the lack of an observed association.



Note: Large dots represent means; bold vertical lines represent medians. Red lines represent ± one standard deviation. For British Columbia, 25th and 75th percentiles were not reported, and so the IQR was assumed to center around the mean value. The maximum value for Southern California was 111.0 µg/m^3. The IQR's were 10, 3.8, and 1.5 µg/m^3, respectively.

Figure 5-33 Exposure measurements from South Coast Air Basin (Karr et al., 2007), Puget Sound Region, WA (Karr et al., 2007), and Georgia Air Basin, British Columbia (Karr et al., 2009b).

A limited number of studies evaluated other respiratory infection endpoints in infants or adults. MacIntyre et al. (2014b) examined parental reported pneumonia, otitis media, and croup in an ESCAPE Project pooled analysis of 10 European cohorts. $PM_{2.5}$ estimated outside birth residence was associated with an imprecise increase in odds of pneumonia in the first 36 months of life across all cohorts (OR [95% CI]: 2.58 [0.91, 7.27]). The association with $PM_{2.5}$ was attenuated, but still positive, in a two-pollutant model adjusting for NO_2 (1.91 [0.56, 6.57]; r = 0.42−0.8). A sensitivity analysis looking at alternative outcome windows showed the strongest association between long-term $PM_{2.5}$ and pneumonia diagnosed in the first year of life. Associations were null or negative for croup and otitis media. In a

case-control study in Ontario, Canada, Neupane et al. (2010) assessed the risk of hospitalization for community-acquired pneumonia in adults 65 years of age or older in relation to long-term exposure to $PM_{2.5}$. A notable strength of this study was the use of radiologically confirmed pneumonia to reduce potential outcome misclassification. The authors assigned exposure at the residential level using two deterministic interpolation methods, bicubic splines and inverse distance weighting, to estimate $PM_{2.5}$ concentrations at locations not coinciding with four air-quality monitors. Risk of hospitalization for pneumonia was associated with annual average $PM_{2.5}$ concentration, as estimated by both bicubic splines (OR [95% CI]: 1.6 [0.99, 2.63]) and inverse-distance weighting (3.7 [1.3, 10.1]). However, given the acute nature of the examined outcome, some uncertainty remains regarding potential confounding due to short-term $PM_{2.5}$ exposure.

In summary, recent epidemiologic studies do not indicate a clear relationship between long-term $PM_{2.5}$ exposures and respiratory infection in infants or adults. While the limited number of studies reviewed generally reported associations between $PM_{2.5}$ and at least some of the examined respiratory infection outcomes, there was limited overlap in endpoints across studies. Where the same endpoint was examined across multiple studies, large birth cohort studies found some evidence of an association between $PM_{2.5}$ and infant bronchiolitis (Karr et al., 2009b; Karr et al., 2007), but the results were not entirely consistent (Karr et al., 2009a).

5.2.7 Severity of Respiratory Disease

The 2009 PM ISA (U.S. EPA, 2009) reported evidence of an association between long-term $PM_{2.5}$ concentrations and increased severity of respiratory disease in two cohort studies. In one of these, an association between long-term $PM_{2.5}$ concentrations and increased disease severity was indicated by higher odds of bronchitic symptoms in children with asthma (McConnell et al., 2003). Stages of asthma can range in severity from mild, moderate, moderate-persistent, to severe (NHLBI NAEPP, 2007). In a second cohort study reported in the 2009 PM ISA (U.S. EPA, 2009), there was evidence for higher odds of exacerbation in persons with cystic fibrosis (CF). Goss et al. (2004) observed that long-term $PM_{2.5}$ exposure was associated with increased odds of two or more CF exacerbations. CF exacerbations were defined as a CF-related pulmonary condition requiring admission to the hospital or use of home intravenous antibiotics. Particle deposition is increased in CF and particle distribution in the lungs is enhanced in poorly ventilated tracheobronchial regions in CF patients (Brown et al., 2001). Such focal deposition may partially explain the reported association of PM and CF exacerbation. No recent studies examined CF exacerbations in relation to long-term $PM_{2.5}$ concentrations. The 2009 PM ISA also evaluated an animal toxicological study that reported exacerbation of an asthma-like phenotype following long-term DE exposure. However, this study did not distinguish between effects due to gases or particles in the mixture. In addition, animal toxicological evidence for COPD exacerbation following long-term exposure to urban air exposure was reported, however there was no measurement of $PM_{2.5}$ concentrations.

A limited number of recent epidemiologic studies show an association between long-term exposure to $PM_{2.5}$ and severity demonstrated by increased risk of asthma hospitalizations and ED visits in children. A recent study also provides evidence of a similar association in adults. However, potential confounding by short-term exposures remains an uncertainty in ascertaining the independent effect of long-term $PM_{2.5}$ exposure. One recent animal toxicological study evaluated the exacerbation of asthma in an animal model of allergic airway disease.

5.2.7.1 Epidemiologic Studies

Exacerbation of asthma symptoms is an indicator of severity, with more severe symptoms potentially resulting in hospitalization. Recent studies have evaluated the relationship between long-term exposure to $PM_{2.5}$ and asthma-related hospitalizations and ED visits in children. In a cross-sectional analysis using data from the California Health Interview Survey (CHIS), Wilhelm et al. (2008) assessed asthma hospitalization and emergency room visits in children 0 to 17 years old. Annual average $PM_{2.5}$ concentrations in Los Angeles and San Diego counties, measured by the nearest monitor within a 5-mile range, were not strongly associated with increased odds of asthma-related hospitalizations or emergency room visits (OR: 1.04 [95% CI: 0.68, 1.58]). However, there was an association in a copollutant model controlling for O_3 (OR: 1.9 [95% CI: 0.99, 3.7]). Meanwhile, a population-based cohort study of children in Quebec, Canada, the design of which is described in more detail in Tétreault et al. (2016a) and Section 5.2.3.1, also examined exacerbation of asthma in children (Tétreault et al., 2016b). The authors reported increases in hospital admissions and ED visits in relation to $PM_{2.5}$ concentrations measured outside birth residence (HR: 1.15 [95% CI: 1.14 to 1.15]) and using a time-varying model (HR: 1.07 [95% CI: 1.05 to 1.09]). $PM_{2.5}$ concentrations were estimated over a 10 × 10 km grid using satellite-based AOD observation data downscaled by the GEOS-Chem CTM. While these studies provide some evidence of an association between long-term exposure to $PM_{2.5}$ and asthma severity, neither study controlled for short-term exposures. Given the acute nature of the health endpoint, the observed effect could be partially or fully attributable to short-term increases in air pollution on the days prior to admission. Increases in asthma symptoms were also associated with long-term $PM_{2.5}$ concentrations in a cross-sectional study of adults (Balmes et al., 2014). Although asthma symptoms were self-reported using a nonvalidated ordinal questionnaire, responses are unlikely to be differentially misclassified according to exposure. Overall, recent studies examine asthma exacerbation in children and adults and provide additional evidence of a $PM_{2.5}$ effect on asthma severity. However, given the acute nature of the examined outcomes, some uncertainty remains regarding potential confounding due to short-term $PM_{2.5}$ exposure.

5.2.7.2 Animal Toxicological Study

Recently, a study evaluating the effects of $PM_{2.5}$ on severity of disease has become available. In Farraj et al. (2010), the effects of long-term DEP exposure were studied in an allergic mouse model.

BALB/c mice, which had been sensitized with OVA, were exposed to DEP for 4 weeks, with OVA challenges occurring at 2 and 4 weeks. DEP exposure had no effect on the many OVA-induced changes in BALF cells, cytokines, and injury markers (LDH, albumin, protein), except for a decrease in IL-4 ($p < 0.05$). This may be due to the analysis occurring 5 days after the last DEP exposure. Typically, acute inflammatory responses are measured at 24−48 hours after exposure to PM. Furthermore, Farraj et al. (2010) found that DEP exposure had no effect on airway responsiveness, as assessed by methacholine-induced changes in lung resistance, in the allergic mice. Additional study details for this study are found in Table 5-24.

Table 5-24 Study-specific details from an animal toxicological study of long-term $PM_{2.5}$ exposure and severity of an asthma-like phenotype.

5.2.8 Subclinical Effects in Healthy Populations

Animal toxicological studies provide evidence for subclinical effects potentially underlying the development of respiratory disease in healthy populations. The 2009 PM ISA (U.S. EPA, 2009) reported several studies that evaluated the effects of long-term exposure to $PM_{2.5}$ on subclinical effects in healthy populations. These studies provided evidence of pulmonary injury, inflammation, oxidative stress, and morphological alterations following long-term exposure to DE, GE, and woodsmoke. While most studies made no effort to distinguish between effects due to gases or particles in the mixture, one study examined the effects of particle filtration. Injury and inflammatory responses to DE were diminished as a result of particle filtration, indicating that PM played a role in the responses. Recent animal toxicological studies examined subclinical effects related to an asthma-like phenotype as discussed above (see

Section 5.2.3.3.2 and Section 5.2.7). Other respiratory-related subclinical effects, including oxidative stress, inflammation, and altered morphology have been investigated in studies of long-term $PM_{2.5}$ exposure. These results are discussed below, with additional study details found in Table 5-25.

Pulmonary Oxidative Stress

The 2009 PM ISA (U.S. EPA, 2009) evaluated several studies that examined pulmonary oxidative stress following long-term exposure to DE. These studies did not distinguish between effects due to gases or particles in the mixture. Recently, Kampfrath et al. (2011) investigated the effects of a 20-week exposure to $PM_{2.5}$ CAPs in Columbus, OH on oxidized phospholipids in the lung. Responses were compared in wild type and Toll-like receptor 4 (TLR4) deficient BALB/c mice. Increased levels of two oxidized forms of 1-palmitoyl-2-arachidonoyl-sn-glycero-3-phosphocholine (PAPC), the most common phospholipid in BALF, were observed in wild type mice exposed to $PM_{2.5}$ CAPs. Statistical analysis of these results was not presented. In a follow up study, Deiuliis et al. (2012) demonstrated the presence of oxidized PAPC in BALF in C57BL/6 mice exposed for 28 weeks to $PM_{2.5}$ CAPs in Columbus, OH ($p = 0.001$), thus confirming the results of (Kampfrath et al., 2011). Since oxidized lipids play a role in activating T cells, inflammatory T cells were also examined (see below). Aztatzi-Aguilar et al. (2015) found increased lung tissue heme oxygenase-1 activity in Sprague Dawley rats following 8-weeks exposure $PM_{2.5}$ CAPs in Mexico City ($p < 0.05$), while no changes in γ-glutamyl cysteine ligase catalytic subunit, another index of oxidative stress, were observed.

Table 5-25 Study-specific details from animal toxicological studies of long-term $PM_{2.5}$ exposure and subclinical effects.

Study/Study Population	Pollutant	Exposure	Endpoints

Study/Study Population	Pollutant	Exposure	Endpoints
Kim et al. (2016a) Species: Mouse Strain: BALB/c Sex: Female Age/Weight: 5−6 weeks	DEP nebulized Particle size: Mean diameter 0.4 µm before nebulization and 1−5 µm after nebulization Control: Saline aerosol	Dose/Concentration: 0.1 and 3 mg/m^3 DEP or saline (only results from 0.1 mg/m^3 reported here) Duration: 1 h/day, 5 days/week for 4, 8, and 12 weeks Time to analysis: 1 day after last exposure	BALF cells BALF cytokines Histochemistry • Masson trichome staining of lung
Ramanathan et al. (2017) Species: Mouse Strain: C57BL/6 Sex: Male Age/Weight: 8 weeks	$PM_{2.5}$ CAPs Baltimore, MD Particle size: $PM_{2.5}$ Control: Filtered air	Dose/concentration: 60.92 ± 21.31 µg/m^3 Controls: 8.09 ± 2.61 µg/m^3 Duration: 6 h/day, 5 days/week, 16 weeks	Nasal histopathology Nasal airway lavage: Inflammatory cells, cytokines, albumin
Tyler et al. (2016) Species: Mouse Strain: C57BL/6 and ApoE knockout Age/Weight: 6−8 weeks	DEP, resuspended Particle size: 1.5−3.0 µm ± 1.3−1.6 µm Control: Filtered air	Route: Whole-body inhalation Dose/Concentration: 315.3 ± 50.7 µg/m^3 Duration: 6 h/days for 30 days	BALF cells and cytokines Particle uptake in bronchial macrophages

ApoE = apolipoprotein E; ATPase = adenosine triphosphatase; BALF = bronchoalveolar lavage fluid; CD = cluster of differentiation; CXCR3 = chemokine receptor CXCR3; DEP = diesel exhaust particle; Foxp3 = forkhead box P3; IL-6 = interleukin-6; IL-17 α = interleukin-17 α; PAPC = 1-palmitoyl-2-arachidonoyl-sn-phosphatidylcholine; RAS = renin-angiotensin system; SOD = superoxide dismutase, T-regs = regulatory T lymphocytes; TLR4 = toll-like receptor 4.

Pulmonary Inflammation

The 2009 PM ISA (U.S. EPA, 2009) reported several studies evaluating pulmonary inflammation following long-term exposure to DE and woodsmoke. These studies did not distinguish between effects due to gases or particles in the mixture. Recently, Deiuliis et al. (2012) exposed wild type C57BL/6 mice and mice deficient in T cell chemokine receptor 3 (CXCR3) for 28 weeks to $PM_{2.5}$ CAPs in Columbus, OH. $PM_{2.5}$ CAPs exposure resulted in increased numbers of CD11c+, but not CD11b+, macrophages ($p < 0.0002$) in the lungs of wild type mice, as assessed by flow cytometry. CXCR3 deficiency decreased basal numbers of these macrophage subtypes and responses to $PM_{2.5}$ CAPs exposure. In wild type mice, $PM_{2.5}$ CAPs exposure resulted in increased numbers of T cell subsets, including $CD3^+$ ($p = 0.005$), $CD4^+$ ($p = 0.007$), and CD8+ lymphocytes ($p = 0.04$), Basal levels of these subsets and responses to $PM_{2.5}$ CAPs exposure were attenuated in CXCR3-deficient mice. A similar pattern of response was observed for activated CD44 + CD62L - CD4 + T cells ($p = 0.01$). However, in the case of central memory CD44 + CD62L - CCR7 + T cells, $PM_{2.5}$ CAPs exposure induced increases in both wild-type ($p = 0.01$) and CXCR4-deficient mice ($p = 0.04$). Expression of CXCR3 on $CD4^+$($p = 0.005$), but not $CD8^+$, T cells was increased by $PM_{2.5}$ CAPs. Gene expression was also evaluated in isolated lung $CD4^+$ T cell.

Long-term $PM_{2.5}$ CAPs exposure increased expression of CXCR3 and, IL-17α, but not CCR3, CCR4, and IL-4. These results show that long-term exposure to $PM_{2.5}$ CAPs induced T cell infiltration and increased activation of effector T cells in the lungs and suggests a Th1 rather than a Th2 response. The role of CXCR3 in mediating the effects of $PM_{2.5}$ CAPs is unclear since its deficiency had effects on both basal and PM-stimulated inflammation. Results of this study indicate that activation of macrophages by oxidized phospholipids (see above) may lead to the release of cytokines which recruit and activate T cells as part of a proinflammatory Th1 response.

Kim et al. (2016a) exposed BALB/c mice to nebulized DEP for 4, 8, and 12 weeks. DEP exposure resulted in increased numbers of BALF lymphocytes at 4 and 12 weeks ($p < 0.05$). Numbers of other inflammatory cells and total cells in BALF were not altered. However, increased levels of cytokines IFN-γ, IL-6, VEGF, and TGF-β were observed in BALF at 12 weeks ($p < 0.05$). In contrast, two other studies found no evidence of inflammation following long-term $PM_{2.5}$ exposure. No increase in BALF inflammatory cells or cytokines or particle uptake into bronchial macrophages was observed in C57BL/7 mice exposed to resuspended DEP for 30 days (Tyler et al., 2016). However, inflammatory effects were observed in the hippocampus (Section 8.1.3). Aztatzi-Aguilar et al. (2015) exposed Sprague Dawley rats for 8 weeks to $PM_{2.5}$ CAPs in Mexico City and found decreased protein expression of IL-6 in lung tissue ($p < 0.05$). However, long-term $PM_{2.5}$ CAPs exposure also had several effects on the RAS in the lung ($p < 0.05$). This included induced lung expression of the angiotensin 1 receptor gene, and increased angiotensin 1 receptor protein levels. Protein levels and mRNA of angiotensin converting enzyme were not impacted. Components of the RAS play an important role in the pulmonary circulation.

Morphological Effects

In a long-term exposure study involving DEP, Kim et al. (2016a) found increased collagen deposition, as assessed by Masson trichrome staining, at 4, 8, and 12 weeks ($p < 0.05$) (see Section 5.2.3.3.2). Increased and disordered collagen deposition underlies lung fibrosis, which is mediated in part by the cytokine TGF-β, whose levels were increased as a result of DEP exposure in this study ($p < 0.05$).

Recent studies also examine effects on nasal mucosa (Guo et al., 2017) (Ramanathan et al., 2017). (Guo et al., 2017) evaluated nasal injury and oxidative stress in Sprague Dawley rats following 30-day inhalation of two concentrations of resuspended $PM_{2.5}$ from Shanghai, China. Long-term Exposure to $PM_{2.5}$ resulted in increased malondialdehyde levels in nasal mucosa ($p < 0.05$). Morphological alterations were observed, including nasal epithelial necrosis, disarray of cilia, vascular congestion, and edema. At the ultrastructural level, mitochondrial alterations were observed, including swelling, cristae disorder, and vacuolization. Activities of several enzymes (superoxide dismutase, sodium potassium ATPase, calcium ATPase) in nasal mucosa were decreased by exposure ($p < 0.01$). Gene expression and protein levels of OPA1 and Mnf1, which are involved in mitochondrial fusion and fission, were increased by long-term exposure to both concentrations of $PM_{2.5}$ ($p < 0.01$). Ramanathan et al. (2017) examined the effects of a

16-week exposure to $PM_{2.5}$ CAPs in Baltimore, MD on the sinonasal barrier of C57BL/6 mice. Numbers of macrophages, neutrophils, and eosinophils were increased in NALF ($p < 0.05$). Levels of proinflammatory cytokines were also increased in NALF, including IL-1β, IL-13, and eotaxin-1. Immunostaining of sinonasal mucosa revealed increased staining for myeloperoxidase and eosinophil major basic protein positive cells ($p < 0.05$). Evidence for sinonasal epithelial cell barrier dysfunction was provided by decreased expression of tight junction and adherens junction proteins claudin-1 and E-cadherin and by increased levels of serum albumin in NALF ($p < 0.05$). Furthermore, morphometric analysis of the septal subepithelial thickness showed an increase as a result of long-term exposure to $PM_{2.5}$ ($p < 0.001$).

Summary of Subclinical Effects in Healthy Populations

Recent studies and one older study provide evidence for several subclinical effects potentially underlying the development of respiratory disease following long-term $PM_{2.5}$ exposure in healthy animal models. These include pulmonary injury, oxidative stress, inflammation and altered morphology. In particular, increases in tissue and BALF expression of antioxidant genes and proteins and increases in BALF levels of oxidized phospholipids were found. Upregulation of cytokines in the lungs and infiltration of inflammatory cells, including lymphocytes, monocytes, and specific T-cells subtypes consistent with a Th1 proinflammatory response, were also observed. In addition, long-term $PM_{2.5}$ exposure resulted in increased collagen deposition, an early step in the development of lung fibrosis, and upregulation of the RAS. While the above-mentioned studies focused on the lower airways, changes to the upper airways were also demonstrated. Two studies found evidence of oxidative stress, injury, inflammation, and morphologic changes in nasal mucosa resulting from long-term exposure to $PM_{2.5}$.

5.2.9 Subclinical Effects in Populations with Cardiovascular Disease

Animal toxicological studies provide evidence for subclinical effects potentially underlying the development of respiratory disease in populations with cardiovascular disease. The 2009 PM ISA (U.S. EPA, 2009) reported several studies that evaluated the effects of long-term exposure to $PM_{2.5}$ in animal models of cardiovascular disease, mainly focusing on pulmonary inflammation. In ApoE and LDL knock-out mice, exposure for 1−5 months to $PM_{2.5}$ CAPs resulted in upregulation of gene expression in lung tissue, although no increases in BALF inflammatory cells were found. Inflammation and altered morphology were observed following long-term exposure to DE in spontaneously hypertensive (SH) rats. However, there was no attempt to distinguish between effects due to gases or particles in the DE mixture.

Recent studies examined pulmonary oxidative stress and inflammation. Evidence for pulmonary inflammation was found in SH rats exposed to $PM_{2.5}$ CAPs in Columbus, OH for 15 weeks (Ying et al., 2015). Expression of TNFα and IL-6 mRNA in lung tissue was increased at 15 weeks ($p < 0.05$) and remained elevated 5 weeks following the end of exposure. Xu et al. (2012) exposed ApoE knockout mice

to $PM_{2.5}$ CAPs in Tuxedo, NY for 3 months. Monocytic infiltration into the lung was observed, as evidenced by increased numbers of $F4/F80^+$ macrophage ($p < 0.001$). Wan et al. (2014) conducted a 2-month long field study of ApoE knockout mice exposed to ambient air in Beijing and fed a Western diet. Urban air PM mainly consisted of $PM_{2.5}$, but it also contained some PM_{10}; other ambient pollutants were also present. Control mice were exposed to filtered ambient air, which contained greatly reduced concentrations of $PM_{2.5}$. Long-term exposure to Beijing urban air increased BALF levels of oxidized LDL and MDA, decreased BALF SOD and GSHPx activity and increased BALF levels of IL-6 and TNF-a protein ($p < 0.05$). In contrast, Tyler et al. (2016) exposed ApoE knockout mice to resuspended DEP for 30 days and found no increase in inflammatory cells or cytokines in the BALF, although particle uptake into bronchial macrophages was increased ($p < 0.001$). Effects were also seen in the hippocampus (Section 8.2.3). Overall, evidence for inflammation was found in lung tissue following long-term exposure to $PM_{2.5}$ CAPs, but not in BALF following long-term exposure to DEP. Interpretation of effects due to long-term urban air exposure is complicated by the presence of $PM_{10–2.5}$. Additional study details are found in Table 5-26.

Table 5-26 Study-specific details from animal toxicological studies of long-term $PM_{2.5}$ exposure and subclinical effects in populations with cardiovascular disease.

Study/Study Population	Pollutant	Exposure	Endpoints
Tyler et al. (2016) Species: Mouse Strain: ApoE knockout Age/Weight: 6−8 weeks	DEP, resuspended Particle size: 1.5−3.0 µm ± 1.3−1.6 µm Control: Filtered air	Route: Whole-body inhalation Dose/Concentration: 315.3 ± 50.7 µg/m^3 Duration: 6 h/day for 30 days	BALF cells and cytokines Particle uptake in bronchial macrophages
Wan et al. (2014) Species: Mouse Strain: Apo E knockout C57BL/6) Sex: Male Age/Weight: 9 weeks	Beijing PM Particle sizes: $PM_{2.5}$ + PM_{10} Control: HEPA-filtered ambient air	Route: Ambient Beijing air Dose/concentration: $PM_{2.5}$ 63.1 µg/m^3 $PM_{10-2.5}$ 37.2 µg/m^3 (estimated as the difference of PM_{10} and $PM_{2.5}$ concentration measurements made with one continuous monitor) Duration of exposure: 24 h/day, 7 days/week for 2 mo Coexposure Western Diet	BALF Cytokines- IL-6 and TNF-α Oxidative stress markers—Ox LDL, malondialdehyde, SOD and GSHPx
Xu et al. (2012) Species: Mouse Strain: Apo E knockout Sex: Male Age/Weight: 8 weeks	$PM_{2.5}$ CAPs Tuxedo NY Particle sizes: $PM_{2.5}$ Control: Filtered air	Route: Whole-body inhalation Dose/concentration: $PM_{2.5}$ CAPs 70 µg/m^3 Duration of exposure: 6 h/day, 5 days/week for 3 mo	Histopathology—lung
Ying et al. (2015) Species: Rat Strain: SHR Sex: Male Age/Weight: 5 weeks	$PM_{2.5}$ CAPs from Columbus, OH Particle sizes: $PM_{2.5}$ Control: Filtered air	Route: Whole-body inhalation Dose/Concentration: 128.3 ± 60.4 µg/m^3 Duration: 6 h/day, 5 days/week for 15 weeks Time to analysis: Immediately or 5 weeks later	Gene expression—inflammatory markers in lung

ApoE = apolipoprotein E; BALF = bronchoalveolar lavage fluid; DEP = diesel exhaust particle; GSHPX = glutathione peroxidase; HEPA = high efficiency particulate absorber; IL-6 = interleukin-6; OxLDL = oxidized low density lipoprotein; SHR = spontaneously hypertensive rat; SOD = superoxide dismutase; TNF α = tumor necrosis factor α.

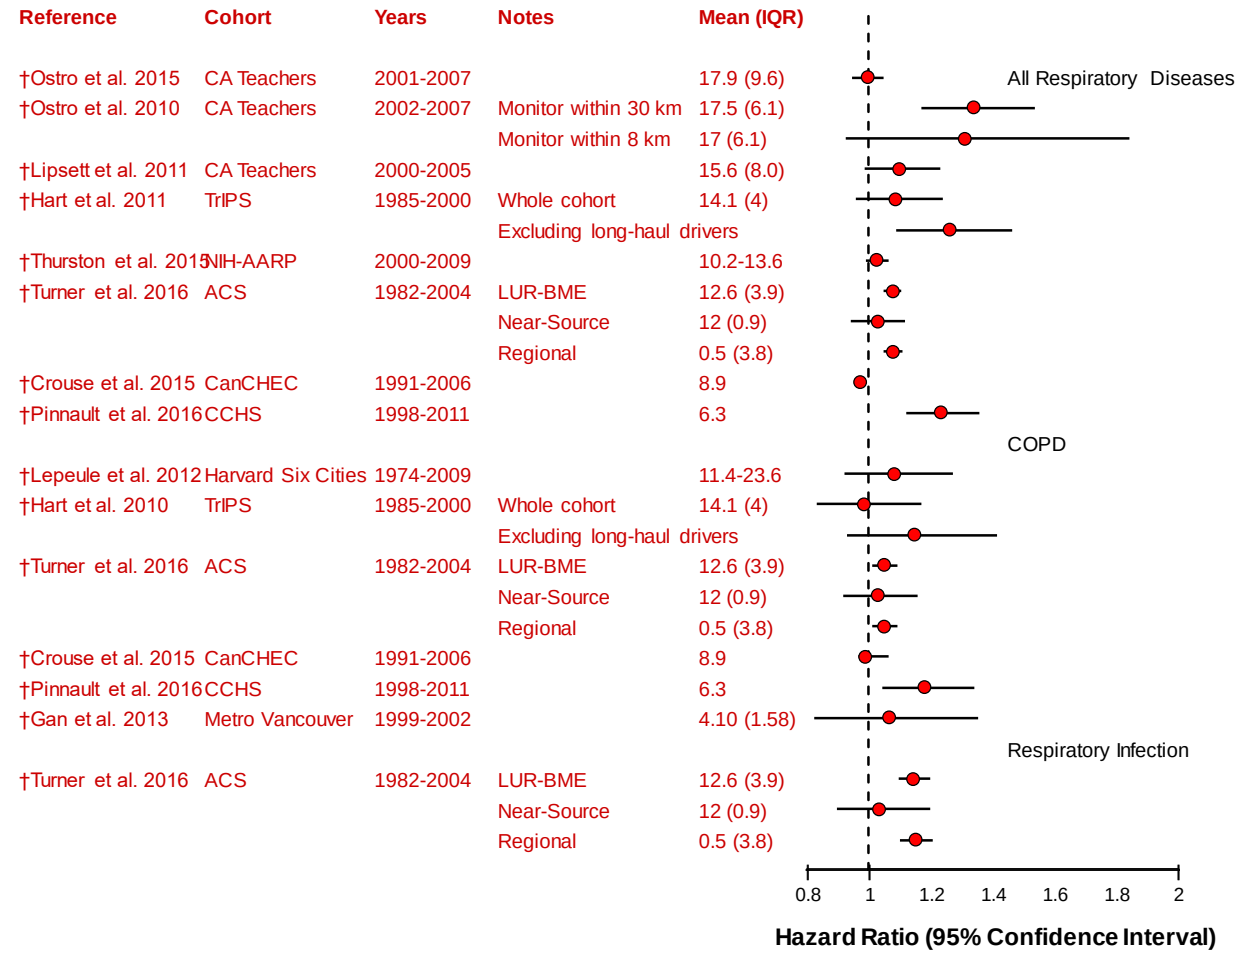
5.2.10 Respiratory Mortality

Studies that examine the association between long-term $PM_{2.5}$ exposure and cause-specific mortality outcomes, such as respiratory mortality, provide additional evidence for $PM_{2.5}$-related respiratory effects, specifically whether there is evidence of an overall continuum of effects. Evidence from studies of long-term $PM_{2.5}$ exposure and mortality are presented in detail in CHAPTER 11.

Evidence from studies investigating respiratory mortality provided limited and inconsistent evidence for a respiratory effect related to long-term $PM_{2.5}$ exposure in the 2009 PM ISA (U.S. EPA, 2009) and are summarized here to inform the effect of long-term $PM_{2.5}$ exposure on the continuum of respiratory health effects. The 2009 PM ISA (U.S. EPA, 2009) included evidence from two large, multicity U.S. studies: the American Cancer Society (ACS) cohort (Pope III et al., 2004) and the Harvard six cities cohort (Laden et al., 2006). Recent updates to these studies, as well as results from recent cohort studies, contribute to the body of evidence for this relationship (Figure 5-34).

Several recent analyses further evaluated the associations of long-term $PM_{2.5}$ exposures with risk of respiratory mortality based on the original ACS study (Pope et al., 1995), adding details about deaths due to respiratory disease (including COPD), and extending the follow-up period for the ACS to 22 years (1982−2004). In particular, Pope et al. (2014) and Turner et al. (2016) used the extended follow-up period of the ACS to examine the associations between long-term $PM_{2.5}$ exposure and respiratory disease and COPD. The results of these extended analyses demonstrated positive associations with respiratory disease and COPD mortality, which had not been previously evaluated among the ACS cohort. Similarly, Lepeule et al. (2012) reported the results of an extended analysis of the Harvard Six Cities cohort, extending the follow-up period to include deaths between 1974 and 2009. This was the first time that COPD mortality was evaluated among the Harvard Six Cities cohort; the relative risk was positive, but imprecise due to the smaller number of COPD deaths compared to deaths from other causes.

Several additional U.S. cohort studies evaluated the association between long-term $PM_{2.5}$ exposure and respiratory mortality. In a nationwide cohort of older Americans, Thurston et al. (2015) used monthly estimates of $PM_{2.5}$ concentration to assign annual mean concentrations to participants in the NIH-AARP cohort study and observed a positive association with respiratory mortality. The California Teachers Study (Lipsett et al., 2011; Ostro et al., 2010) examined the association between $PM_{2.5}$ and mortality among female public-school teachers and observed positive associations between long-term $PM_{2.5}$ exposure and respiratory mortality. In a reanalysis of the cohort with refined exposure assessment, Ostro et al. (2015) used a chemical transport model (CTM) to predict $PM_{2.5}$ concentrations with a 4-km spatial resolution, observing a null association between $PM_{2.5}$ exposure and respiratory mortality. Hart et al. (2011) examined the association between residential exposure to $PM_{2.5}$ estimated from a single year of monitoring data (2000) and mortality among men in the U.S. trucking industry in the Trucking Industry Particle Study (TrIPS). The results for respiratory mortality were similar to those reported by Lipsett et al. (2011) for respiratory mortality. The results for COPD mortality were null for the cohort and positive, though imprecise for a sensitivity analyses excluding long-haul drivers.



CanCHEC = Canadian Census Health and Environment Cohort; IQR = interquartile range; TrIPS = Trucking Industry Particle Study; NIH-AARP = National Institutes of Health American Association of Retired Persons Diet and Health Cohort; ACS = American Cancer Society Cohort; CCHS = Canadian Community Health Survey; LUR-BME = land use regression-Bayesian maximum entropy exposure model.

Note: †Studies published since the 2009 PM ISA. Associations are presented per 5 μg/m^3 increase in pollutant concentration. Circles represent point estimates; horizontal lines represent 95% confidence intervals for $PM_{2.5}$. Study results from Lepeule et al. (2012) are representative of results from the Harvard Six Cities Cohort; Study results from Turner et al. (2016) are representative of the results from the American Cancer Society Cohort.

Figure 5-34 Associations between long-term exposure to $PM_{2.5}$ and respiratory mortality in recent North American cohorts.

In an extended reanalysis of the Canadian CanCHEC cohort Crouse et al. (2015) observed associations for respiratory and COPD mortality that were just below the null value. The general pattern and magnitude of these associations were generally unchanged in cumulative risk models that include O_3 and/or NO_2. Pinault et al. (2016) linked a subset of participants from the CanCHEC cohort to the Canadian Community Health Survey and observed positive associations with respiratory mortality. Pinault et al. (2016) was able to make use of the individual-level covariate data on age, sex, smoking, alcohol consumption, obesity, and fruit/vegetable consumption that was not available in the larger

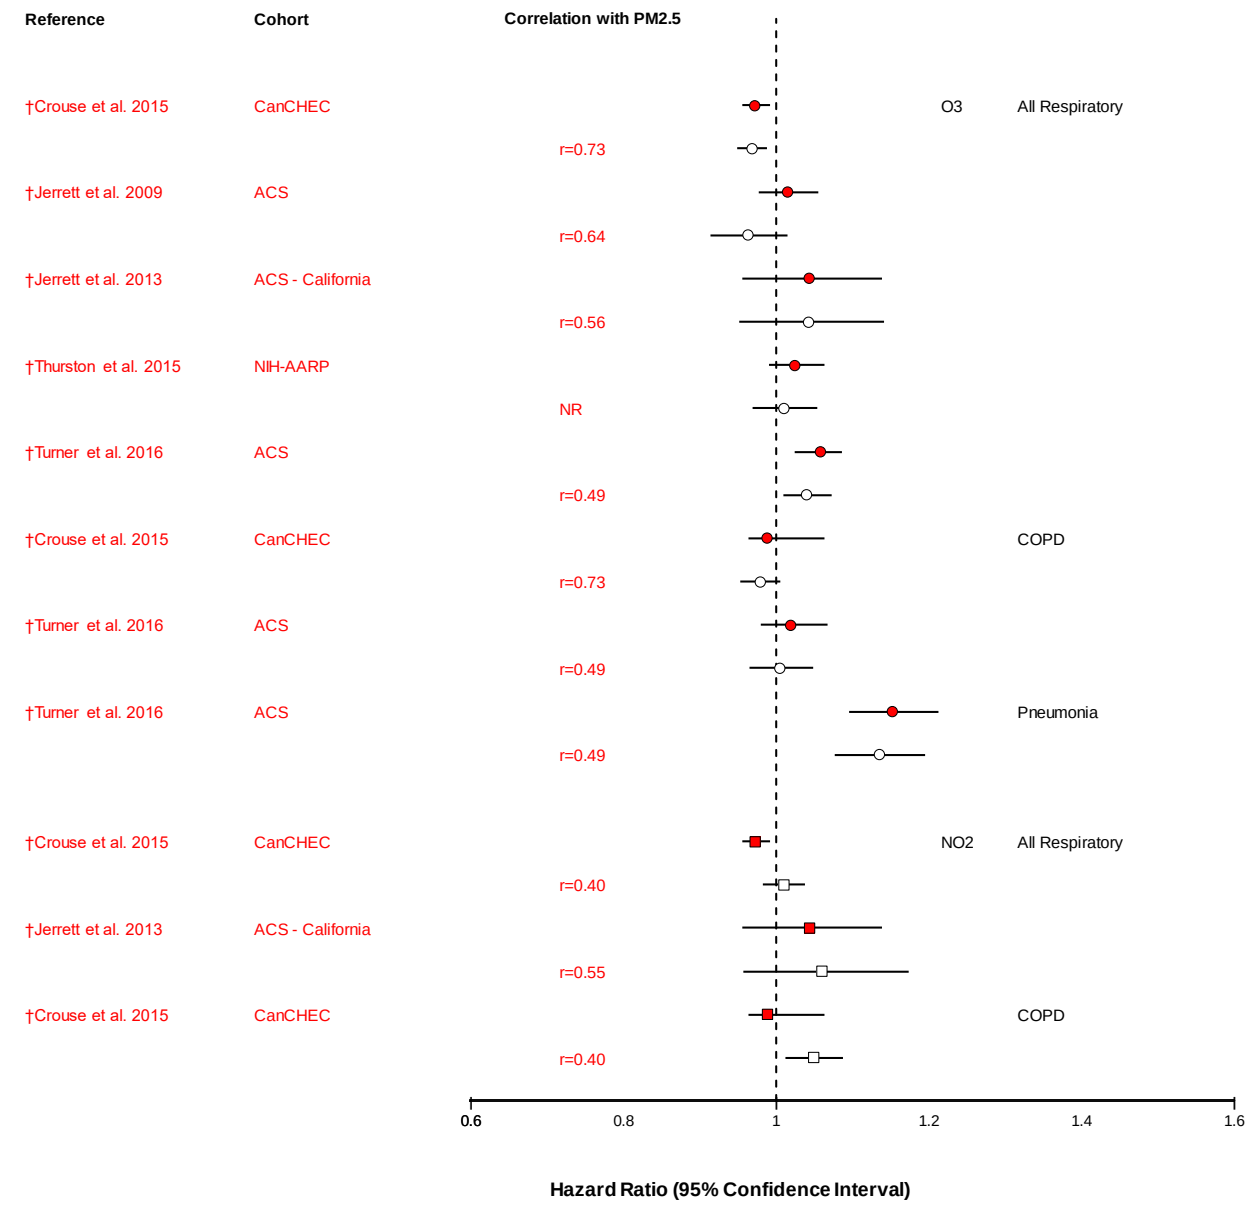
CanCHEC cohort. The inclusion of these individual-level data may help to explain the inconsistent results observed by Crouse et al. (2015) and Pinault et al. (2016).

Overall, the results of these recent U.S. cohort studies demonstrate a generally consistent, positive association between long-term $PM_{2.5}$ exposure and respiratory mortality, though the results from the two Canadian studies are inconsistent. In addition, a study conducted in Europe that pooled data from 22 existing cohort studies and evaluated the association between long-term $PM_{2.5}$ exposure and respiratory mortality observed an association for respiratory mortality near the null value (Dimakopoulou et al., 2014). The associations for respiratory mortality in analysis of pooled data were generally positive, though some inconsistencies among the results from different analyses of the same cohort provide some uncertainty in the stability of these results (Pinault et al., 2016; Crouse et al., 2015; Ostro et al., 2015; Ostro et al., 2010). Recent studies have evaluated the association between long-term $PM_{2.5}$ exposure and COPD mortality, a cause of death for which there has previously been little examination. These studies report modest positive associations with COPD mortality and the hazard ratios are generally less precise than those for respiratory mortality. A single study (Turner et al., 2016) examined deaths due to respiratory infection and long-term $PM_{2.5}$ exposure and observed a positive association.

5.2.10.1 Potential Copollutant Confounding of the $PM_{2.5}$-Mortality Relationship

In the examination of potential confounding effects of copollutants on the relationship between long-term $PM_{2.5}$ exposure and respiratory mortality, it is informative to evaluate whether $PM_{2.5}$ risk estimates are changed in copollutant models. Recent studies have examined the potential for copollutant confounding by evaluating copollutant models that include O_3 and NO_2 (Figure 5-35). These recent studies address a previously identified data gap by informing the extent to which effects associated with exposure to $PM_{2.5}$ are independent of coexposure to correlated copollutants in long-term analyses.

The results for associations between long-term $PM_{2.5}$ exposure and respiratory mortality in single pollutant models and copollutant models adjusted for O_3 and NO_2 are shown in Figure 5-35. The correlations between $PM_{2.5}$ and O_3 exposures in the studies that conducted copollutant analyses were generally positive and moderate to strong, ranging from $r = 0.49$ to 0.73. Generally, the $PM_{2.5}$ effect estimates remained relatively unchanged in copollutant models adjusted for O_3. The associations persisted across different specific causes of respiratory mortality. The correlations between $PM_{2.5}$ and NO_2 exposures in studies that conducted copollutant analyses were positive and moderate ($r = 0.40$; $r = 0.55$). In one study (Jerrett et al., 2013), the $PM_{2.5}$ effect estimates remained relatively unchanged in a copollutant model adjusted for NO_2, while in another (Crouse et al., 2015), the $PM_{2.5}$ estimates increased and changed from negative to positive after adjusting for NO_2 for respiratory and COPD mortality.



ACS: American Cancer Society Cohort; CanCHEC = Canadian Census Health and Environment Cohort; AHSMOG = Adventist Health Air Pollution Study; COPD = chronic obstructive pulmonary disease; NR = not reported.

Note: †Studies published since the 2009 PM ISA. Circles and squares represent point estimates; horizontal lines represent 95% confidence intervals for $PM_{2.5}$. Filled symbols represent effect of $PM_{2.5}$ in single pollutant models, open circles represent effect of $PM_{2.5}$ adjusted for O_3; open squares represent effect of $PM_{2.5}$ adjusted for NO_2. Associations are presented per 5 $\mu g/m^3$ increase in pollutant concentration.

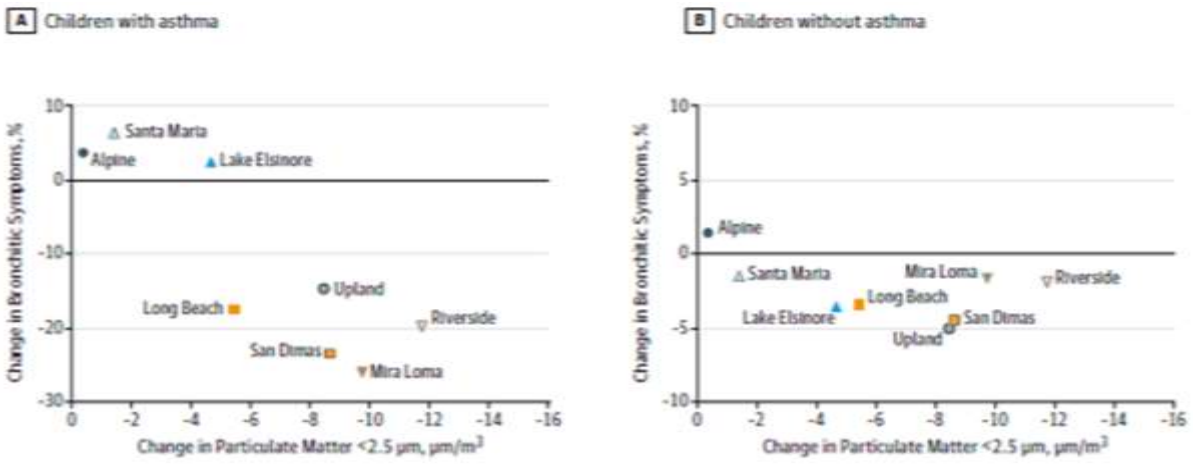
Figure 5-35 Long-term exposure to $PM_{2.5}$ and mortality in single pollutant models and models adjusted for ozone or nitrogen dioxide.

5.2.11 Respiratory Effects and Declining $PM_{2.5}$ Concentrations

In the 2009 PM ISA (U.S. EPA, 2009), none of the reviewed studies related declining concentrations of long-term $PM_{2.5}$ to respiratory health endpoints. A reduction in air pollution can restore "biological normality by removal of an abnormal exposure" (Rose, 1981). In populations, this has been shown to lead to a reduction of risk in a large number of people and result in a decline in cases of respiratory disease or improved lung function and development. Recent studies examine $PM_{2.5}$ decreases and improvements in respiratory health in children and adults. The majority of this recent evidence comes from prospective cohort studies of decreased $PM_{2.5}$ concentrations in CHS communities that observed improved respiratory health in children (Berhane et al., 2016; Gauderman et al., 2015).

5.2.11.1 Bronchitis

Since the beginning of the CHS studies, pollutant levels have been declining in the CHS southern California communities. Recently, Berhane et al. (2016) prospectively examined the relationship between declining pollutant levels and self-reported chronic bronchitis symptoms in three cohorts of children (n = 4,602) in eight communities. From 1992 to 2012, mean $PM_{2.5}$ concentrations declined across all communities from 20.5 to 14.4 $\mu g/m^3$. Due to significant differences in chronic bronchitis prevalence by asthma status, the authors presented separate results for children without asthma and children with asthma. As depicted in Figure 5-36, communities with greater reductions of $PM_{2.5}$ had larger unadjusted reductions of bronchitis symptoms. The relationship was noticeably stronger in children with asthma. In adjusted models, a 5 $\mu g/m^3$ decrease in $PM_{2.5}$ was associated with a 25% (95% CI: 11, 37%) decrease in odds of bronchitic symptoms in 10-year old children with asthma. Berhane et al. (2016) also observed decreases in bronchitic symptoms in 10-year olds without asthma (OR = 0.84 [95% CI: 0.76, 0.93] per 5 $\mu g/m^3$ decrease in $PM_{2.5}$). The observed associations were relatively unchanged in copollutant models controlling for O_3 (r = 0.54). Copollutant models with other pollutants were not examined due to high correlations (NO_2: r = 84; PM_{10}: r = 0.88). Meanwhile, observed decrements in bronchitic symptoms in 15-year olds were similar, but slightly stronger than those seen in 10-year-olds.

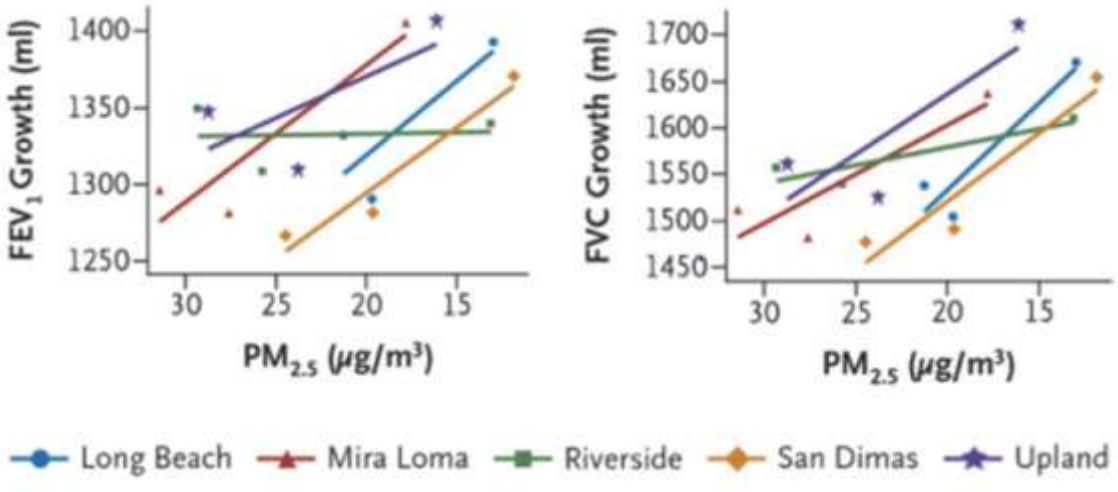


Source: Permission pending, Berhane et al. (2016).

Figure 5-36 Estimated bronchitic symptom prevalence at age 10 versus mean air pollutant concentrations among Children's Health Study (CHS) participants by asthma status.

5.2.11.2 Pulmonary Function

A recent study combined data obtained from three separate CHS cohorts to examine the association between long term reductions in air pollution and lung development in children between the ages of 11 and 15 (Gilliland et al., 2017; Gauderman et al., 2015). Study specific details, including results, are presented in Table 5-19 (Section 5.2.2.1). Briefly, the study sample included children recruited from three separate CHS cohorts spread out over a 20-year period. The analysis was restricted to the five study communities (Long Beach, Mira Loma, Riverside, San Dimas, and Upland) in which pulmonary function testing was performed in all three cohorts (n = 2,120). Significant improvements in lung-function growth were observed within and across communities as air quality improved over the study period (see Figure 5-37 for unadjusted relationship and Table 5-19 for fully-adjusted model results).



Note: The 4-year mean growth in forced expiratory volume in 1 second (FEV_1) and the mean growth in forced vital capacity (FVC) from 11 to 15 years of age are plotted against the corresponding levels of $PM_{2.5}$ for each community and cohort.
Source: Permission pending, Gauderman et al. (2015).

Figure 5-37 Mean 4-year lung-function growth versus the mean levels of $PM_{2.5}$.

A similar study examined the impact of improved air quality on lung function in adults (Boogaard et al., 2013). Boogaard et al. (2013) conducted a small population-based study in the Netherlands, aiming to describe the effect of traffic policy-related reductions in air pollution in 12 locations in the Netherlands (8 urban, 4 suburban). Study details and results are presented in Table 5-20 (Section 5.2.2.2). In summary, baseline lung function was measured in 746 participants prior to implementation of a low emission zone traffic policy. Lung function was measured again at follow-up, 2 years after policy implementation (87% follow-up). In adjusted analyses, 2-year declines in $PM_{2.5}$ were associated with increases in FVC and decreases in airway resistance, indicating improvements in lung function associated with reductions in $PM_{2.5}$.

5.2.11.3 Summary

Initial studies examining the relationship between improvements in air quality and whether this resulted in beneficial changes in respiratory effects observed a consistent relationship between decreasing $PM_{2.5}$ concentrations and improved respiratory health. These results provide corroborating evidence of an association between $PM_{2.5}$ and lung development (Section 5.2.2) and bronchitis (Section 5.2.5). Examination of potential copollutant confounding was limited, but there was evidence that the $PM_{2.5}$ effect was robust in models including O_3 (Berhane et al., 2016).

5.2.12 Associations Between $PM_{2.5}$ Components and Sources and Respiratory Effects

The 2009 PM ISA (U.S. EPA, 2009) did not include an organized discussion of the potential relationship between long-term exposure to $PM_{2.5}$ components and respiratory effects. The limited number of available studies found some evidence of an association between respiratory health and exposure to elemental and organic carbon (EC and OC), but no studies examining metals were available. In addition to constituting a small body of evidence, the EC and OC results did not adjust for $PM_{2.5}$ mass, which raises additional uncertainties considering that EC and OC are components within the complex mixture that is $PM_{2.5}$, and the generally high correlations ($r > 0.7$) between EC, OC, and $PM_{2.5}$. Since the completion of the 2009 PM ISA, a number of recent studies have further examined $PM_{2.5}$ components, including metals, and a limited number of these studies have attempted to control for potential confounding by $PM_{2.5}$ mass. In addition to studies of carbon fractions and metals, a recent study also examined respiratory health effects related to the oxidative potential (OP) of $PM_{2.5}$. Due to a limited number of studies for most individual components, and even fewer studies for any given endpoint, no single component is identified as having a stronger relationship with respiratory effects or one that clearly differs from that of $PM_{2.5}$ total mass. All of the studies presented in Table 5-27 are discussed in greater detail throughout this chapter, such that the discussion in this section will not focus on specific study details unless they are specifically relevant to interpretation of $PM_{2.5}$ component results.

Figure 5-38 charts the trend of results for $PM_{2.5}$ mass and individual $PM_{2.5}$ components studies detailed in Table 5-27. The focus of the figure and the ensuing discussion is on studies of lung function and asthma, for which there is evidence of an association with long-term exposure to $PM_{2.5}$. Where available, the chart reflects $PM_{2.5}$ mass-adjusted component results.

Table 5-27 Heat map of associations observed between long-term exposure $PM_{2.5}$ and $PM_{2.5}$ components and respiratory health.

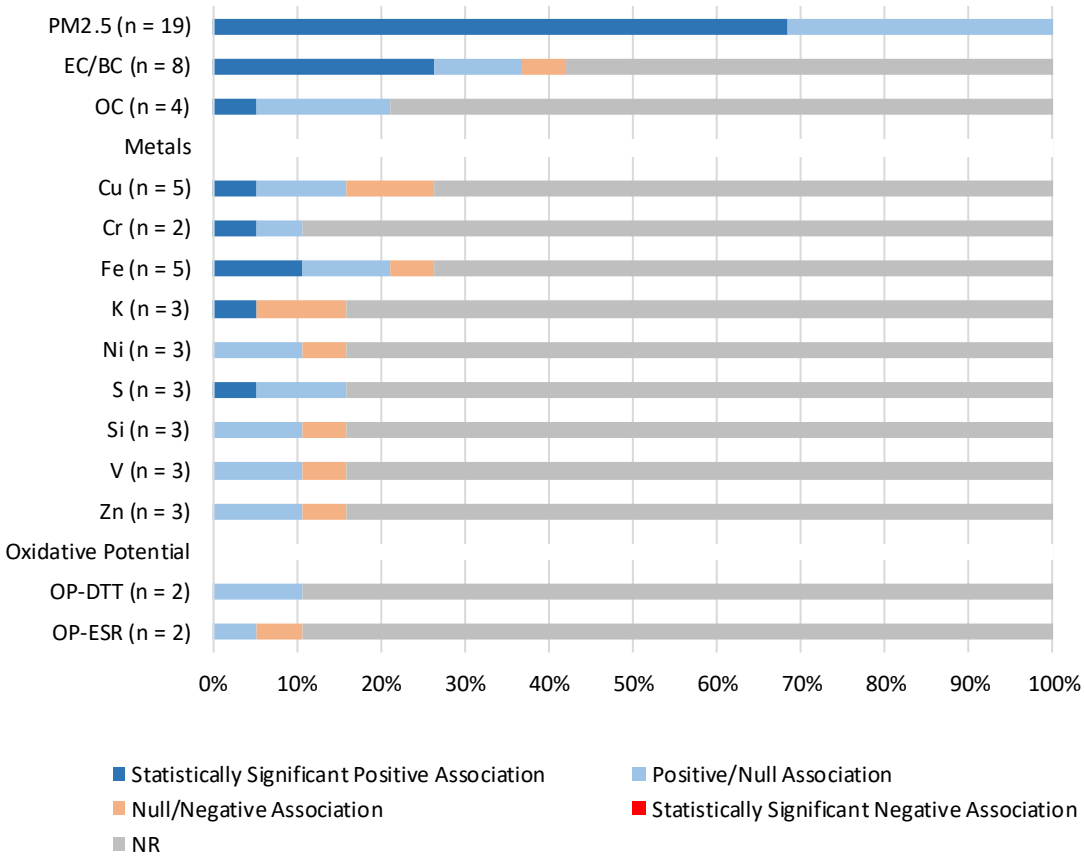
[a]$PM_{2.5}$ estimate came from a different study of the same cohort (Eeftens et al., 2014).

‡Associations adjusted for $PM_{2.5}$ mass.

Note: † $PM_{2.5}$ component studies published since the 2009 PM ISA. Dark blue = study reported statistically significant association between $PM_{2.5}$/component and impaired respiratory health outcome; light blue = study reported association between $PM_{2.5}$/component and impaired respiratory health outcome regardless of width of confidence intervals; light orange = study reported null or inverse association; red = study reported statistically significant association between $PM_{2.5}$/component and improved respiratory health outcome; gray = study did not examine individual component. Studies sorted by outcome.



Note: Bars represent the percentage of results for $PM_{2.5}$ mass or $PM_{2.5}$ components from lung function and asthma studies detailed in Table 5-27 that show statistically significant impaired respiratory health (dark blue), impaired respiratory health (light blue), null/improved respiratory health (light orange), or statistically significant improved respiratory health (red). n = number of estimates across the studies detailed in Table 5-27 for $PM_{2.5}$ mass or the individual $PM_{2.5}$ components. When available, this figure uses $PM_{2.5}$ mass-adjusted component associations. See Table 5-27 for more details.

Figure 5-38 Distribution of associations for $PM_{2.5}$ and $PM_{2.5}$ components examined in studies detailed in Table 5-27.

5.2.12.1 Elemental Carbon, Black Carbon, and Organic Carbon

As discussed in the 2009 PM ISA (U.S. EPA, 2009), Gauderman et al. (2004) examined the relationship between lung function growth and long-term exposure to EC and OC. The authors observed evidence of an association between EC and OC exposure and lung development in children, as measured by 8-year growth in FEV_1, FVC, and MMEF. In a recent, expanded CHS analysis examining an additional cohort, Breton et al. (2011) observed similar results to Gauderman et al. (2004). However, $PM_{2.5}$ effects were noted in both studies, and EC and OC were highly correlated with $PM_{2.5}$ (r = 0.91 for both components), adding uncertainty to the independent effect of either component. Results from a limited number of recent studies also suggest a potential link between EC and asthma incidence in children. However, the results are not as consistent as those for $PM_{2.5}$.

5.2.12.2 Metals

Elemental fractions of $PM_{2.5}$ were examined as predictors of lung function in two European cohort studies (Gehring et al., 2015a; Eeftens et al., 2014). In an ESCAPE project analysis of 6- to 8-year-old children in five European birth cohorts, Eeftens et al. (2014) reported small reductions in FEV_1, between 0.5 and 1.5%, associated with IQR increases in Cu, Fe, Ni, S, and V. However, after adjustment for $PM_{2.5}$ mass, all negative associations were null except for Fe and S. Similar single-pollutant results were noted in 8- to 12-year-old children in the PIAMA cohort (Gehring et al., 2015a), which was also included in the ESCAPE analysis. The authors did not report $PM_{2.5}$-mass adjusted results. Gehring et al. (2015a) also reported associations between all of the examined metals and asthma incidence (Cu, Fe, K, Ni, S, Si, V, and Zn).

As discussed previously for EC and OC, moderate to high correlations with $PM_{2.5}$, as well as negated effects in models adjusting for $PM_{2.5}$, indicate uncertainty about the independence of the observed associations between elemental fractions of $PM_{2.5}$ and respiratory health. Additionally, the ESCAPE cohorts, including PIAMA, implemented LUR models to estimate exposure to $PM_{2.5}$ components. The models predicted concentration variance with varying degrees of accuracy (R^2 = 0.53−0.79), potentially introducing more exposure measurement error for some components compared to others (de Hoogh et al., 2013). Overall, explained variance was generally higher for $PM_{2.5}$ mass compared to components, indicating greater confidence in the $PM_{2.5}$ concentrations as compared to components.

5.2.12.3 Oxidative Potential

Information from recent studies on the oxidative potential (OP) of $PM_{2.5}$ (i.e., the inherent capacity of PM to generate reactive oxygen species) is presented in a study of the PIAMA cohort in the Netherlands (Yang et al., 2016). The authors propose a link between oxidative potential of $PM_{2.5}$, $PM_{2.5}$ exposure, oxidative stress and inflammation, and respiratory health effects. Yang et al. (2016) reported associations with asthma incidence and lung function decrements (FEV_1 and FVC). Results were dependent on the methods used to quantify OP, with health effects observed with OP measured using the dithiothreitol assay, but null effects for OP measured using spin resonance assay. Results also differed by exposure period, with stronger associations generally observed between the aforementioned respiratory health effects and OP estimated (by LUR) for the concurrent period, compared to OP estimated at participants' birth address. Asthma and lung function associations with OP persisted with adjustment in two-pollutant models for $PM_{2.5}$, NO_2, and a number of $PM_{2.5}$ metals.

5.2.12.4 Summary

Overall, recent studies add evidence for respiratory effects related to long-term $PM_{2.5}$ component exposures. However, evidence remains limited for any component being more strongly associated with a specific respiratory effect compared to $PM_{2.5}$ mass. Additionally, due to generally high component correlations with $PM_{2.5}$ mass, it is uncertain whether the exposure estimates adequately represent exposure to the components rather than a marker for $PM_{2.5}$, which is more strongly associated with respiratory health effects across a large number of studies.

5.2.13 Summary and Causality Determination

The 2009 PM ISA (U.S. EPA, 2009) evaluated long-term $PM_{2.5}$ exposure and respiratory effects and concluded that a causal relationship is likely to exist between long-term $PM_{2.5}$ exposure and respiratory effects (U.S. EPA, 2009).[58] This conclusion was based mainly on epidemiologic evidence demonstrating associations between long-term $PM_{2.5}$ exposure and changes in lung function or lung function growth rate in children. Correlations of $PM_{2.5}$ concentrations with concentrations of other air pollutants, and a limited number of studies that examined potential copollutant confounding, made the interpretation of epidemiologic results more challenging. However, the consistency of findings across different locations supported an independent effect of $PM_{2.5}$. Biological plausibility was provided by a single animal toxicological study involving pre- and -post-natal exposure to $PM_{2.5}$ CAPs which found impaired lung development. Recent studies enhance the evidence base. The evidence for the relationship between long-term exposure to $PM_{2.5}$ and respiratory effects is summarized in Table 5-28, using the framework for causality determinations described in the Preamble to the ISAs (U.S. EPA, 2015).

[58] As detailed in the Preface , risk estimates are for a 5 $\mu g/m^3$ increase in annual $PM_{2.5}$ concentrations unless otherwise noted.

Table 5-28 Summary of evidence for a likely to be causal relationship between long-term $PM_{2.5}$ exposure and respiratory effects.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{2.5}$ Concentrations Associated with Effects[c]
Lung function and development			
Consistent epidemiologic evidence from multiple, high quality studies at relevant $PM_{2.5}$ concentrations	Studies provide evidence of decrements in lung function growth and for decrements in attained lung function in children in multiple cohorts.	Children: Gauderman et al. (2015); Gehring et al. (2015a); Gauderman et al. (2004)	Children: CHS community mean concentration range: 6−28 µg/m^3 PIAMA Cohort: 16.4 µg/m^3
	Associations are also observed for $PM_{2.5}$-related acceleration of lung function decline in adults.	Adults: Rice et al. (2015a) Adam et al. (2015) Section 5.2.2	Adults: Framingham: 10.8 µg/m^3 ESCAPE Range: 9.5−17.8 µg/m^3
	Supporting evidence is provided by improvements in lung function growth associated with declining $PM_{2.5}$ concentrations.	Gauderman et al. (2015) Boogaard et al. (2013) Section 5.2.11	
Limited evaluation of confounding by copollutants	Potential copollutant confounding for lung function growth is examined in a limited number of studies, with some evidence that associations remain robust in models with gaseous pollutants. However, there is uncertainty regarding studies in Asia due to high annual $PM_{2.5}$ concentrations.	Hwang et al. (2015) Gehring et al. (2013) Wang et al. (2015b)	
Limited evidence from toxicological studies at relevant concentrations	Pre- and post-natal exposure to ambient levels of urban particles impaired mouse lung development.	Mauad et al. (2008)	17 µg/m^3
Biological plausibility	Evidence from an animal toxicological study provides biological plausibility for epidemiologic findings for lung function growth.	Section 5.2.1	

Table 5-28 (Continued): Summary of evidence for a likely to be causal relationship between long term $PM_{2.5}$ exposure and respiratory effects.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{2.5}$ Concentrations Associated with Effects[c]
Development of asthma			
Consistent epidemiologic evidence from multiple, high quality studies at relevant $PM_{2.5}$ concentrations	Longitudinal studies provide evidence of associations with asthma incidence in children.	Carlsten et al. (2011) Tétreault et al. (2016a) Gehring et al. (2015b) Section 5.2.3.1	5.2−16.5 µg/m^3
	Supporting evidence is provided by studies of asthma prevalence in children and by studies of childhood wheeze.	Chiu et al. (2014) Section 5.2.3.1	11.2 µg/m^3
Limited evaluation of confounding by copollutants	Potential copollutant confounding for asthma incidence in children is examined in a single study, with limited evidence that associations remain robust in models with NO_2.	MacIntyre et al. (2014a)	
Coherence in epidemiologic studies across the continuum of effects	Supporting evidence provided by associations with eNO, a marker of pulmonary inflammation.	Dales et al. (2008) Berhane et al. (2014)	
Limited evidence from toxicological studies at relevant concentrations	Results show the development of an allergic Th2 phenotype, increased bronchial obstruction, and collagen deposition in the lungs of DEP-exposed mice.	Kim et al. (2016a)	100 µg/m^3
Biological plausibility	Evidence from an animal toxicological study provides biological plausibility for epidemiologic findings for the development of asthma.	Section 5.2.3.3	
Respiratory effects in healthy populations			
Strong evidence from toxicological studies at relevant concentrations	Results show oxidative stress, inflammation, and morphologic changes in both the upper (nasal) and lower airways. Upregulation of the RAS was also found. Other results relevant to the development of asthma, allergic disease, and COPD and to impaired lung development are mentioned above.	Section 5.2.8	61−200 µg/m^3

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{2.5}$ Concentrations Associated with Effects[c]
Coherence of related effects across disciplines	Evidence from an animal toxicological study provides coherence with epidemiologic findings for the development of an allergic phenotype.	Kim et al. (2016a)	100 µg/m^3
	Exposure to DEP did not worsen the asthma phenotype.	Farraj et al. (2010)	2,000 µg/m^3
Other uncertainties	Studies of COPD development and severity of respiratory disease may not account for the potential effect of short-term exposures leading to these acute events.	Section 5.2.5 Section 5.2.7	

[a]Based on aspects considered in judgments of causality and weight of evidence in causal framework in Table I and Table II of the Preamble to the ISAs (U.S. EPA, 2015).

[b]Describes the key evidence and references, supporting or contradicting, contributing most heavily to causality determination and, where applicable, to uncertainties or inconsistencies. References to earlier sections indicate where full body of evidence is described.

[c]Describes the $PM_{2.5}$ concentrations with which the evidence is substantiated.

Multiple cohort studies measuring lung function development over time continue to support the relationship between long-term $PM_{2.5}$ exposure and decrements in lung function growth, providing evidence for a robust and consistent association across study locations, exposure assessment methods, and time periods (Section 5.2.2). The relationship between $PM_{2.5}$ and lung function development is further supported by a recent study that related declining $PM_{2.5}$ concentrations to improvements in pulmonary function growth. Epidemiologic studies also examined asthma development in children (Section 5.2.3). A few recent prospective cohort studies in children found generally positive associations, but several are imprecise (i.e., reporting wide confidence intervals). Supporting evidence is provided by studies of asthma prevalence in children, by studies of childhood wheeze, and by studies of eNO, a marker of pulmonary inflammation. A recent animal toxicological study showing the development of an allergic phenotype and an increase in a marker of airway responsiveness provides biological plausibility for allergic asthma. One epidemiologic study reports a copollutant model with NO_2, in which the $PM_{2.5}$ effect persisted. Other epidemiologic studies focusing on lung function in adults and report a $PM_{2.5}$-related acceleration of lung function decline in adults, while improvement was observed with declining $PM_{2.5}$ concentrations (Section 5.2.11). Declining $PM_{2.5}$ concentrations are also associated with an improvement in chronic bronchitis symptoms in children in a recent longitudinal study, strengthening evidence reported in the 2009 PM ISA for a relationship between increased chronic bronchitic symptoms and long-term $PM_{2.5}$ exposure (Section 5.2.11).

A common uncertainty across the epidemiologic studies is the lack of examination of copollutants to assess the potential for confounding. While there is some evidence that associations remain robust in models with gaseous pollutants, a number of studies examining copollutant confounding are conducted in Asia, and thus have limited generalizability due to high annual pollutant concentrations. Exposure measurement error is less likely for long-term $PM_{2.5}$ compared with shorter averaging times and other size fractions (Section 3.4.5). Animal toxicological studies continue to provide evidence that long-term exposure to $PM_{2.5}$ results in a variety of respiratory effects. Recent studies show pulmonary oxidative stress, inflammation, and morphologic changes in the upper (nasal) and lower airways. Other results show changes consistent with the development of allergy and asthma and impaired lung development, which are mentioned above. **Overall, the collective evidence is sufficient to conclude that a causal relationship is likely to exist between long-term $PM_{2.5}$ exposure and respiratory effects.**

5.3 Short-Term $PM_{10-2.5}$ Exposure and Respiratory Effects

The 2009 PM ISA (U.S. EPA, 2009) concluded that the relationship between short-term exposure to $PM_{10-2.5}$ and respiratory effects is "suggestive of a causal relationship" (U.S. EPA, 2009), based on a limited number of epidemiologic studies supporting associations with some respiratory effects and a limited number of experimental studies that provide biological plausibility.[59] Epidemiologic findings were consistent for hospital admissions and ED visits for respiratory infection and respiratory-related diseases, but not for COPD. Evidence that short-term $PM_{10-2.5}$ exposure exacerbates asthma was inconsistent in epidemiologic studies. In addition, these studies were characterized by overall uncertainty in the exposure assignment approach. Limited information was available regarding potential copollutant confounding across the array of respiratory effects examined. Controlled human exposure studies of short-term $PM_{10-2.5}$ exposure found no lung function decrements and inconsistent evidence for pulmonary inflammation in healthy individuals or human subjects with asthma. Animal toxicological studies were limited to those using noninhalation (e.g., intra-tracheal instillation) routes of $PM_{10-2.5}$ exposure.

Recent epidemiologic findings more consistently link $PM_{10-2.5}$ to asthma exacerbation, and a recent controlled human exposure study in individuals with asthma found pulmonary inflammation and other alterations of the immune system following short-term exposure to $PM_{10-2.5}$ CAPs (Section 5.3.2). Recent animal toxicological studies use noninhalation routes of $PM_{10-2.5}$ exposure and demonstrate enhanced allergic responses in models of allergic airway disease, which share phenotypic features with asthma in humans. Recent epidemiologic findings are more consistent than previous findings for COPD exacerbation (Section 5.3.3), consistent with previous findings for respiratory-related diseases (Section 5.3.5), and somewhat inconsistent with previous findings for respiratory infection (Section 5.3.4). Respiratory effects related to short-term $PM_{10-2.5}$ exposure in healthy people remain

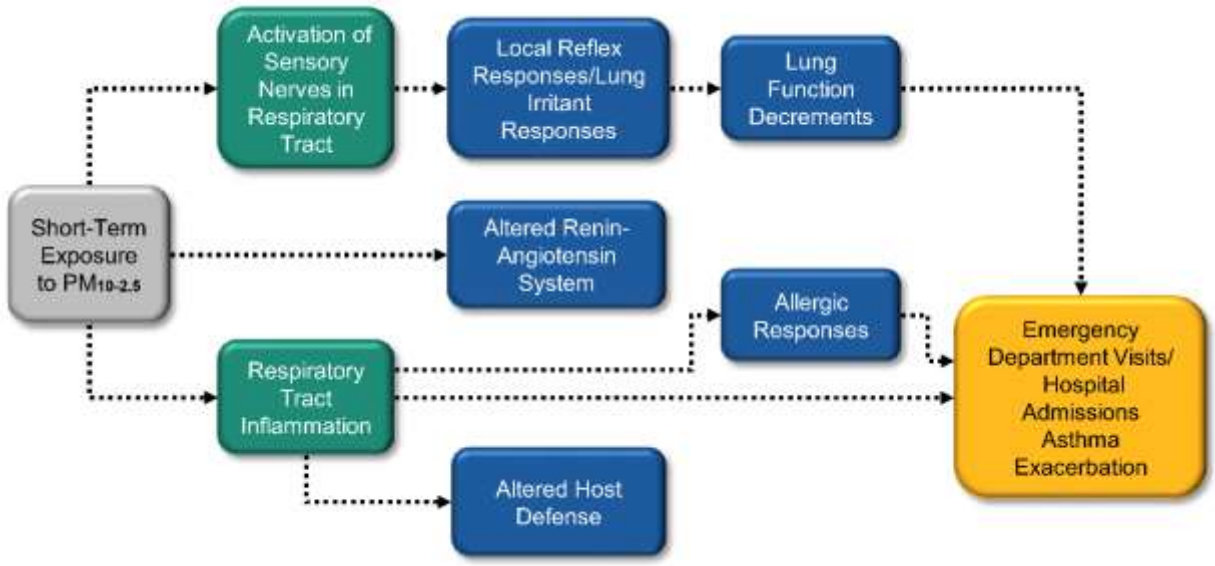
[59] As detailed in the Preface, risk estimates are for a 10 $\mu g/m^3$ increase in 24-hour average $PM_{10-2.5}$ concentrations unless otherwise noted.

uncertain (Section 5.3.6). Evidence from recent epidemiologic studies is inconsistent. A controlled human exposure study found no evidence for changes in lung function. In contrast, a few recent studies involving short-term inhalation exposure of rodents showed decreased lung function and increased pulmonary inflammation.

Previous epidemiologic studies using a single dichotomous $PM_{10-2.5}$ monitor or averaging across monitors to obtain an estimate for $PM_{10-2.5}$ concentration likely have more uncertainty in the exposure surrogate compared with $PM_{2.5}$, given spatiotemporal variability in ambient $PM_{10-2.5}$ concentrations (Section 3.3.1.1 and Section 3.4.2.2). Uncertainties were compounded for previous epidemiologic studies that estimate $PM_{10-2.5}$ concentration as the difference between PM_{10} concentration and $PM_{2.5}$ concentration from monitors that were not collocated. For asthma exacerbation, recent epidemiologic studies have improved exposure assessment with $PM_{10-2.5}$ measurements in subjects' microenvironments using personal samplers. However, across respiratory outcome groups, uncertainties remain regarding copollutant confounding.

5.3.1 Biological Plausibility

This section describes biological pathways that potentially underlie respiratory health effects resulting from short-term exposure to $PM_{10-2.5}$. Figure 5-39 graphically depicts the proposed pathways as a continuum of upstream events, connected by arrows, that may lead to downstream events observed in epidemiologic studies. This discussion of "how" short-term exposure to $PM_{10-2.5}$ may lead to respiratory health effects contributes to an understanding of the biological plausibility of epidemiologic results evaluated later in Section 5.3.



Note: The boxes above represent the effects for which there is experimental or epidemiologic evidence, and the dotted arrows indicate a proposed relationship between those effects. Progression of effects is depicted from left to right and color-coded (gray, exposure; green, initial event; blue, intermediate event; orange, apical event). Here, apical events generally reflect results of epidemiologic studies, which often observe effects at the population level. Epidemiologic evidence may also contribute to upstream boxes. When there are gaps in the evidence, there are complementary gaps in the figure and the accompanying text below.

Figure 5-39 Potential biological pathways for respiratory effects following short-term $PM_{10-2.5}$ exposure.

Once $PM_{10-2.5}$ deposits in the respiratory tract, it may be retained, cleared, or solubilized (see CHAPTER 4). Insoluble and soluble components of $PM_{10-2.5}$ may interact with cells in the respiratory tract, such as epithelial cells, inflammatory cells, and sensory nerve cells. One way in which this may occur is through reduction-oxidative (redox) reactions. As discussed in Section 2.3.3, PM may generate reactive oxygen species (ROS) and this capacity is termed "oxidative potential." Furthermore, cells in the respiratory tract may respond to the presence of PM by generating ROS. Further discussion of these redox reactions, which may contribute to oxidative stress, is found in Section 5.1.1 of the 2009 PM ISA (U.S. EPA, 2009). In addition, poorly soluble particles may translocate to the interstitial space beneath the respiratory epithelium and accumulate in the lymph nodes (see CHAPTER 4). Immune system responses due to the presence of particles in the interstitial space may contribute to respiratory health effects.

Evidence that short-term exposure to $PM_{10-2.5}$ may affect the respiratory tract generally informs two proposed pathways (Figure 5-39). The first pathway begins with injury, inflammation, and oxidative stress responses, which are difficult to disentangle. Inflammation generally occurs as a consequence of injury and oxidative stress, but it may also lead to further oxidative stress and injury due to secondary production of ROS by inflammatory cells. The second pathway begins with the activation of sensory

nerves in the respiratory tract that can trigger local reflex responses and transmit signals to regions of the central nervous system that regulate autonomic outflow.

Injury, Inflammation and Oxidative Stress

Experimental evidence that short-term exposure to $PM_{10–2.5}$ may affect the respiratory tract by inflammation-mediated pathways is provided by a limited number of inhalation studies. In healthy human subjects, some studies involving short-term exposure to $PM_{10–2.5}$ CAPs found inflammatory responses (Graff et al., 2009; Alexis et al., 2006), while others did not (Behbod et al., 2013; Jr et al., 2004). In human subjects with asthma, Alexis et al. (2014) found increased neutrophils in the BW, increased cytokines in BALF and BW, decreased expression of markers of innate immune and antigen presentation cell surface receptors, and increased expression of inflammatory cell surface receptors and the low-affinity IgE receptor. These changes indicate that alterations in innate host defense and allergic responses may occur. However, no increased markers of airway inflammation or changes in lung function were found by Jr et al. (2004) in humans with asthma. Variability in results of studies that involved short-term exposure to $PM_{10–2.5}$ CAPs may reflect differences in concentration and sources of $PM_{10–2.5}$ present in the airshed. Some epidemiologic studies linked short-term exposure to $PM_{10–2.5}$ to eNO, a marker of airway inflammation, in healthy individuals (Matt et al., 2016; Kubesch et al., 2015) and in children with asthma (Sarnat et al., 2012). Inflammatory and allergic responses in the context of asthma provide plausibility for epidemiologic findings of hospital admissions and ED visits for asthma (Section 5.3.2.1).

Two recent inhalation studies in rodents demonstrated inflammatory responses (Aztatzi-Aguilar et al., 2015; Amatullah et al., 2012). Increases in BALF total cells and macrophages and increased tissue IL-6 levels were observed following short-term exposure to $PM_{10–2.5}$ CAPs. Since rodents are obligatory nasal breathers (as opposed to humans who are oro-nasal breathers), deposition of inhaled $PM_{10–2.5}$ is expected to primarily occur in the extrathoracic airways (i.e., the nose) of rodents and to result in a much smaller fraction deposited in the lower respiratory tract compared with humans. Supportive evidence for respiratory tract effects is provided by animal toxicological studies involving noninhalation routes of exposure (i.e., oropharyngeal aspiration, intra-nasal instillation, subcutaneous injection). Pulmonary injury, oxidative stress, inflammation, and morphological changes were observed in healthy animals and in an animal model of cardiovascular disease (Section 5.3.6.3). In models of allergic airway disease, exposure to $PM_{10–2.5}$ by noninhalation routes enhanced allergic responses (Kurai et al., 2016; McGee et al., 2015; Kurai et al., 2014; He et al., 2012). The enhancement of allergic responses may underly exacerbation of asthma resulting from short-term exposure to $PM_{10–2.5}$ (Section 5.3.2).

Activation of Sensory Nerves

One of the recent inhalation studies in rodents involving short-term $PM_{10–2.5}$ CAPs exposure demonstrated changes in lung function (Amatullah et al., 2012). Baseline total respiratory resistance and

the maximum response to methacholine were increased and quasi-static compliance was decreased. The rapid nature of the lung function responses, which indicate airway obstruction, seen in the study by Amatullah et al. (2012) (i.e., immediately following the 4-hour exposure) indicates that activation of sensory nerves in the respiratory tract, possibly in the nasal airways, and the triggering of local reflex responses may have contributed to the effects of $PM_{10-2.5}$. Activation of sensory nerves in the respiratory tract can also transmit signals to regions of the central nervous system that regulate autonomic outflow and influence all the internal organs, including the heart. No changes in heart rate or heart rate variability were observed, indicating that altered autonomic outflow to the heart did not occur. Findings of lung function changes in this experimental study provide plausibility for epidemiologic findings related to asthma exacerbation.

Aztatzi-Aguilar et al. (2015) also found changes in components of the RAS. The RAS and the sympathetic nervous system, which is one arm of the ANS, are known to interact in a positive feedback fashion (Section 8.1.2) with important ramifications in the cardiovascular system. However, it is not known whether SNS activation or some other mechanism mediated the changes in the RAS observed in the respiratory tract in this study.

Summary

As described here, there are two proposed pathways by which short-term exposure to $PM_{10-2.5}$ may lead to respiratory health effects. One pathway involves respiratory tract inflammation and allergic responses, which are linked to asthma exacerbation. The second pathway involves the activation of sensory nerves in the respiratory tract leading to lung function decrements, which are also linked to asthma exacerbation. While experimental studies involving animals or human subjects contribute most of the evidence of upstream effects, epidemiologic studies found associations between short-term exposure to $PM_{10-2.5}$ and respiratory tract inflammation. Together, these proposed pathways provide biological plausibility for epidemiologic evidence of respiratory health effects and will be used to inform a causality determination, which is discussed later in the chapter (Section 5.3.8).

5.3.2 Asthma Exacerbation

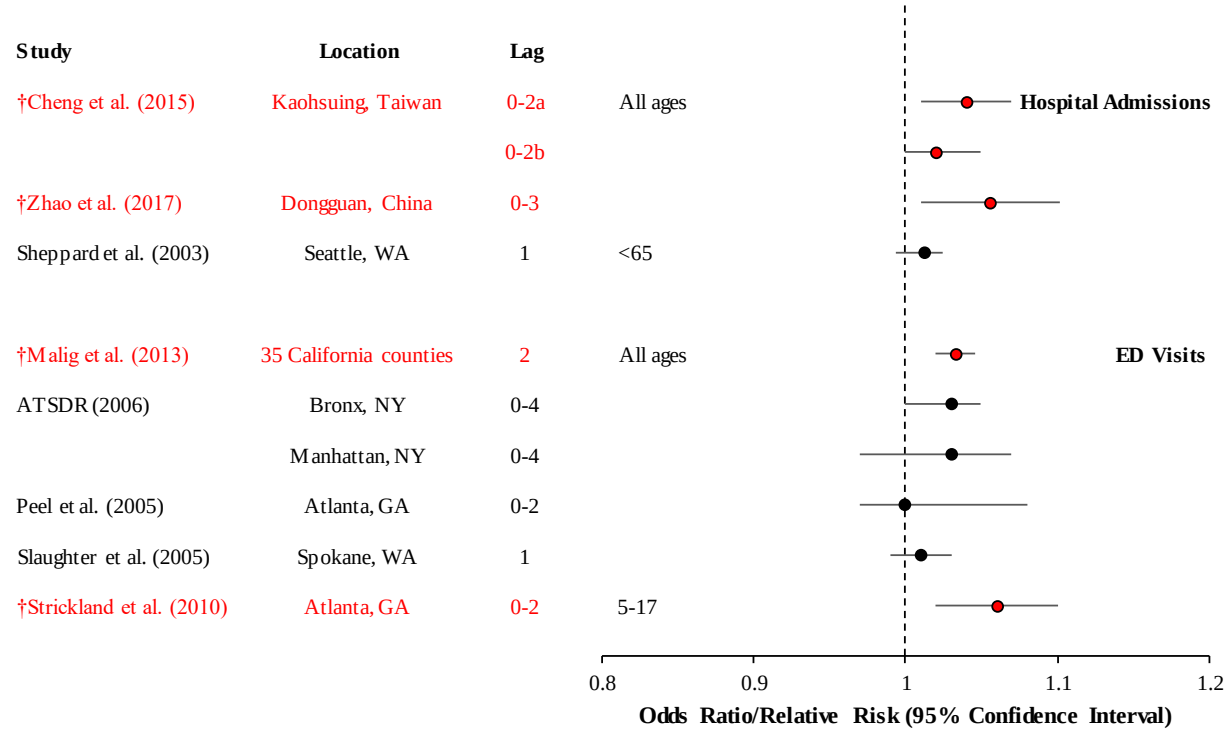
In the 2009 PM ISA (U.S. EPA, 2009), the evaluation of the relationship between short-term $PM_{10-2.5}$ exposure and asthma hospital admissions and ED visits was limited to single-city studies. These studies primarily focused on analyses of people of all ages, with a smaller number of studies examining associations in children and older adults. Across studies, there was inconsistent evidence of an association between short-term $PM_{10-2.5}$ exposure and asthma hospital admissions and between short-term $PM_{10-2.5}$ exposure and asthma ED visits, with some studies reporting evidence of a positive association while others did not. In addition, there was **limited epidemiologic evidence linking short-term $PM_{10-2.5}$ exposure and respiratory symptoms in children with asthma.** As detailed in Section 5.1.2, it is often

difficult to reliably diagnose asthma in children <5 years of age, potentially complicating the interpretation of results from studies that focus on $PM_{10-2.5}$ effects in children. **In the single controlled human exposure study which was evaluated, no evidence for decrements in pulmonary function or inflammation was found.**

5.3.2.1 Hospital Admissions and Emergency Department (ED) Visits

Recent epidemiologic studies continue to examine whether there is evidence of an association between short-term $PM_{10-2.5}$ exposure and asthma hospital admissions and ED visits, but the overall assessment remains limited to a small number of studies. Across studies, there is evidence of generally consistent, positive associations between $PM_{10-2.5}$ and asthma hospital admissions and between short-term $PM_{10-2.5}$ exposure and asthma ED visits (Figure 5-40). The results from asthma hospital admission and ED visit studies in children are supported by a study focusing on asthma physician visits in Atlanta, for the initial time period of the study, but this pattern of associations was not observed for the later time period at lag 3−5 days (Sinclair et al., 2010). However, as mentioned in Section 5.1.2.1, insurance type may dictate whether an individual visits the doctor or a hospital, making it difficult to readily compare results between studies focusing on physician visits versus hospital admissions and ED visits.

Across $PM_{10-2.5}$ studies, a remaining uncertainty is the varying methods employed to measure ambient $PM_{10-2.5}$ concentrations (Section 2.5.1.2.3) and the subsequent impact on exposure measurement error (Section 3.3.1.1). Similar to previous hospital admission and ED visit sections, the focus of this section is on those studies that address uncertainties and limitations in the evidence as detailed in the 2009 PM ISA (U.S. EPA, 2009), such as potential copollutant confounding and model specification. For each of the studies evaluated in this section, Table 5-29 presents the air quality characteristics of each city, or across all cities, the exposure assignment approach used, and information on copollutants examined in each asthma hospital admission and ED visit study. Other recent studies of asthma hospital admissions and ED visits are not the focus of this evaluation because they did not address uncertainties and limitations in the evidence previously identified. Additionally, many of these studies were conducted in small single-cities, encompassed a short study duration, or had insufficient sample size. The full list of these studies can be found in HERO: https://hero.epa.gov/hero/particulate-matter.



Note: †Studies published since the 2009 PM ISA. Black text = U.S. and Canadian studies included in the 2009 ISA. a = results for temperatures <25°C; b = results for temperatures ≥25°C. Corresponding quantitative results are reported in Supplemental Material (U.S. EPA, 2018).

Figure 5-40 Summary of associations from studies of short-term $PM_{10-2.5}$ exposures and asthma hospital admissions and emergency department (ED) visits for a 10 μg/m^3 increase in 24-hour average $PM_{10-2.5}$ concentrations.

†Studies published since the 2009 PM ISA.

Recent studies that examine the association between short-term $PM_{10-2.5}$ exposure and asthma hospital admissions were conducted in Taiwan (Cheng et al., 2015) and China (Zhao et al., 2016). Cheng et al. (2015), in a study conducted in Kaohsiung, Taiwan, focused on whether the association between short-term $PM_{10-2.5}$ exposure and asthma hospital admissions varied if the mean temperature of each day was above or below 25°C. The authors reported positive associations similar in magnitude for both temperature ranges (≥25°C: RR = 1.02 [95% CI: 1.00, 1.05]; <25°C: RR = 1.04 [95% CI: 1.01, 1.07]). Zhao et al. (2016), in a study conducted in Dongguan, China, also reported evidence of a positive association with $PM_{10-2.5}$ that was similar in magnitude (5.5% [95% CI: 1.0, 10.2]; lag 0−3). Both Cheng et al. (2015) and Zhao et al. (2016) examined potential copollutant confounding with gaseous pollutants (i.e., NO_2, SO_2, O_3, and CO). In both studies, moderate (r, >0.4 and <0.8) to low correlations (r < 0.4) were reported between $PM_{10-2.5}$ and all pollutants (Table 5-29). In Cheng et al. (2015), the results from copollutant analysis were similar to those reported in the single-pollutant analyses (≥25°C: Single-pollutant, RR = 1.02, copollutant, RR = 1.01 to 1.02; <25°C: Single-pollutant, RR = 1.04, copollutant RR = 1.02 to 1.04). Zhao et al. (2016) also reported that results remained relatively unchanged in copollutant models with SO_2 and O_3, but the association with NO_2 was attenuated and uncertain (1.8% [95% CI: −2.9, 6.8]).

A limited number of epidemiologic studies evaluated in the 2009 PM ISA (U.S. EPA, 2009) examined asthma ED visits and short-term exposure to $PM_{10-2.5}$, and were limited to single-city studies. Recent studies of ED visits consist of studies conducted in the U.S. that collectively provide evidence of a positive association between asthma ED visits and $PM_{10-2.5}$. Malig et al. (2013), in a study of 35 California counties, observed positive associations across single-day lags ranging from 0 to 2 days, with the strongest association in terms of magnitude and precision at lag 2 (3.3% [95% CI: 2.0, 4.6]) in an analysis of people of all ages. This result was found to persist when excluding extreme (i.e., highest 5%) $PM_{10-2.5}$ concentrations. Additionally, Malig et al. (2013) provided some evidence that the association between asthma ED visits and $PM_{10-2.5}$ is larger in magnitude in the warm months (quantitative results not presented). The all-year results of Malig et al. (2013) are supported by Strickland et al. (2010) in a study conducted in Atlanta, GA that focused on pediatric asthma ED visits where the authors reported a RR = 1.06 (95% CI: 1.02, 1.1) for a 0−2-day lag. However, when examining seasonal associations, the authors reported evidence that contradicts Malig et al. (2013), with associations being larger in magnitude in the cold months (RR = 1.07 [95% CI: 1.02, 1.13]) compared to the warm months (RR = 1.04 [95% CI: 0.99, 1.10]). Of the ED visit studies only, Malig et al. (2013) examined potential copollutant confounding with $PM_{2.5}$ and reported that results were robust to the inclusion of $PM_{2.5}$ in the model (3.0% [95% CI: 1.8, 4.2], lag 2).

Across both asthma hospital admissions and ED visits studies there was a rather limited assessment of the influence of model specification on the relationship with $PM_{10-2.5}$, as well as the lag structure of associations. Zhao et al. (2016) examined whether varying the degrees of freedom (df) per year to account for temporal trends and increasing the df for the temperature covariate impacted the

association between $PM_{10–2.5}$ and asthma hospital admission. In both cases, the authors reported results consistent with those observed in the main model (quantitative results not presented). Strickland et al. (2010) took a different approach to examining model misspecification by examining associations with asthma ED visits 1 day after the visit (lag −1 day), which can provide evidence of residual confounding. In an analysis limited to the warm season, the authors did not observe any evidence of potential residual confounding (RR = 1.01 [95% CI: 0.97, 1.04]). Overall, the limited association of model specification provides initial evidence indicating that models adequately account for temporal trends and the confounding effects of weather.

5.3.2.1.1 Concentration-Response Relationship

To date, very few studies have conducted analyses to examine the C-R relationship between short-term $PM_{10–2.5}$ exposure and respiratory-related hospital admissions and ED visits, including asthma. Recent studies provide a limited analysis of the C-R relationship and are limited to examining linearity without conducting a systematic evaluation of potential alternatives to linearity (Zhao et al., 2016; Malig et al., 2013), along with quintile analyses used to examine whether there is evidence that the risk of asthma ED visits changes at different $PM_{10–2.5}$ concentrations (Strickland et al., 2010).

Malig et al. (2013) examined the C-R relationship between short-term $PM_{10–2.5}$ and asthma ED visits in 35 California counties by focusing on model fit and whether replacing a linear term in the model with a squared term for $PM_{10–2.5}$ improved model fit. The authors reported no evidence of an improvement in model fit when allowing for the potential of nonlinearity in the $PM_{10–2.5}$-asthma ED visits relationship. The results of Malig et al. (2013) are consistent with Zhao et al. (2016) in a study conducted in Dongguan, China where there was evidence of a linear relationship when including a natural spline along the range of $PM_{10–2.5}$ concentrations where the data density is the highest (Figure 5-41).

Instead of examining the shape of the C-R curve, Strickland et al. (2010) conducted a quintile analysis to examine whether the association between $PM_{10–2.5}$ and asthma ED visits changed at different concentrations. For the warm season, the authors did not observe any evidence of an association when comparing each quintile to the referent (i.e., quintile 1). However, when examining the cold season, Strickland et al. (2010) reported evidence that the risk of an asthma ED visit increased as $PM_{10–2.5}$ concentrations increased, with the strongest associations observed for the 4th (RR = 1.05 [95% CI: 0.99, 1.10]) and 5th (RR = 1.08 [95% CI: 1.02, 1.14]) quintiles.

Figure 5-41 Concentration-response relationship between short-term $PM_{10-2.5}$ exposure and asthma emergency department (ED) visits at lag 2 for a natural spline model with three degrees of freedom (df) for Dongguan, China.

5.3.2.2 Respiratory Symptoms and Medication Use

As discussed in Section 5.1.2.2, uncontrollable respiratory symptoms can lead people with asthma to seek medical care. Thus, studies examining the relation between $PM_{10-2.5}$ and increases in asthma symptoms may provide support for the observed increases in asthma hospital admissions and ED visits in children, as discussed in Section 5.3.2.1. A single U.S. study evaluated in the 2009 PM ISA (U.S. EPA, 2009) examined respiratory symptoms in people with asthma. Mar et al. (2004) reported $PM_{10-2.5}$-related increases across a number of self-reported symptoms in children, including wheeze, shortness of breath, cough, increased sputum, and runny nose. The authors did not observe associations in healthy adults.

Evidence from a limited number of recent panel studies further supports an association between $PM_{10-2.5}$ and respiratory symptoms in asthmatic children. Wheeze was associated with $PM_{10-2.5}$ in a panel study of children in Fresno, CA (Mann et al., 2010). The reported association was observed with 3-day lag $PM_{10-2.5}$ concentrations from a single monitor (OR: 1.07 [95% CI: 1.01, 1.14]), but the authors noted that the association was relatively stable across lags. Associations are also supported with $PM_{10-2.5}$ measured on the rooftops of two schools in El Paso, TX (Zora et al., 2013). 4-day average $PM_{10-2.5}$ concentrations measured outside of the schools were associated with poorer asthma control scores, which reflect symptoms and activity levels. The two schools included in the study differed in nearby traffic levels but varied similarly in outdoor $PM_{2.5}$ concentration over time (Section 3.4.3.1). Prieto-Parra et al. (2017) also observed associations between 7-day average coarse PM and cough and wheeze in Santiago,

Chile. Notably, the authors reported that $PM_{10–2.5}$ was associated with decreased bronchodilator use (Prieto-Parra et al., 2017).

5.3.2.3 Lung Function

There were no epidemiologic studies evaluated in the 2009 PM ISA (U.S. EPA, 2009) that examined the association between $PM_{10–2.5}$ and lung function in populations with asthma. One recent study observed a decrease in FEV_1 in children associated with 4-day average $PM_{10–2.5}$ concentrations measured outside of two El Paso schools (Greenwald et al., 2013).

A single controlled human exposure study evaluated in the 2009 PM ISA (U.S. EPA, 2009) examined the effects of short-term exposure to $PM_{10–2.5}$ on lung function. Jr et al. (2004) did not observe significant decrements in pulmonary function in human subjects with asthma exposed to $PM_{10–2.5}$. Recently, Alexis et al. (2014) conducted a proof-of-concept study to confirm the assumption that $PM_{10–2.5}$, like other pollutants, can initiate deleterious responses in individuals with asthma at concentrations not observed in healthy individuals. This assumption is based on people with asthma having elevated levels of pre-existing inflammation and altered innate immune function compared to healthy individuals, which may enhance their susceptibility to $PM_{2.5–10}$-induced health effects. Alexis et al. (2014) exposed individuals with mild asthma for 2 hours to either $PM_{10–2.5}$ CAPs or filtered air collected from ambient air in Chapel Hill, NC (see Table 5-30 for study details). No measure of lung function (i.e., FEV_1 and FVC) was affected in $PM_{10–2.5}$-exposed subjects.

Table 5-30 Study-specific details from a controlled human exposure study of short-term $PM_{10-2.5}$ exposure and lung function in populations with asthma.

Study	Study Design	Disease Status; n; Sex; (Age)	Exposure Details (Concentration; Duration; Comparison Group)	Endpoints Measured
Alexis et al. (2014)	Single-blind cross-over	Mild to moderate individuals with asthma; n = 10; sex not stated (18−45 yr)	86.9 ± 17.4 µg/m^3 $PM_{10-2.5}$ for 2 hr with intermittent exercise (15 min of rest followed by 15 min of exercise on recumbent bicycle). Comparison group was clean air; a wash-out period of at least 4 weeks was used between exposures.	BAL and BW (24-hr post-exposure): Differential leukocyte counts, IL-6, IL-8, IL-1β, TNF-α, flow-cytometry to identify cell surface phenotypes Spirometry (24-hour post-exposure): FEV_1, FVC

BAL = bronchoalveolar lavage; BW = bronchial wash; FEV1 = forced expiratory volume in 1 second; FVC = forced vital capacity; IL-6 = interleukin 6; IL-8 = interleukin 8; IL-1β = interleukin 1β; TNFα = tumor necrosis factor α.

5.3.2.4 Subclinical Effects Underlying Asthma Exacerbation

5.3.2.4.1 Epidemiologic Studies

No epidemiologic studies evaluated in the 2009 PM ISA (U.S. EPA, 2009) examined the association between short-term exposure to $PM_{10-2.5}$ and subclinical respiratory effects in populations with asthma. Recent panel studies of schoolchildren in El Paso provide inconsistent evidence of an association between $PM_{10-2.5}$ and eNO, an indicator of pulmonary inflammation. Among children at four schools in the neighboring cities of El Paso, TX and Ciudad Juarez, Mexico, eNO was associated with 48-hour average outdoor $PM_{10-2.5}$ (Sarnat et al., 2012). While Sarnat et al. (2012) reported an association between 2-day average outdoor $PM_{10-2.5}$ concentrations and eNO in El Paso, a follow-up study of children in the same schools in El Paso observed a null association with 4-day average outdoor $PM_{10-2.5}$ concentrations (Greenwald et al., 2013). The associations observed by Sarnat et al. (2012) appear to have been driven largely by results from children in one school (Ciudad Juarez) with the highest mean $PM_{10-2.5}$ concentrations.

5.3.2.4.2 Controlled Human Exposure Studies

A single study evaluated in the 2009 PM ISA (U.S. EPA, 2009) investigated whether short-term exposure to $PM_{10–2.5}$ was associated with subclinical outcomes in individuals with asthma. Jr et al. (2004) did not observe changes in lung function or markers of airway inflammation in individuals with asthma who were exposed to $PM_{10–2.5}$. Recently, Alexis et al. (2014) exposed individuals with mild asthma for 2 hours to either $PM_{10–2.5}$ CAPs or filtered air collected from ambient air in Chapel Hill, NC. Differential leukocyte numbers and cell surface markers on recovered leukocytes were examined (see Table 5-31 for study details). The authors reported an increase in BW polymorphonuclear neutrophil concentration (8 vs. 13%, $p < 0.05$) and that this effect was different from effects observed when healthy subjects were exposed to a similar concentration of course PM (Graff et al., 2009). Levels of IL-1β and IL-8 were also elevated in both BW and bronchoalveolar lavage (BAL) samples ($p < 0.05$). Short-term exposure to $PM_{10–2.5}$ CAPs also induced decreased expression of innate immune (CD11b/CR3, CD64/FcγRI) and antigen presentation (CD40, CD86/B7.2) cell surface receptors, and increased expression of inflammatory cell surface receptors (CD16/FcγRIII) and the low-affinity IgE receptor (CD23). The up-regulation of the CD23/IgE receptor reported by Alexis et al. (2014) suggests an asthma-specific pathway induced by $PM_{10–2.5}$, a pathway not typically observed with other xenobiotics, such as O_3 or endotoxin. In summary, the observations reported by Alexis et al. (2014), namely that significant $PM_{10–2.5}$ CAPs-induced pulmonary inflammation, altered innate host defense response, and potentially enhanced IgE signaling, supports the hypothesis that individuals with asthma have greater sensitivity to the inflammatory and immune modifying effects of short-term $PM_{10–2.5}$ CAPs exposure. Furthermore, short-term $PM_{10–2.5}$ CAPs exposure may increase the airway responsiveness of individuals with allergic asthma to inhaled allergens and thereby enhancing the overall risk of asthma exacerbation.

Table 5-31 Study-specific details from a controlled human exposure study of short-term $PM_{10-2.5}$ exposure and subclinical effects underlying asthma.

Study	Study Design	Disease Status; n; Sex; (Age)	Exposure Details (Concentration; Duration; Comparison Group)	Endpoints Measured
Alexis et al. (2014)	Single-blind cross-over	Individuals with mild to moderate asthma; n = 10; sex not stated (18−45 yr)	86.9 ± 17.4 ug/m^3 $PM_{10-2.5}$ for 2 hr with intermittent exercise (15 min of rest followed by 15 min of exercise on recumbent bicycle). Comparison group was clean air; a wash-out period of at least 4 weeks was used between exposures	BAL and BW (24-hr post-exposure): Differential leukocyte counts, IL-6, IL-8, IL-1β, TNF-α, flow-cytometry to identify cell surface phenotypes Spirometry (24-hr post-exposure): FEV_1, FVC

BAL = bronchoalveolar lavage; BW = bronchial wash; FEV_1 = forced expiratory volume in 1 second; FVC = forced vital capacity; IL-6 = interleukin 6; IL-8 = interleukin 8; IL-1β = interleukin 1β; TNFα = tumor necrosis factor α.

5.3.2.4.3 Animal Toxicological Studies

There were no studies evaluated in the 2009 PM ISA (U.S. EPA, 2009) that investigated the effects of short-term exposure to $PM_{10-2.5}$ in animal models of allergic airway disease, which share phenotypic features with asthma (see Section 5.1.2.4). Inhalation exposure of rodents to $PM_{10-2.5}$ is technically difficult since rodents are obligatory nasal breathers. A group of recent studies involving noninhalation routes of exposure (i.e., oropharyngeal aspiration, intra-nasal instillation, subcutaneous injection) provide biological plausibility for a role of $PM_{10-2.5}$ in enhancing allergic responses (Kurai et al., 2016; McGee et al., 2015; Kurai et al., 2014; He et al., 2012; Alberg et al., 2009).

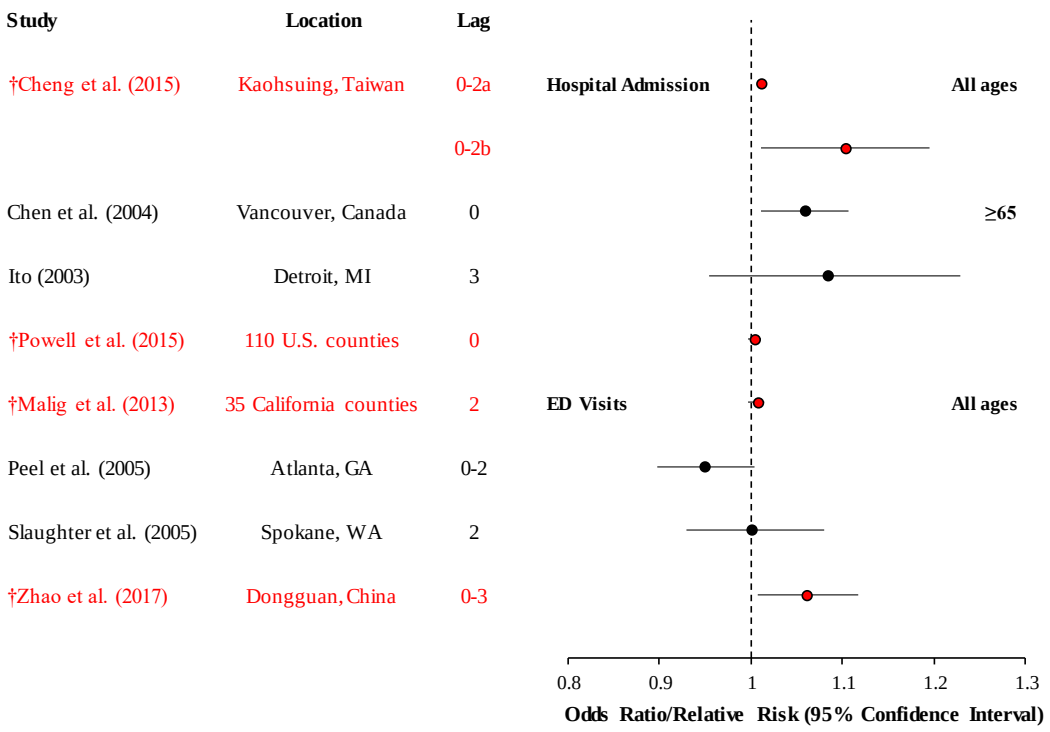
5.3.2.5 Summary of Asthma Exacerbation

Recent epidemiologic findings more consistently link $PM_{10-2.5}$ to asthma exacerbation than studies reported in the 2009 PM ISA. Studies of asthma hospital admission and ED visits include children older than 5 years. These findings are supported by epidemiologic studies observing respiratory symptoms in children, but coherence does not clearly extend to other asthma-related effects since associations were not observed between short-term $PM_{10-2.5}$ exposure and lung function and epidemiologic evidence for pulmonary inflammation was inconsistent. There is limited evidence that

associations remain robust in models with gaseous pollutants and $PM_{2.5}$. An uncertainty related to $PM_{10-2.5}$ measurements is how adequately the spatiotemporal variability is represented given that measurements are mainly based on subtraction of $PM_{2.5}$ from PM_{10} at different locations. Evidence for an independent effect of short-term $PM_{10-2.5}$ exposure was provided by a controlled human exposure study showing effects on inflammation and the immune system.

5.3.3 Chronic Obstructive Pulmonary Disease (COPD) Exacerbation

Among the few epidemiologic studies available for the 2009 PM ISA (U.S. EPA, 2009), short-term exposure to $PM_{10-2.5}$ were inconsistently associated with hospital admissions for COPD and lung function changes in adults with COPD. Recent studies are relatively limited in number but improve on previous studies with residential exposure assessment, additional outcomes, and analysis of potential copollutant confounding (Figure 5-42 and Table 5-32). Recent studies show associations of $PM_{10-2.5}$ with COPD hospital admissions, ED visits, respiratory symptoms, and pulmonary inflammation. However, the evidence overall is inconsistent across several U.S. and Canadian cities, for older adults, and for direct $PM_{10-2.5}$ measurements.



Note: †Studies published since the 2009 PM ISA. Black text = U.S. and Canadian studies included in the 2009 PM ISA. Corresponding quantitative results are reported in Supplemental Material (U.S. EPA, 2018).

Figure 5-42 Summary of associations between short-term $PM_{10-2.5}$ exposures and chronic obstructive pulmonary disease (COPD) hospital admissions and emergency department (ED) visits for a 10 μg/m^3 increase in 24-hour average $PM_{10-2.5}$ concentrations.

Table 5-32 (Continued): Epidemiologic studies of $PM_{10-2.5}$ and exacerbation of chronic obstructive pulmonary disease.

Study	Exposure Assessment	Outcome Assessment	Mean (SD) Concentration ($\mu g/m^3$)[a]	Upper Percentile Concentrations ($\mu g/m^3$)[a]	$PM_{10-2.5}$ Copollutant Model Results and Correlations
†Zhao et al. (2016) Dongguan, China 2013−2015	Difference of collocated PM_{10} and $PM_{2.5}$ concentration, averaged over five monitoring sites.	Hospital clinic visits All ages	18.6 (9.2)	75th: 22.6 Max: 96.4	Correlation (r) = 0.42 O_3, 0.58 SO_2, 0.60 NO_2 Copollutant models examined: O_3, SO_2. NO_2
†Cheng et al. (2015) Kaohsiung, Taiwan 2006−2010	Difference of PM_{10} (β ray absorption) and $PM_{2.5}$ (TEOM) concentrations collocated, averaged across six monitoring sites.	Hospital admissions All ages	Median (IQR) 24.8 (24.4)	75th: 30.8 Max: 490	Correlation (r) = 0.64 $PM_{2.5}$, 0.89 PM_{10}, 0.24 O_3, 0.53 NO_2, 0.47 CO, 0.19 SO_2 Copollutant models examined: O_3, NO_2, CO, or SO_2
Slaughter et al. (2005) Spokane, WA 1995−1999	$PM_{10-2.5}$ concentration estimated by calculating difference between PM_{10} and $PM_{2.5}$ at collocated monitors at one site.	ED visits All ages	NR	NR	Correlation (r) = 0.31 $PM_{2.5}$, 0.94 PM_{10} No copollutant model
†Powell et al. (2015) 110 U.S. counties 1999−2010	Difference of PM_{10} and $PM_{2.5}$ concentrations collocated at one monitoring site for each county.	Hospital admissions Older adults ≥65 yr	Median (IQR) 12.78 (3.06)	75th: 15.84	No copollutants examined

CO = carbon monoxide, ED = emergency department, IQR = interquartile range, max = maximum, NO_2 = nitrogen dioxide, NR = not reported, O_3 = ozone, $PM_{10-2.5}$ = particulate matter with a nominal mean aerodynamic diameter ≤10 µm and >2.5 µm, $PM_{2.5}$ = particulate matter with a nominal mean aerodynamic diameter ≤2.5 µm, PM_{10} = particulate matter with a nominal mean aerodynamic diameter ≤10 µm, r = correlation coefficient, SD = standard deviation, SO_2 = sulfur dioxide.

[a]All data are for 24-h average.

†Studies published since the 2009 PM ISA.

5.3.3.1 Hospital Admissions and Emergency Department (ED) Visits

The body of literature reviewed in the 2009 PM ISA (U.S. EPA, 2009) that examined the association between short-term $PM_{10-2.5}$ exposure and hospital admissions for COPD was small and consisted of single-city studies conducted in the U.S. and Canada. Across studies, there was inconsistent evidence of an association, with the strongest evidence for hospital admissions in adults over the age of 65 years. An initial assessment of the potential confounding effects of copollutants provided some evidence that COPD associations may be attenuated in models with NO_2. Similarly, an international single-city study reported an association between ED visits for COPD and asthma combined and $PM_{10-2.5}$, but the positive association was attenuated after adjustment for $PM_{2.5}$, NO_2 and CO. Similar to the 2009 PM ISA, the evidence base remains limited when examining the association between short-term $PM_{10-2.5}$ exposure and hospital admissions for COPD, but provides some additional evidence for a positive association (see Figure 5-42).

5.3.3.1.1 Hospital Admissions
