## Table of contents

### CHAPTER 1

Introduction and Background	1
-----------------------------	---

### CHAPTER 2

Subjects and Methods	5
2.1.1 Study population	5
2.1.2 Vital status ascertainment and mortality data	7
2.2 Radiation data	9
2.2.1 Measurement of external exposure to gamma or x-rays	9
2.2.2 Measurement of internal exposure to alpha- and beta-emitting radionuclides	11
2.3.1 Exposure definition	17
2.3.2 Outcome definition	18
2.4 Statistical methods	20
2.4.1 External comparisons	20
2.4.2 Internal comparisons	21
2.5 Confounding factors	24

## **CHAPTER 3**

<b>Results</b>	<b>28</b>
3.1 External comparisons	
3.1.1 External comparisons for HPRMP members monitored for external radiation exposure	28
3.1.2 External comparisons for HPRMP members monitored for internal radiation exposure	29
3.2. Internal comparisons	
3.2.1 Internal comparisons for HPRMP members monitored for external radiation exposure	30
3.2.2 Internal comparisons for HPRMP members monitored for internal radiation exposure	32

## **CHAPTER 4**

<b>Discussion</b>	<b>35</b>
4.1 External radiation exposure	39
4.2 Internal radiation exposure	42
4.3 Issues of confounding and effect modification	45

<b>TABLES</b>	<b>49</b>

## LIST OF TABLES

### CHAPTER 1

1. 1	Cancer mortality among A-bomb survivors	49
1.2.a	Results from epidemiologic cohort studies of low-level radiation	50
1.2.b	Results from epidemiologic cohort studies of low-level radiation	55
1.3	Results from case-control studies of low-level radiation	58
1.4	Standardized risk ratios for external radiation exposure for employees of the Oak Ridge National Laboratory	59

### CHAPTER 2

2.1.a	Description of the study population with external radiation monitoring	60
2.1.b	Characterstics of 4518 HPRMP members	61
2.2.a	Description of the study population with internal radiation monitoring	62
2.2.b	Characterstics of 2294 HPRMP members	63
2.3	Tobacco smoking prevalence by external radiation exposure level (1961-1969)	64
2.4	Tobacco smoking prevalence by salary type (1961-1969)	65
2.5	Tobacco smoking prevalence by external radiation exposure level (1980-1982)	66
2.6	Tobacco smoking prevalence by salary type (1980-1982)	67
2.5	Tobacco smoking prevalence by external radiation exposure level (1983-1994)	68
2.6	Tobacco smoking prevalence by salary type (1983-1994)	69

### CHAPTER 3

3.1	SMRs for externally monitored white male HPRMP members; comparisons with the US population and all NIOSH cohorts	70
3.2	SMRs for externally monitored white male HPRMP members; comparisons with NIOSH cohorts by salary type	72
3.3	SMRs for externally monitored white female HPRMP members; comparisons with the US population and all NIOSH cohorts	74
3.4	SMRs for internally monitored white male HPRMP members; comparisons with the US population and all NIOSH cohorts	75
3.5	SMRs for internally monitored white male HPRMP members; comparisons with NIOSH cohorts by salary type	77
3.6	SMRs for internally monitored white female HPRMP members; comparisons with the US population and all NIOSH cohorts	79
3.7	Externally monitored HPRMP members, all deaths, and cancer deaths by levels of exposure and exposure lag	80
3.8.a	Rate ratio estimates for external radiation exposure (zero lag)	81
3.8.b	Rate ratio estimates for external radiation exposure (15 year lag)	82
3.9	Rate ratio estimates for external radiation exposure (continuous exposure variable)	83
3.10	Rate ratio estimates for three external-radiation exposure age intervals	84
3.11	Internally monitored HPRMP members, all deaths, and cancer deaths by levels of exposure and exposure lag	85

3.12.a	Rate ratio estimates for internal radiation exposure (zero lag)	86
3.12.b	Rate ratio estimates for internal radiation exposure (15 year lag)	87
3.13.a	Rate ratio estimates for combined effect of internal and external radiation exposure (zero lag)	88
3.13.b	Rate ratio estimates for combined effect of internal and external radiation exposure (15 year lag)	89
<b>CHAPTER 4</b>		
4.1.	Distribution of external radiation exposure in US and Canadian radiation worker cohorts	90
4.2.	Distribution of external radiation exposure in British radiation worker cohorts	91
<b>APPENDIX</b>		
5.1	Number of HPRMP members monitored for external radiation exposure by calender time and age	92
5.2	Number of cancer cases by calender time and age	93
5.3	Person-time for HPRMP members monitored for external radiation exposure by calender time and age	94
5.4	Average cumulative external radiation exposure (in mSv) by calender time and age	95
5.5	Average non-cumulative external radiation exposure (in mSv) by calender time and age	96

5.6	Average cumulative internal radiation exposure (in mSv) by calender time and age	97
5.7	Average non-cumulative internal radiation exposure (in mSv) by calender time and age	98

## ACKNOWLEDGEMENTS

This dissertation is part of the study "Epidemiologic study to determine possible adverse health effects on Rockwell/Rocketdyne workers from exposure to toxic substances and radiation" (Principal Investigator: Hal Morgenstern, Ph.D.). I thank Hal Morgenstern for advising and supporting this work; Sander Greenland for providing programs and analytical as well as moral support; and Douglas Crawford-Brown for making sense out of the internal radiation monitoring data. I am grateful to Barbara Visscher for being available last minute and to Rodney Withers for critical discussion of some of the issues involved.

I like to thank Bambi Youngs for finding the time for many hours of editing and for all her helpful comments. And I am indebted to numerous graduate students who supervised the data entry, managed the data flow and helped the project along in many ways; especially Yan Wang, Fei Yu, Roberta McKean, Nicole Alexopolous, and Carol Yasutomi.

This degree was supported by a fellowship from the DAAD ("German Academic Exchange Fund") and by several years of tuition fellowships from the Department of Epidemiology at UCLA.

## VITA

March 26, 1959	Born, Eschwege, Germany
1983	Medical Examination, Board of Health, Hamburg, registration as physician (M.D.)
1984	Research Fellow at the Institute of Medical-Sociology/University of Hamburg
1987 Sociology	Doctoral degree in Medical- from the University of Hamburg
1987-1988	Research Fellow and Resident at the Psychiatric University-Hospital Eppendorf, Hamburg
1989	Assistant Professor in Medical Sociology at the University of Hamburg
1989-1993	Recipient of a DAAD ("German Academic Exchange Fund") fellowship
1993	M.P.H. from the School of Public Health, UCLA
1993-1995	Assistant Researcher at the Department of Epidemiology, School of Public Health, UCLA

ABSTRACT OF THE DISSERTATION

Cancer mortality of Rockwell workers  
exposed to external low-level  
ionizing radiation and internally-deposited radionuclides

by

Beate Reinilde Ritz

Doctor of Philosophy in Epidemiology  
University of California, Los Angeles, 1995  
Professor Hal Morgenstern, Chair

We conducted a historical cohort study examining cancer mortality of employees of Rockwell/Atomics International. All cohort members were assigned to the company's health physics radiation monitoring program and monitored for external-ionizing radiation exposure and/or for internal radiation exposure due to radionuclides (4518 and 2294 workers respectively) between 1950 and 1993. About 95% of these workers were male. Please note that the following results are preliminary because the mortality follow-up of the cohort was incomplete when the analyses for this dissertation were conducted (about 10% of all causes of deaths were unknown). External comparisons suggested an increased cancer mortality

from leukemia for male Rockwell employees compared to the male US population (SMR=1.62, 95%CI=0.94-2.60). An external comparison of male Rockwell employees with male National Institute of Occupational Safety and Health (NIOSH) cohort members by salary type showed an increased mortality for Rockwell managerial and technical employees from cancers of the esophagus (SMR=3.61 95%CI= 0.97, 9.23) and the stomach (SMR=3.26 95%CI= 1.05, 7.60), the respiratory system and lung (SMR=1.87 95%CI= 1.35, 2.53), the bladder (SMR= 9.53 95%CI= 1.92, 27.8), the brain (SMR= 4.59 95%CI= 1.68, 9.99), leukemias (SMR=4.95 95%CI= 2.37, 9.10), and all hemato- and lymphopietic cancers (SMR=2.32 95%CI= 1.35, 3.71). We employed logistic regression models for cohort data matching non-cases to cases by time of case occurrence and conducted dose-response analyses for radiation exposures. We found increases in mortality with increasing external-radiation dose for total cancers, hemato- and lymphopietic cancers and solid tumors of radiosensitive organs. We also observed an increasing trend for hemato- and lymphopietic cancers with internal exposure to alpha-emitting radionuclides. Our data furthermore suggested a stronger effect of external radiation exposure for solid tumors after age 40. Our results are based on small numbers of exposed cases, but find effects for the same cancer sites as implicated previously in A-bomb survivor and nuclear cohorts studies. However, the size of the effect for external radiation exposure on total cancer mortality found in this study is about 10-fold greater than expected according to extrapolations from A-bomb survivor data.

## CHAPTER 1

### Introduction and Background

Please note that all of the following results are preliminary because the mortality follow-up of the cohort was incomplete when the analyses for this dissertation were conducted (about 10% of all causes of deaths were unknown).

Much controversy remains concerning the carcinogenic potential of chronic exposure to low-level ionizing radiation encountered in occupational settings. Studies of nuclear workers over the past 20 years have yielded conflicting findings (Stewart 1990). Among A-bomb survivors, single whole-body exposures of less than 200 mSv have not resulted in an increased cancer rate (Shimizu et al. 1990, see Table 1.1). Traditional radiobiologic theory suggests that the fractionated doses (doses spread over time) characteristic of occupational and diagnostic radiation exposures should be less harmful than the same amount of radiation concentrated in a single dose. Thus, fractionation is thought to give the tissue a chance to repair damages caused by the irradiation (BEIR V, 1990). On the other hand, the repeated repair of even minor but recurrent injuries to the cell-DNA could theoretically increase the likelihood for repair mechanisms to fail or miss.

Extrapolations from the A-bomb-survivor data to low-dose external radiation exposure based on a linear no-threshold model suggest an excess relative risk for all cancers of 0.41% (90%CI 0.32-0.52) per 10 mSv of external whole-body exposure. In contrast, the corresponding estimates derived from radiation-worker studies range from 0% to 4.94%, depending on assumptions about lag periods and the models used to estimate risk (Gribbin et al. 1993, Wing et al. 1993). Thus, the results obtained from some nuclear-worker cohort studies raise

the possibility that risk estimates for all cancers extrapolated from the A-bomb-survivor data might underestimate the carcinogenic effect of low-level radiation by as much as 10-fold. On the other hand, results from occupational studies are also consistent with the possibility of no effect at the levels and rates of exposure studied (see also Tables 1.2 - 1.4).

Internal radiation exposure is caused by deposition of radioactive particles in the human body after inhalation, ingestion, or entry through wounds. In animal experiments, high levels of internal exposure to alpha- and beta/gamma-emitting radionuclides have resulted in immuno-suppressive and carcinogenic effects to the organs in which these particles concentrate (ICRP, 1980). Recently, reduced DNA-repair response capabilities of cells have been found in long-term residents of communities 1.5 mile downwind from uranium mining facilities (Au et al. 1995). These residents were considered potentially exposed to radionuclides contaminating soil and water from these mining operations. The carcinogenic potential of internally deposited radionuclides has been confirmed in heavily exposed human populations like uranium miners and millers and radium dial painters and patients treated with Thorotrast and  $^{224}\text{Ra}$  (Mays 1988). The cancer sites implicated coincided well with radionuclide-distribution patterns throughout the body, with increases in the incidence of lung, liver, and head-sinus carcinomas, as well as of leukemias and bone sarcomas.

These populations have experienced carcinogenic effects of internal radiation exposure in the high-dose range, specifically greater than 1 Sv to organ systems through which the radionuclides pass or in which they accumulate. EPA

recommendations for the amount of radon allowable in drinking water are based on the results from studies of these high-dose human exposures (BEIR IV, 1988).

Twenty-six white male workers who had been exposed to airborne plutonium during World War II were followed for 42 years, to 1986 (Voelz and Lawrence, 1991). At that time, the mean age of the workers followed was 66 years. By 1990, seven subjects had died. Three of these 7 deceased individuals were diagnosed with lung cancer, one with osteosarcoma, and another with fatal chronic respiratory disease. The individual who died from osteosarcoma had received an estimated average skeletal dose of only 16 mSv just half a year before his death. In contrast, the lowest average skeletal dose received by individuals who died of bone sarcomas among the radium dial painters was 800 mSv. Some animal experiments support the low-dose estimate: osteosarcomas developed in beagle dogs irradiated with only 20 mSv from 229-Pu.

Evidence about lower-dose internal exposure to less than 1 Sv has been obtained from studies of predominantly alpha-emitting radionuclides in the nuclear industry. These studies suggest increased rates of lung cancer among workers exposed to uranium, of lung and hemato- and lymphopietic cancers among workers exposed to plutonium and of prostate cancers among employees exposed to tritium (Checkoway et al. 1988, Wilkinson et al. 1987, Beral et al. 1988, Beral et al. 1985, Wiggs et al. 1994). However, these studies have not been conclusive with respect to the carcinogenic potential of such low-dose levels since the estimates were based on very small numbers of cases and the confidence limits did not consistently exclude the null value of one.

The inconsistencies in results across studies could be attributable to random error, selection biases resulting in healthy worker effects, differences in length of follow-up, lag assumptions and exposure distributions, as well as residual confounding. The present study will add to the discussion and the pool of information about the cancer-causing potential of occupational low-level ionizing external and internal radionuclide radiation exposures.
